Influence of Ions.—The systolic digitalis action occurs only in the presence of Ca ions in the perfused solution. Excess of alkali or absence of potassium rather increases the systolic action; excess of Ca has little effect (Clark, 1912). On the other hand, strophanthin delays the standstill of the heart when this is perfused with Ca-free solutions or with pure K solutions; but it hastens the arrest when added to a solution from which Ca and K are both absent (O. Loewi, 1912; Korschegg, 1913). Strophanthine may therefore to a certain extent replace Ca, and thereby antagonize the K ions. The effects of the ions on the vagus action are quite different (Clark, 1914).

Antagonism with Alkaloids.—A perfused frog heart that has been slowed and weakened by the vagus action of pilocarpine is strengthened but not quickened by digitalis (Ransom, 1917). Lhota, 1909, claims that cocaine diminishes the toxicity of strophanthine by lessening the cardiac excitability. Wilbur, 1911, found that strychnine often removed the ouabain heart-block in terrapin's heart.

Wilbur, 1911, reports that *irritants* (iodine) produce effects similar to digitalis on terrapin's heart.

Effect of Auricular Distention on the Ventricular Tone.—Pietrowski, 1917, found that forcible distention of the auricles of the frog heart produces a systolic tendency and arrest similar to the tone effect of digitalis. This suggests that clinical auricular distention may potentiate the therapeutic response to digitalis. This tonus effect is not removed by atropine or epinephrine.

Peculiarities of the Heart of Toads.—This is very resistant to the digitaloid drugs, so that the action proceeds only to diastolic arrest. It shows a similar peculiarity in its behavior to excess of calcium, which diminishes the tonus of the heart, instead of increas-

ing it as in the frog. Wieland, 1922, suggests that the two phenomena are connected, on the basis of Loewi's interpretation of digitalis action as increased calcium-susceptibility. The skin of the toad contains two principles, *bufonin* and *bufotalin* which exert typical digitalis actions; but this of course need not have any connection with their cardiac resistance.

Perfused Mammalian Heart.—The effect of moderate doses, corresponding to the therapeutic stage, consists in increased excursions, especially in systole, and slowing by prolongation of the diastolic pause. The output per beat may be more than double. The time required to produce maximal slowing is an hour for digitalis, one-fourth hour for strophanthin (Haynes, 1906). *Existing irregularities are removed*, and a fibrillating heart may resume regular contractions (Hedbom, 1898; Braun and Mager, 1899; Gottlieb and Magnus, 1903).

The oxygen consumption of the heart is increased in proportion to the activity (Rohde and Ogawa, 1912).

With *toxic doses*, the contractions after the therapeutic stage, become quicker and irregular. The diastolic relaxation becomes progressively less complete, and the heart has a systolic tendency. It finally passes through delirium cordis into systolic standstill, the tone increasing even after the heart has stopped. Stretching of the muscle (as by increasing the coronary pressure) may temporarily restore the pulsations (Hedbom, 1898; Braun and Mager, 1899; Gottlieb and Magnus, 1903; Haynes, 1906; Etienne, 1909).

Intact Mammals.—In these the cardiac effects are modified by stimulation of the vagus center, and the blood pressure changes by the direct

FIG. 13.—Digitalis on blood-pressure, dog. The upper tracing is taken on a very slowly moving drum, to show the successive effects. The lower tracing is taken with a faster speed. The vertical lines indicate the correspondence of the fast and slow tracings. The upper abscissa corresponds to the original mean pressure; the lower abscissa to zero pressure. The digitalis is injected at *a*. (See text.)

effects on arterial muscle. The typical phenomena may again be conveniently divided into the therapeutic and toxic stages. They are shown in Figure 13.

Fall on Intravenous Injection.—During the injection of digitalis, there is a sharp anaphylactoid fall of blood-pressure (*a*) (Blake). Although this does not last long, it should be borne in mind when contemplating intravenous injections. It does not occur with other methods of administration.

Cardiac Changes in the Therapeutic Stage.—(Fig. 13, *b* and *c*). This is characterized by marked slowing of the pulse, due to lengthening of the diastolic pause; increased diastolic distention of the heart, and more complete systole, if this has previously been incomplete. The heart is

therefore both better filled and better emptied (Cushny, 1897). The output per beat is therefore greatly increased; the "pulse pressure" or "pulse volume" is improved. This increase more than offsets the slowing, so that the minute-output is also increased (Cohn and Levy, 1920). This tends to raise the blood pressure; in animals this tendency is supported by a more or less powerful vasoconstriction, involving particularly the intestines and liver. In man, the blood pressure is not much altered, presumably because of the more efficient vasomotor regulation; nor is the normal human heart usually slowed by ordinary doses, although the conduction of auricular impulses is delayed.

Behavior of the Different Chambers of the Heart.—The two sides of the heart behave very much alike to digitalis; but the auricles tend to show relatively greater inhibitory effects (since they are more subject to vagus control), whilst the ventricles are more disposed to the muscular action. In the therapeutic stage, the rhythm of the auricles and ventricles is synchronous.

The relaxation of the *auricles* is but little changed; their contraction is more complete; but with slightly larger doses the inhibition predominates so much that the contractions are less complete. The inhibitory effects disappear if the vagi are divided (Cushny, 1897).

The Digitalis Slowing.—In normal mammals, this is practically entirely vagal, and involves almost exclusively the vagus center: for it is almost completely eliminated by section of the vagi (Traube, 1851; Ackermann, 1873; Kochmann, 1906, 1909; Etienne, 1909), and atropinized animals show practically no slowing. The slowing produced by digitalis in auricular fibrillation is a different phenomenon. It occurs even after atropine, and is there quite peripheral (Cushny and Mackenzie; Gottlieb, 1914).

The different digitalis drugs probably differ quantitatively, in the degree of vagus stimulation (Kochmann; Etienne, 1909; Haynes, 1906). This might be of practical importance were our information more complete.

The dose required to produce distinct slowing, on intravenous injection, is from 25 to 70 per cent. of the minimum fatal dose; (Halsey, 1917; Robinson and Wilson, 1918); i.e., it is about the same as that required to produce the muscular effect, the reversal of the T wave.

The slowing is due mainly to direct stimulation of the vagus center, and not merely to the rise of blood pressure (as was supposed by A. B. Meyer); for the slowing occurs in the clinical cases in which the blood pressure is unchanged or even diminished (Fraenkel and Schwartz, 1906). Greene and Peeler, 1915, found the turtle heart slowed or stopped when digitalis was perfused through the brain only; the slowing being abolished by dividing the vagi. In animals the rise of pressure undoubtedly contributes to the slowing for the slowing is about twice as great if the pressure rises than if the pressure is kept just level by hemorrhage (Kochmann, 1906).

Vagus Stimulation from Rise of Blood Pressure.—It is well known that the tone of the vagus center is governed largely by the blood pressure, the heart being slowed as the pressure rises and quickened when the pressure falls (Bernstein, 1867; Verworn, 1903). The slowing on rise of pressure is entirely vagal, for it does not occur if the vagi have been divided. It is also absent if the pressure is raised in the cerebral arteries alone; so that the stimulation is not due to compression of the brain, but to a reflex, mainly from the heart (Kochmann, 1906).

Persistence of Vagus Center Stimulation.—This probably persists till near death; but the heightened contractility of the cardiac muscle renders the heart less and less responsive to inhibitory impulses. Vagus stimulation will therefore fail to slow the heart in the later toxic stage (Liagre, 1906); but that this is not due to paralysis of the vagus may be judged by the fact that vagus stimulation still weakens the beats.

Relative Duration of Systole and Diastole.—In the digitalis heart, the duration of the actual contraction and relaxation are practically unchanged. The speed of the systolic

contraction is somewhat increased (deHeer, 1912). The slowing occurs mainly in the diastolic pause; the systolic pause is also lengthened a trifle.

The increased output per beat amounted to 50 per cent. in the cardiometer experiments of Cushny, 1897. If the slowing is excluded by atropine, the *time-output* would be increased proportionately. If the slowing occurs, the increase would be proportionately less; but in the therapeutic stage it is still considerable—to 20 per cent. in Cushny's experiments. Tigerstedt, 1907, also showed with the stromuhr that the output is generally increased. Heinz, 1900, found the flow of blood from the carotid, at a constant pressure, to be increased by 50 to 250 per cent. The effect would be the greater, the weaker the heart was before the digitalis; that is, the more removed the excursions were from the physiologic optimum.

Extrasystoles are produced by smaller stimuli in hearts under the influence of the therapeutic and the smaller toxic doses of digitalis (Pletnew).

Electrocardiographic Changes.—The reversal of the P and T waves which is characteristic of the therapeutic dosage in man occurs in dogs and cats promptly after the intravenous injection of about 30 per cent. of the minimum fatal dose (ranging from 25 to 60 per cent. in different cats, but constant in a given individual, Levine, 1919). The reversal occurs after section of the vagi and after atropine, and is therefore a muscular phenomenon (Halsey, 1917; Cohn and Levy, 1918).

Blood Pressure.—In most animals (but not in man), there is a marked and sustained rise of blood-pressure during the therapeutic and toxic stage, except when the vagus-slowness or the irregularities become excessive. The rise is due partly to the increased output of the heart, but mainly to the direct constrictor action on the arterioles, especially of the intestinal vessels.

Influence of the Cardiac Action on the Blood Pressure.—The increased output of the heart should result in a rise of pressure. Accordingly, the pressure rises even when changes in the peripheral vessels are definitely excluded (*f.i.*, in Bock's method, where the aorta is tied, the circulation being shunted through the carotid directly to the jugular vein—Bock, 1898; C. W. Greene, 1910).

No Effect on the Maximal Pressure.—Whilst the digitalis heart can discharge a larger volume of blood against a normal pressure, the maximal pressure—*i.e.*, the rise of pressure on clamping the aorta—is not increased (Bode; Heinz, 1900).

Vasoconstriction.—The predominant share of this in the rise of pressure is shown most conclusively by the observation that the volume of the important splanchnic organs decreases as the blood pressure rises (Gottlieb and Magnus, 1901). Further evidence is that the venous outflow is also decreased; and that the rise is not always accompanied by increased output of the heart (Tigerstedt, 1907, stromuhr).

These experiments, however, were made with doses far larger than are used in therapeutics. Small therapeutic doses may produce intestinal constriction even when the blood pressure does not rise. The vascular effects are more lasting than the cardiac (Joseph, 1913).

The vasoconstrictor effect is peripheral because it occurs in excised organs (Donaldson and Steffens, 1883; Kobert, 1886; Brunton and Tunnicliffe, 1896, etc.). It occurs also after the nerve-endings are paralyzed by apocodeine (Dixon, 1903). The action is therefore presumably exerted directly on the arterial muscle.

Vasomotor Center.—Strophanthus produces a moderate stimulation; digitalis much less or none. In no case is the central action sufficient to make itself felt through the other actions of the drugs. Fatal doses result in sudden cardiac arrest and asphyxia, thereby producing intense stimulation of the vasomotor center (Pilcher and Sollmann, 1915).

Vasodilator Action.—Very dilute solutions of digitalis produce an opposite effect; *i.e.* the perfused vessels are dilated (Kasztan, 1910; Fahrenkamp, 1911).

Differences in Digitaloids.—The constrictor effect is often said to be greatest with digitoxin, and relatively weak with strophanthin, but the data are inadequate for definite conclusions. *F. i.*, de Heer, 1912, and Joseph, 1913, found that ouabain had a strong constrictor effect in mammals; while Moog, 1912, claims that its constrictor action is but one-tenth that of digitoxin. Stroomann, 1914, finds strophanthin the weakest constrictor in frogs. Caffeine is antagonistic. Vogt, 1909, claims that strophanthin does not produce constriction in *man*, but Straub, 1909, finds evidence of constriction with the string-galvanometer.

Differences in Vascular Areas.—The constriction is strongest in the intestinal and splenic vessels, less in the renal, and weak in the vessels of the skin, brain, etc. The dilator and constrictor effects vary in degree in different animals; but with therapeutic doses, in animals, the most constant and predominant effect is the slow constriction of the intestinal vessels. The dilator effect occurs earlier, but the constriction lasts longer (Joseph, 1913). In *man*, the volume of the arm is not changed by intravenous digitalis or strophanthin (Hewlett, 1913).

Altered Distribution of Blood.—The different susceptibility of the vessels leads to alterations in the distribution of the blood in living animals. The intestinal vessels will tend to be constricted; those of the skin, extremities and brain will tend to be dilated (Gottlieb and Magnus, 1901). The renal vessels occupy an intermediate position; with therapeutic doses they tend to dilate (Loewi and Jonescu, 1908); with toxic doses, they will be constricted. The dilations may be due to the direct dilator action; or to mechanical displacement of blood from the more powerfully constricted areas; or to nervous reflexes.

In the experiments of Gottlieb and Magnus, 1901, the dilation of the vessels of the extremities was shown to be mainly mechanical; for it did not occur (or rather, the leg vessels constricted), if the displacement of blood was prevented by ligating the splanchnic vessels.

The direct dilator effect has been rendered very probable for the *kidneys*; for it has been shown on the excised organs that certain concentrations dilate the renal vessels, whilst they constrict the intestinal vessels.

Pulmonary Vessels.—These are somewhat constricted in perfusion experiments (Tschistowitch). Excised arterial rings are also constricted by all digitaloids, except digitonin, which dilates (Macht, 1914). In life this action is unimportant; for the slight rise of pressure in the pulmonary artery is mainly cardiac (Plumier, 1905; Wiggers, 1911). The *circulation time* is shortened in the pulmonary and in the general circulation (Langlois and Desbouis, 1915).

Meningeal Vessels.—The filling of the vessels of the pia mater and retina follows the general blood pressure (Hirschfelder, 1915).

Coronary vessels may be constricted, especially by digitoxin, less by strophanthin (O. Loeb, 1903; Haynes, 1906; Rabe, 1912). Excised arterial rings are also constricted (Voegtlin and Macht, 1913). In any case, the constriction would be overcome by the improved contraction; so that, with therapeutic doses, the *coronary flow in life* was found unaltered (Bond, 1911), or even increased (F. Meyer; Sakai and Saneyoshi, 1915). J. L. Miller, 1908, found that digitalis enabled the heart to tolerate a greater degree of *coronary obstruction*. Large toxic doses contract the coronary vessels even in life, with rising blood pressure; this is sometimes followed by increased flow with falling pressure (Sakai and Saneyoshi, 1915).

Venous Pressure.—This is not materially altered, even when the arterial pressure rises (Capps and Matthews, 1913; it has also been studied by Ackermann and by Popper).

Blood Pressure in Rabbits.—These do not show as great or constant a rise as do other animals. This is probably explained by the lesser resistance of their blood vessels, which, therefore dilate if the pressure tends to rise above the normal. If the pressure has been lowered by hemorrhage, digitalis produces an effective rise toward the normal level (Hernando, 1911). Digitalis did not produce much rise after chloral, presumably because the heart was too greatly injured. The effects of small therapeutic doses were studied by Joseph, 1913.

Thoracic Lymph Flow.—In normal animals, this is not changed during the rise of arterial pressure; nor is the pressure in the portal capillaries increased (Yanagawa, 1916).

Toxic Effect on the Circulation in Mammals.—These are characterized by irregularities of the rhythm and strength of the cardiac pulsations (Fig. 14).

They are exaggerated manifestations of the vagus and cardiac stimulations which were initiated in the therapeutic stage. The *vagus effects* (slowed rhythm, diastolic tendency, lessened conductivity) reach their

acme most rapidly; so that the first indications of overdosage are commonly those of marked inhibition. This inhibition is in turn overcome as the *muscular excitability* becomes greater and greater; so that the final effects are mainly muscular (increased tone, heightened irritability, spontaneous ventricular rhythm, extrasystoles). The irregularities which result from these interactions weaken the circulation and interfere with the nutrition of the heart, until this becomes arrested.

FIG. 14.—Blood-pressure tracings under digitalis, to show some of the types of irregularity in the toxic stages. A, B, C and D represent four different dogs. (a) is the normal tracing; (b) the therapeutic stage; the following letters represent the successive toxic changes.

Cushny's Stages.—The successive effects have been studied most carefully by Cushny, 1897, who divides them into the inhibitory stage and the stage of muscular irregularity.

In the typical course, the effects pass successively through the therapeutic, vagus and muscular stages; but the vagus stage is often omitted in animals. The "toxic effects" in man are generally of the inhibitory type.

The Inhibitory Stage (Fig. 14, A).—This corresponds to strong vagus stimulation. The rhythm becomes very much slowed—to 40 or 50 beats

per minute. It is often irregular; there are scattered diastolic pauses which become more frequent and lasting, particularly in the auricles. These irregularities are partly exaggerations of the normal respiratory variations; but they are often independent. The two sides of the heart contract at the same rate, but the ventricles are apt to assume a spontaneous rhythm, which may be faster or slower than that of the auricles. This independent rhythm is due to the blocking of the auricular impulses by the lessened conductivity. The excessive slowing and the irregularity diminish the time-output of the heart in this stage, although the amplitude is increased. The blood pressure falls.

Occurrence and Duration of the Inhibitory Stage.—This stage occurred in about 30 per cent. of Cushny's animals. After lasting a few minutes, it passes quite suddenly into the muscular irregularity. It is more frequent and more persistent in man. The difference may be due to different dosage and administration.

The Stage of Muscular Irregularity.—The rate, rather suddenly, becomes more and more accelerated, as if the heart escaped from the vagus influence. Electric vagus stimulation has less and less effect on the rate; but since it still increases the diastole the vagus can not be paralyzed. The escape is due to the excitability of the heart becoming so greatly increased that the vagus is unable to restrain it. The auricles and ventricles may at first keep the same rate; but the ventricles soon assume a rapid rhythm independent of that of the auricles; for the conduction of the auricular impulses is more and more blocked, whilst the spontaneous excitability of the myocardium is more and more increased. The accelerators usually do not respond to stimulation (Fredericq, 1913).

Periodic Grouped Beats.—This independence of the auricular and ventricular contractions results in curious periodic variations in the volume of the pulse, the rhythm at this time being fairly regular.

One or more enormously strong beats are followed by very much weaker beats, sometimes quite imperceptible in the pulse, which is therefore *intermittent* (see Fig. 14, *B*, *e* and *g*). These phenomena recur in groups, which remain fairly regular for a short time, but soon change to some other type, as may be seen in Fig. 14, *B* and *C*. These effects are sometimes due to respiration. In other cases, however, they are cardiac. These are also seen in the atropinized heart, and are mainly due to the *arrhythmia of the auricles and ventricles* (Cushny, 1899). As a consequence, the contractions will sometimes alternate, sometimes coincide, forming groups. If the auricular systole occurs during the ventricular diastole, the ventricles will be filled with blood when they contract, and the result will be a large pulse-wave; if the auricular and ventricular systole coincide, no blood will be moved, and there will be no pulse.

The two sides of the heart continue to beat synchronously, although the periodic variations of strength have no relation.

After a time, *extrasystoles* (*i.e.*, premature contractions by which no blood is expelled) appear, and the pulse shows corresponding intermissions. These become more numerous. The rate continues to increase, becoming faster than in atropine poisoning. Various complex irregularities are super-added; and the contractions become thoroughly disorganized.

Terminal Changes.—The quickening of the rate soon exceeds the optimal limits. The contractions become superficial, fluttering, much less effective, and more fatiguing. The blood pressure falls and the heart is unable to keep the pace. First the auricles, then the ventricles, pass into fibrillation and the circulation is arrested. The chambers stop in median position, and then gradually become greatly dilated.

Muscular Changes in Rabbits.—In acute death from large doses, all parts of the heart may be suddenly arrested. Auer, 1912, found the endocardial muscles of the right ventricle hardened. He believes that this change involves the conducting system, and that even the earlier actions of digitalis are due to slighter degrees of these chemic changes. Similar abnormalities occur in anaphylaxis.

Racial Tolerance.—Great differences exist in the susceptibility of different species to the digitalis poisons. Rodents, toads (Vulpian, 1856) and the grass-snake are especially resistant but not immune. With mammals the difference is perhaps partly a matter of excretion; but the resistance seems to be mainly in the tissues.

Curiously, the *resistance of the toad and snake* does not extend to the related action of barium or saponin (Heuser, 1902; Clark, 1913). The toad resistance is generally attributed to habituation for its own poison; and Filippi, 1913, claims that toads deprived of their poison are very sensitive to digitalis.

The fatal dose for rats is nearly a thousand times greater (per kilogram) than that for cats, even hypodermically (Hatcher, 1909); and thirty times as much as for rabbits. Gunn, 1913, found that the concentration required to arrest the isolated heart in a given time is also forty times greater for rats than for rabbits; showing that the difference lies in the heart itself. Similar relations hold for the toad and snake (Clark).

Lhota, 1912, asserts that rabbits acquire an added tolerance by habituation; this needs confirmation. Klein, 1914, describes a similar induced tolerance in cats. Salvisberg, 1907, claims that ruminants are more resistant to oral administration, but not to intravenous, indicating, that in these animals the drugs are partly destroyed in the digestive canal. Lhota, 1909, states that young animals are more resistant than adults.

Seasonal Variations in Susceptibility.—These occur in frogs and guinea pigs (Haskell 1912 and 1914; Vanderkleed and Pittenger, 1913; Baker, 1913). It is interesting that they run reverse to the seasonal variations of acetonitrile and diphtheria toxine (Haskell, 1913).

THERAPEUTIC USES OF DIGITALIS

Historical.—The professional use of Digitalis is relatively recent. It was recognized by Wm. Withering of Birmingham (Cushny, 1915;) as an ingredient of an old woman's secret formula. After ten years of experimentation, he published his results in 1785. He was chiefly interested in the diuretic effect, and mentions the cardiac action only incidentally. The evidence for the connection of the circulatory and diuretic effect was first emphasized by John Ferriar in 1799. The drug quickly assumed an important place, though its proper field was not recognized. The cardiac slowing particularly attracted attention, and as late as 1851 Traube referred the clinical effects entirely to this "depressant" action; hence, Digitalis was used in aneurysm, internal hemorrhage, etc., for which it would be entirely unsuitable. Ten years later, Traube accepted the rise of blood pressure, which had been discovered in animals, as the basis of the therapeutic effect. This has been disproven only quite recently.

Strophanthus was brought to Europe in the early sixties, and its cardiac actions were promptly discovered. Its introduction into medicine is due mainly to Th. R. Fraser, 1885.

The use of *Scilla* dates from the ancient Greeks, although its cardiac action was not recognized.

Apoecynum was used by the early settlers as a hydragogue cathartic and diuretic; presumably they learned its use from the Indians.

Convallaria has also been used for several centuries in domestic medicine, against cardiac symptoms.

Bibliography.—The diuretic data are reviewed by G. Canby Roinson, 1922.

Field of Clinical Usefulness.—Digitalis and the allied drugs are highly useful in the course of chronic diseases, when the heart contracts imperfectly and becomes dilated; either because of incoordinated or irregular contractions, as in auricular fibrillation; or because of exhaustion of the cardiac muscle by its inability to compensate for the mechanical defects of structural lesions. The indications for its employment are governed by the functional conditions of the cardiac muscle, and only indirectly and to a minor degree by the gross anatomic lesions.

The most striking results are seen in auricular fibrillation; but definite though less obvious improvement occurs in chronic dilation with normal rhythm. In this case, the improvement tends to be self-perpetuating, so that digitalis needs to be given only at intervals. With auricular fibrillation, the effect must generally be maintained by more or less continuous administration.

Digitalis medication has not given definite clinical results in acute cardiac conditions, other than exacerbations of chronic lesions; partly perhaps because it was administered by methods in which its action is developed too slowly to meet acute conditions; but mainly because acute heart failure is generally due either to profound intoxication of the cardiac muscle, or is secondary to other conditions (for instance vascular paralysis in fevers, etc.), which must be the real object of treatment.

Explanation of Clinical Effects.—The slowed conduction and the muscular stimulation are both important; the slowed conduction being most important in auricular fibrillation; the muscular stimulation in uncomplicated dilation. The improved tone and contractibility of the muscle increases the amplitude of the systolic contraction, and thus the time-output. It counteracts the dilation directly, and may narrow a leaking valvular ring.

In auricular fibrillation the slowed conduction is especially important. This blocks the majority of the confusing impulses and permits the ventricle to make effective contractions.

All these actions increase the efficiency of the circulation, insuring a better filling of the arteries, improving nutrition and oxygenation, and relieving the congested veins. The heart is among the first to feel the effects of this improvement. The vicious circle of weaker heart, poorer circulation is reversed into the beneficial circle of stronger heart, improved circulation; so that the effects outlast the administration of the drug, and the improvement is perpetuated. At the same time, the circulation in the kidneys is improved, by the faster blood flow, the increase of pulse pressure, and the relief of the venous pressure. The kidneys are thus placed in the best condition for filtration or secretion. The anuria is relieved. If there has been edema, the improved kidney action results in extensive diuresis and thus in the absorption of the edematous fluid. This in turn improves the heart action and the whole circulation, by relieving them of the compression of the ascites. The vasoconstrictor action may also play some part; since it is strongest in the intestines and liver, it may help to relieve the congestion of these organs.

Rise of blood pressure, as such, has no important share in the action; for it rarely occurs clinically, even with intravenous injection, or in cases which are greatly benefited (Fraenkel and Schwartz, 1907).

Effects of Subtoxic Doses of Digitalis on Normal Man.—The most constant and definite change is the *reversal of the T wave of the electrocardiogram* (Cohn, 1915). It is ascribed to the increased muscular irritability. Diminution of the wave is distinct in about 10 hours, with relatively small doses ($\frac{1}{4}$ minim of the standard tincture per pound body weight); and this may serve for a physiologic assay. With the intensive dosage (1 minim per pound, at one dose), the effect is visible in 2 hrs. and reaches its maximum in 8 or 9 hrs. (Pardee, 1923).

Normal Auriculo-ventricular Conduction in Man.—This is constantly impaired, being an early and positive sign of digitalis action. It may be observed within forty-eight hours, and increases with the administration, from simple lengthening to heart-block. After withdrawal, it persists generally about two days, but sometimes two weeks.

Full therapeutic doses (a total of about 25 c.c. of the tincture) are required to produce a definite lengthening of the auriculoventricular interval. The effect is largely vagal, for it is generally removed by atropine (White and Sattler, 1916).

Heart Rate in Man.—Patients with auricular fibrillation, or with adynamic or unstable hearts, respond by slowed pulse to ordinary doses; but the rate of the normally rhythmic heart, whether the rate be fast or slow or normal is generally slowed only moderately, and only by doses that produce toxic effects (0.4 gm. per day for five to seven days). Some patients, especially children, may react to smaller doses. Slowing of the rhythmic heart is therefore generally a toxic rather than a therapeutic phenomenon. It is partly but not entirely vagal; for in many patients it cannot be completely removed by atropine (Wedd, 1919).

Blood Pressure in Man.—The rise of pressure which is so characteristic for most animals is not often seen in man, either in health or disease (Czylharz, 1900; Schwartz, 1906; Cushny, 1911; Mackenzie, 1911; Price, 1913; Cohn, 1915; Eggleston, 1917). In heart disease, the improvement under digitalis may even be accompanied by a fall of pressure, if this has been abnormally high (Fraenkel, 1905; Price, 1914; Martinet, 1914). A rise is very exceptional, occurring only if the pressure has been below the normal level. The diastolic pressure is always lowered when digitalis relieves uncompensated lesions, no matter what the changes in the systolic pressure. The pulse pressure is therefore generally increased (Martinet, 1914).

The difference can not be explained by dosage; for in animals the rise occurs with the smallest doses which have a noticeable effect on the heart. The explanation must be sought in the more perfect blood pressure regulation of man, which compensates the pressor tendency by inhibition of the vasomotor center and by stimulation of the vagus center. If the digitalis slowing is prevented by atropine, the pressure rises also in the human subject (Fraenkel, 1905).

The compensatory vasomotor regulation has not been investigated in man. From what is known of it in animals, it would be expected that the vessels of the extremities and of the kidneys would probably be dilated, whilst the intestinal and portal vessels would tend toward constriction. The altered distribution of the blood may contribute to the therapeutic result.

Digitalis in Auricular Fibrillation.—This condition which constitutes a half of all cardiac irregularities (Lewis), and two-thirds of all serious cardiac failures (Mackenzie), shows the most striking improvement under digitalis (Cushny, 1911; Mackenzie, 1911). The effect on the auricles themselves is relatively slight; the auricular tone should be increased, and the auricular distention would be relieved by the improved circulation; but the multiple irregularity of the fibrillating auricle is not notably altered, even under continued digitalization. The fixed circuit of auricular flutter (Lewis, Feil and Stroud, 1920), is often broken up by the increase of the refractory phase, under digitalis, and is temporarily split up, as it were, into multiple circuits, *i.e.* fibrillation (Lewis, 1911); and with further increase of refractoriness, these temporary paths may also be blocked and a regular rhythm attained (Review, Garrey, 1924).

The main improvement, however, is in the ventricular contractions. These do not become regular, but the irregularity is decreased, and the rate is reduced from 120–160 to 80–100. The ventricular efficiency, which was greatly impaired by the disorganized rhythm, is greatly improved; and with it the cardiac output and the blood flow (G. N. Stewart and Scott, 1915). The dyspnea and all the other symptoms of cardiac insufficiency are relieved.

The slowing and regularization of the ventricles is due mainly to decreased auriculo-ventricular conduction, which blocks many of the excessive auricular impulses from the ventricle (Cushny, 1917; 1918), so that the ventricles respond more forcibly and more effectively to the remaining impulses. Such a block might be established either by the muscular action of digitalis, *i.e.* by the increased refractoriness that follows the stronger contraction of the bundle; it might also be produced by vagus-stimulation (Robinson and Draper, 1911), which decreases refractoriness (Dale and Mines, 1913), but which lowers the excitability of the bundle, so that it does not transmit the weaker impulses. The vagus stimulation is not an essential part of the digitalis blockage in auricular fibrillation, for the block persists after atropine (Cushny, Marris and Silverberg, 1912), but it is quite probable that the effect is enhanced by vagus stimulation (Wedd, 1919). A third mechanism of blockage is illustrated by quinidine, which increases refractoriness directly, *i.e.* by checking the restorative metabolism. The effects of the three measures are contrasted in the table. It may be added that over-dosage with digitalis (also with barium, aconite, etc.) may produce auricular fibrillation (Cushny, 1911), by causing intra-auricular blocks that interfere with the orderly progress of the excitation wave. This is especially likely to occur with intravenous injections if the myocardium was severely damaged, and in coronary occlusion (Robinson et al., A. M. A. Committee 1924).

TABLE OF CONTRAST OF CARDIAC ACTION

Function	Digitalis	Vagus stimulation	Quinidine
Tone.....	Increased	Decreased	Decreased
Contractions.....	Stronger	Weaker	Weaker
Refractory phase.....	Longer	Shorter	Longer
Conduction.....	Stronger but slower	Faster but weaker	Slow and weak
Partial heart block...	Exaggerated by long refractory pause.	Exaggerated by weak conduction.	Probably exaggerated by long refractory pause and poor conduction.
Auric. Fibrillation	May be decreased by lengthened refractory or increased by heightened irritability.	Increased by shortened refractory period.	Decreased by lengthened refractory per. and diminished excitability.
	Slowed by lengthened refract. P. of bundle	Slowed by weak conduction in bundle.	Slowed by lengthened refract. per. and diminished excitability of bundle and muscle.

To obtain the best results in auricular fibrillation, the digitalis must be started with full doses. Smaller doses must then be continued for a long time, giving just enough to keep the rate between 70 and 80 per minute. Over-dosage is often indicated by occasional reduplication of the pulse ("coupled beats", "pulsus bigeminus"), due to ventricular extrasystoles (Lewis, 1911). Although this may occur with relatively small doses, it is considered an indication to reduce or to discontinue the digitalis.

If the auricular fibrillation occurs in cardiosclerosis or when the myocardium is excessively weakened, digitalis is much less effective and much more dangerous.

Influence of Cardiac Irregularities on Cardiac Output.—Experiments on dogs show that *extrasystoles* have very little effect, even when they are frequent (1 in 4 to 8). *Auricular flutter* and especially *auricular fibrillation* reduce the output considerably. This is due to the irregularity (premature beats, etc.) rather than to the rapid rate. *Heartblock*, partial or complete diminishes the output greatly, proportional to the slowing (Eyster and Swarthout, 1920).

Other Arrhythmias.—Irregularities other than those arising from auricular fibrillation and flutter are not materially improved by digitalization, and this is contra-indicated in partial heart block. It must not be forgotten that overdosage of Digitalis may provoke any of the clinical types of irregularity even in a healthy heart, and this may occur more readily when the heart is disposed to them by disease. It is therefore necessary to watch carefully for the appearance of any irregularities.

Partial Heart-block (diminished conductivity of the auriculo-ventricular bundle).—This is always exaggerated by digitalis: a slight retardation between the auricular and ventricular contraction may thus be converted into a partial block, so that the ventricles respond only to every second or third beat of the auricles; or a partial block of this kind may be converted into a complete block, the ventricles assuming their characteristic slow independent rhythm. In partial heart-block (even when the a-c interval in the jugular tracing is merely lengthened) digitalis should be avoided, and employed only with caution when it is otherwise urgently needed. If the need for it exists, however, it may relieve the symptoms even though it exaggerates the partial block.

Complete Heart-block.—In this, digitalis can do no further harm; for it does not slow the spontaneous ventricular rhythm. On the contrary, it would tend to quicken the beat; at all events it would tend to render it more effective. It might therefore be of some use (Bachmann).

In complete experimental heart-block (dogs) strophanthin first increased the rate and strength of the ventricular contraction. This was followed by sudden ventricular arrhythmia and tachycardia, increasing to fibrillation. The auricles were strengthened, their rate sometimes quickened or slowed. The blood pressure rose in the first, and still more in the second stage (van Egmond, 1913).

Irregularities in the Strength of the Cardiac Contractions (*Pulsus alternans*).—These, as contrasted with irregularities of rhythm, are currently attributed to exhaustion of the myocardium. They are therefore improved by digitalis (Windle, 1917; Christian, 1915). It must be employed with caution, however, for similar irregularities are prominent in digitalis poisoning, and an exhausted heart is more subject to these effects.

Extrasystoles.—These are not removed by digitalis since they are probably due to heightened irritability of the myocardium—a condition which could only be exaggerated by digitalis. Extrasystoles due to nervous exhaustion, indigestion, nicotine, etc., do not require medicinal treatment; they tend to disappear under suitable hygiene, and in any case, they have no serious significance. (The influence of various drugs on extrasystoles has been studied by McCord, 1912.)

Guthrie, 1917, reports that digitalis (toxic doses) decreases the irritability of frog and turtle heart to extra systoles by electric stimulation.

Periodic changes in sinus rhythm (such as the exaggerated respiratory variations, which occur in general nervous exhaustion, rather than in cardiac disease) are not benefited by digitalis. On the contrary, the vagus stimulation would tend to render them more marked.

Paroxysmal Tachycardia.—The response varies. In some cases, digitalis is practically ineffective; in others, intravenous strophanthin reduces the rate very strikingly.

Febrile Tachycardia.—The heart rate in fever is not materially affected by digitalization, although the reversal of the T wave and the effect on auricular fibrillation are produced in fever just as with normal temperature (Cohn and Jamieson, 1917).

Irritable Heart.—The simple tachycardia of the “effort syndrome” is not slowed by digitalization (J. Parkinson, 1917), nor is that of Basedow’s disease (Cohn, 1915).

Myocardial Insufficiency with Normal Rhythm.—In functional impairment of the efficiency of the cardiac muscles, without changes of rhythm and without lesions of the valves, digitalis does not usually slow the heart rate even when this is fast; but it increases the excursions (roentgen observations, A. E. Cohn and Stewart, 1924), and causes the disappearance of the symptoms, including the edema (Cushny, 1911). This may be attributed to the direct muscular stimulation.

If the cardiac muscle is degenerated, as in cardiosclerosis, digitalis will be useless or even harmful, by imposing too great a task on the few weakened muscle fibers.

In *experimental ventricular dilation*, produced by partial occlusion of the aorta, digitalis injection restored the heart to the normal volume. This occurred also after atropine (Hirschfelder, 1918).

Use of Digitalis in the Special Cardiac Lesions.—No cardiac lesion, as such, either indicates or contraindicates digitalis. Whatever the lesion, digitalis would be superfluous so long as compensation is fairly perfect. The indications for its use arise only when compensation fails; and then its possibilities for good or harm are determined by the functional conditions, and not by the location of the anatomic changes.

Mitral Stenosis.—It has been suggested that the lengthened auriculoventricular pause would permit a better emptying of the auricle (Cohn and Fraser, 1913).

Aortic Insufficiency Not a Contraindication.—The older clinicians, since Corrigan, considered digitalis as contraindicated in this condition, fearing that the prolonged diastole would give the blood in the brain a chance to gravitate back into the heart, and thus produce syncope.

The apprehension appears to be unfounded (Christian, 1919). Digitalis is now given freely, as in other lesions. It is advisable to keep the patient in bed during the digitalization.

The occurrence of syncope on changing suddenly from the prostrate to the upright position may occur under the influence of digitalis, even with other lesions; the patient should be cautioned as to this.

Gebhart, 1911, has tried the effect of digitalis on *experimental aortic insufficiency* in rabbits: He found that it lessened the dropsy and mortality; but did not prevent cardiac hypertrophy.

Cardiosclerosis.—It must be remembered that the most useful effects of digitalis are produced by stimulation of the cardiac muscle. As a result of the better nutrition produced in this manner, the muscular fibers may afterward hypertrophy, or new fibers may possibly be formed; but the primary action of digitalis itself is confined to the already existing muscle; consequently it will be of no use if there is practically no muscle left to respond to it. It is therefore useless with a heart which has undergone marked fatty or fibrous degeneration. In this condition it is often contraindicated, because the overworked muscle is more readily poisoned.

High Blood Pressure.—This has little bearing on the usefulness of digitalis. Its existence does not contraindicate the administration.

Acute Myocarditis and Endocarditis.—The use of digitalis is debatable: it can easily lead to dangerous overstrain of the hypersensitive muscle.

Aneurysm.—The sudden distention of the aneurysmal sac by a larger mass of blood, which would be the result of digitalis, is exactly contraindicated. The only reason why digitalis has not done more harm in this way is that it has not generally been used in large enough doses to have a marked effect.

Hemorrhage.—This would similarly contraindicate digitalis.

Digitalis in Pneumonia and Other Fevers. It has been shown conclusively that fever does not modify the digitalis actions, the heart responding just as in non-febrile individuals (Cohn and Jamieson, 1917, T. S. Hart,

1919, Hirschfelder, 1920). Digitalis would therefore be indicated in pneumonia patients with cardiac lesions, and particularly with auricular fibrillation, which develops in 10 per cent. of the pneumonia patients (Cohn, 1915). In the absence of these, however, its usefulness is very doubtful (Hart, 1919). The terminal collapse in fever is apparently not due primarily to cardiac failure; and digitalis is practically ineffective, just as in other forms of "shock" (G. Schwartz, 1906). Cohn considered routine digitalization justifiable in pneumonia as a precaution against fibrillation; but it is also conceivable that it might dispose to fibrillation, (especially in diphtheria, Robinson). Stone, Phillips and Bliss, 1918, found the average mortality of a series of pneumonia patients less under digitalis; but mortality statistics in pneumonia are often deceptive. The question cannot therefore, be definitely answered. It should be remembered that fever renders the heart more susceptible to digitalis, so that the dosage should be smaller (Hirschfelder et al., 1920).

Diuretic Action.—The digitalis drugs are powerful diuretics in cardiac dropsies; the diuretic effect being proportional to the improvement of the circulation and to the absorption of the edemas. In all other conditions they have little or no effect on the urine. Practically negative results are obtained in normal individuals (Schwartz, 1906); in heart disease without effusion (Cushny, 1911; Cohn, 1915) and in purely nephritic edemas (J. Miller, 1912). Moderate doses of digitalis have no effect on either the renal blood flow or the diuresis of normal animals; excessive doses slow the urine and blood flow, although they raise the blood-pressure (Cushny and Lambic, 1921).

The factors involved in the improvement of the renal circulation are mainly the relief of the venous pressure; the increased output of the heart; the increased "pulse pressure;" and the hydremia resulting from the absorption. These mechanical conditions cause corresponding increase of urine filtration even in dead kidneys (Sollmann, 1915).

Gesell, 1913, found that artificial changes in the pulse pressure produced parallel changes in the excretion of urine, chlorides, urea and nitrogen.

Influence of Hydremia.—Martinet, 1914, found that the viscosity of the blood and the protein content of the serum remain unchanged so long as the absorption of edema is in progress. When the edema has disappeared, but the diuresis still persists, the viscosity increases. This indicates that the hydremia is not the primary cause of the diuresis. Loria, 1912, also states that strophanthin or calomel increase the viscosity of the blood even when there is no diuresis.

TOXIC EFFECTS IN THE CLINICAL USE OF DIGITALIS

Digitalis is practically useless clinically unless the dosage is sufficient materially to impair conduction; and this impaired conduction is itself capable of causing arrhythmia, i.e., of producing toxic effects. In other words, the full therapeutic effect practically coincides with the minor toxic manifestations (Eggleston, 1915). There is a fairly wide margin between the therapeutic and the fatal dose (the therapeutic representing about $\frac{1}{3}$ of the fatal, Robinson and Wilson, 1918); and the minor toxic effects usually do no permanent harm, if the dosage is reduced immediately on their occurrence. If they are disregarded permanent irregularities may result.

The toxic phenomena may be grouped under digestive disturbances and some minor phenomena; cardiac irregularities; and fatalities.

Digestive Disturbances.—These occur early and are easily recognized, so that they are very important. They consist in nausea, great malaise, and often headache which may be very distressing. If the drug is continued, vomiting will occur. *Diarrhea* is not very common with digitalis, more frequent with strophanthus, squill and helleborein. When any of these digestive symptoms occur the dosage should be reduced or stopped. They will then subside in one or two days (Cohn, 1915).

Mechanism of the Emetic Action.—The nausea and emesis are not due to local gastric irritation, as was formerly thought. They set in only when the cardiac effects are manifest (Eggleston, 1913), and are best explained on the assumption that the emetic center is stimulated by reflexes set up by the cardiac actions (Hatcher and Weiss, 1923); in other words, the emesis seems to be a secondary manifestation of the cardiac action. It would therefore be useless to search for “non-emetic” digitalis preparations.

The small importance of local irritation is indicated by the fact that emesis occurs more readily with intravenous than with oral administration (Hatcher and Bailey, 1911); and vomiting movements take place when the whole alimentary canal has been excised (Hatcher and Eggleston, 1912). Nor is the action directly on the vomiting center; for if the brain is artificially perfused, emesis results from injection into the femoral vein, from where it cannot reach the brain; and emesis does not result if ouabain is added to the fluid that perfuses the brain, but does not reach the general circulation. Moreover, emesis is prevented if the spinal cord is divided at the level of the second dorsal vertebra (Hatcher and Weiss, 1923).

Very sensitive individuals may, of course, be nauseated by the acrid taste of even small doses, but local irritation sufficient to produce emesis could only occur with doses much larger than the clinical. The *digitonin* must play a very insignificant part, for it is not emetic in doses very much larger than occur in the usual administration. The *fat* of the leaf is also non-emetic (Eggleston and Hatcher, 1913). The oil of strophanthus seed is emetic, but only in quantities 10,000 times as high as are present in a therapeutic dose of the tincture (Hatcher, 1916).

Klocmann, 1912, states that digitalis diminishes *gastric secretion* in fistula-dogs.

Squill was formerly used as nauseant expectorant; *Euonymus* (wahoo) as cathartic.

Ratio of Emetic Action.—This may be expressed as the relation of the emetic to the fatal dose, intravenously. Eggleston and Hatcher found True Digitalin the most emetic (emetic dose = 22 per cent. of the fatal); then come strophanthus, ouabain, digitalis, digipuratum, digalen and adonis (ratio = 40 to 50 per cent.); then digitoxin and amorphous strophanthin (58 to 65 per cent.); least emetic were Squill and Apocynum (75 to 88 per cent.).

Visual Disturbances.—Purkinje in 1825 described a flickering produced by full doses of digitalis (Hanzlik, 1925; Sprague, White and Kellogg, 1925).

Exanthemata.—A few cases of urticaria and scarlatiniform rashes have been reported after digipuratum and digalen.

Cardiac Irregularities from Digitalis.—There may simulate any of the clinical irregularities; so that it is sometimes difficult to distinguish between them, particularly in advanced poisoning. To establish their causation by digitalis, it must be shown that they were absent before the drug was given, and that they disappear in a reasonable time after its discontinuance. The early effects, however, are fairly characteristic. The most common is excessive vagus stimulation (sinus irregularity). It is best seen when the heart is slowing after a little exercise. The rate may fall to 50 or even lower; so that syncope may occur between the contractions. The rhythm may remain regular; but ventricular extrasystoles are common. This stage would not occur in auricular fibrillation, nor in absolute heart-block.

The next stage is usually that of *partial heart-block* (Mackenzie, 1905), especially if the conductivity was naturally low. It may occur with relatively small doses (Windle, 1911), and may be permanent (Taussig, 1912); Christian, 1915, records transient auriculoventricular dissociation.

The final stage is that of *muscular irritability*, first indicated by extrasystoles (Levine & Cunningham, 1920). These are particularly common in auricular fibrillation, giving the "coupled beats." With more advanced toxic action, there occur the same effects as in animals: high blood pressure (vasoconstriction); very rapid rhythm, with periodic changes in amplitude, *pulsus alternans* (rarely).

Dosage.—Eggleston, 1912, finds that the toxic effects depend mainly on the total dose, modified by the weight of the patient, the activity of the preparation, absorption, individual susceptibility and the nature of the heart lesion. With the ordinary energetic administration, the characteristic coupled beats occur when the total quantity of digitalis has reached 2.25 to 6.25 Gm. Since the action persists partly from one to three weeks, these irregularities will recur with a smaller dosage.

Ratio of Toxic and Lethal Dose.—With intravenous injection, the lethal dose of any digitalis preparation is constant for cats. The toxic dose, however, varies with different animals. According to electrocardiograms, it ranges from 25 to 60 per cent. of the lethal dose; averaging about 50 per cent. In any individual cat, however, it is fairly constant (Levine, 1919).

Duration of Irregularities.—This depends on the total dosage, and therefore on the severity of the phenomena. Eggleston, 1912, found that coupled beats generally outlasted the administration by four to twelve days; heart-block, three to six; auricular fibrillation, three; muscular irritability, two; sinus irregularity, two days.

Chronic Digitalis Poisoning in Animals.—von Lhota, 1910, has studied this in dogs which were poisoned for several months by slowly increasing doses of digitalis. The phenomena correspond closely to those observed in man: The pulse after nine or ten days shows occasional short periods of slowing, but with the heart regular and strong. If the administration is continued, the slowing becomes more persistent and more marked and arrhythmic. Later, the pulse rate again increases to normal or somewhat above. The pulse changes outlast the administration for a long time; in severe acute poisoning, they may persist for several weeks; after chronic poisoning, they may last for over a month. Lhota believes that the effect are at first cumulative, but that later some tolerance is acquired especially in rabbits (Lhota, 1912); but the evidence for habituation is not convincing.

Typical cumulative poisoning has also been observed in cats (Klein, 1914).

Fatalities from Oral Administration.—These would be very rare with fractionated doses, since emesis and catharsis set in when $\frac{1}{3}$ to $\frac{2}{3}$ of the drug has been absorbed (Eggleston and Hatcher, 1913) and this would tend to prevent further absorption. Single massive doses (above 2.5 gm. of the leaf) may be fatal.

The symptoms set in relatively late (one to twenty-four hours); and they generally have a long course, so that a week or two may elapse before death. The symptoms are those of cumulation—gastro-intestinal disturbances, slow and arrhythmic pulse, etc., lassitude, muscular and sensory derangements. Death generally occurs suddenly, with dyspneic convulsions. Consciousness persists late.

The symptoms in mammals are very similar.

The treatment would consist in evacuation, quietness, possibly diffusible stimulants, and other symptomatic treatment. A cathartic should be given. (The claim of Krause, 1906, that diastase is an effective antidote to strophanthus is doubtful.)

The fatal dose varies greatly, on account of the variable absorption, the occurrence of vomiting, etc.: 2.5 Gm. of digitalis has been fatal, whilst 4 Gm. has been followed by recovery (Lewin).

Fatalities with Intravenous Injections.—Deaths occurring within a few minutes to an hour after the injection of strophanthin or digitalis must be charged to these drugs, and are not very uncommon (Rahn, 1920). They

are probably due to ventricular fibrillation (Levine, 1919), which can apparently be induced in some diseased hearts, particularly those with impaired conduction, by the too abrupt introduction even of therapeutic doses (Robinson and Wilson, 1918, Levine, 1919); and especially by overdoses, *i.e.*, when insufficient allowance is made for previous digitalis medication. The intravenous injection of fatal doses of strophanthin into cats produces vomiting, diarrhea and convulsions (Hatcher, 1909).

OTHER ACTIONS OF DIGITALIS

Central Effects of Digitalis.—The peripheral effects dominate the symptom-complex so greatly that of the direct central effects only the emetic action is important. The cardiac action is so selective that frogs whose hearts have been stopped by digitalis may hop about as if normal. The *medullary* centers are probably stimulated directly. This is proven for the vagus center, probable for the vasomotor center, and perhaps also for the respiratory center; but the indirect effects from the altered circulation are much more important than any possible direct actions.

Central Symptoms.—When digitalis is injected into the ear vein of *unanesthetized* rabbits, or subdurally, the symptoms occur immediately, and appear to be largely central. They consist in dyspnea; tremors and convulsions; miosis; debility and paralysis of certain muscle groups, especially the neck; abolition of certain reflexes. These effects are followed by asphyxial convulsions with mydriasis and death by paralysis of the respiration or heart. The later symptoms are, at least partly, due to the circulatory changes; but the earlier symptoms are probably due to direct central actions (Santeson and Strindberg, 1916).

Respiration.—Hypodermic or intravenous injection produces a primary increase of the respiration in rabbits. Larger doses depress (Gross, 1914).

Excised bronchial muscles is not affected by strophanthin (Trendelenburg, 1912).

Gall-bladder.—This is stimulated (Lieb and McWhorter, 1915).

Uterus.—Strophanthin revives the movements of the excised uterus when these have been arrested by calcium-free Ringer's solution. Short exposures to strophanthin renders the uterus hypersensitive to calcium (Ransom, 1920).

Epinephrine Output.—This is not affected by strophanthin (Stewart and Rogoff, 1919). Previous workers used inadequate methods.

Local Actions.—Digitalis and the allied drugs, when injected hypodermically, cause fairly severe irritation, pain and abscess formation, which practically preclude their use by this channel. Intramuscular injection is feasible, although not painless. The irritant action varies in different drugs.

Digitalis (particularly digitoxine) and squill are more irritant than strophanthin and ouabain (Haynes, 1906).

Relative Irritant Action.—Holste, 1913, from hypodermic and conjunctival application to rabbits, establishes a series for the isolated principles as: Most irritant = digitoxin; then digitonin, then digitalein and cymarín (from apocynum). Practically non-irritant = digitalin, ouabain and strophanthin. Digalen was much more irritant than digipuratum. On the skin of young pigs, O. Loeb and Loewe, 1916, also found digitoxin and digalen the most irritant. Digipuratum, strophanthin and ouabain were about as irritant as digitalis infusion.

Strophanthin does not inhibit the *emigrations of leucocytes* from inflamed mesentery (Ikeda, 1916).

Anesthetic Action.—Steinach, 1888, and Panas, 1890, found that application of strophanthin to rabbit's conjunctiva produces anesthesia lasting several hours. In man, however, there is considerable inflammation. Other digitaloids are also anesthetic.

DEVELOPMENT AND PERSISTENCE OF ACTION, ADMINISTRATION

Onset of Action.—When small therapeutic doses of the Digitalis drugs are administered by the alimentary canal, the effects develop very slowly. It may be several hours before any action can be noted. The full effect is reached much later; twenty-four to thirty-six hours for the circulatory actions; seventy-two hours for the diuresis.

This delay is due mainly to the insufficient dosage; *i.e.*, several doses must accumulate before the effective dosage is reached. When full therapeutic doses are given at once, as in the Eggleston method, definite effects (T wave) occur within 2 to 4 hours, and reach the maximum in 6 to 24 hours (Robinson, 1919; Pardee, 1920).

With therapeutic doses the *channel of administration* has relatively little effect on the onset of the therapeutic action; for instance with a single dose corresponding to 1 minim of the tincture per pound body weight, distinct clinical effects begin in about 2 hours with oral administration; $2\frac{1}{2}$ hours with rectal, and 5 or 6 hours with intravenous administration (Pardee, 1925). These variations are probably within the experimental error, *i.e.*, absorption from the alimentary tract does not noticeably delay the development of the effects. This would not hold for strophanthus, which is generally absorbed more slowly; nor for the intravenous injection of strophanthin or ouabain, or of dangerous doses of digitalis: with these the circulatory response begins at once, and the diuresis starts in a few hours, although the maximal effects require somewhat longer (Fraenkel and Schwartz, 1907; Hatcher and Bailey, 1910).

Absorption.—The *dose* influences the rate of absorption materially. With oral administration, the rate of adsorption increases with the dose (Hatcher, 1909); but is always quantitatively uncertain. The variation is especially great with *Strophanthus* (Hatcher, 1909). This accounts for the unsatisfactory clinical results from the oral use of this drug. The safe dose would be so small as to be generally ineffective; a really effective dose could be highly dangerous, according to the individual absorption. *Helleborein* is probably not absorbed at all from the alimentary canal, since it commonly produces only diarrhea, without cardiac effects (Cushny, etc., 1912). Digitoxin appears to be better absorbed than digitalis (Eggleston, 1915) or strophanthin (Hatcher and Eggleston, 1919). The tincture of digitalis is absorbed more rapidly than the infusion.

The chloroform-soluble extract is absorbed more completely and uniformly (Hatcher, 1920; Eggleston and Wyckoff, 1922). Digipuratum and digalen are most decidedly superior (Haskell, McCants and Gardner, 1916).

Different Portions of the Digestive Tract.—Quantitative studies by Ogawa, 1912, indicate that digitalis is not absorbed from the stomach. From the intestines, 34 to 45 per cent. were absorbed in two hours from digitalis leaves; with digipuratum, the absorption was 52 to 61 per cent. in two hours; 65 per cent. in three hours.

Destruction in Alimentary Canal.—The digitaloids are practically unaffected by pepsin or trypsin (Goodall and Reid, 1914); but a small quantity of the glucosides is probably destroyed by the acidity of the gastric juice (Hale, 1911; Ilolste, 1912; Segond, 1912). Johannessohn, 1914, found that alkalies weakened only crystalline K-strophanthin; acids, this and amorphous K-strophanthin and strophanthus tincture. The amorphous strophanthin is changed mostly to strophanthidin, and partly to an inactive resin. Ouabain is unaltered by either acids or alkalies, which is an advantage in its administration. However, with the usual short contact, the destruction of the other principles is probably also unimportant (Hatcher, 1909).

In the rat, with the oral administration, strophanthin is mostly destroyed in the large intestine. Of digitoxin also, variable amounts are destroyed before absorption (Hatcher and Eggleston, 1919).

Lhota, 1912 and 1913, invokes gastric destruction to explain the habituation which he believes to occur in rabbits.

Duration of Action.—The digitalis effects endure for a long time after the administration has stopped, whether the drug was given by the mouth or vein. It is difficult to establish a time for the clinical reaction, because when compensation has been established, it tends to persist, independently of the drug (except in auricular fibrillation), until some extra demand causes a fresh break of compensation. This probably holds true to some degree of the other cardiac changes. The persistence of the drug-effect depends also upon the total dose. One can therefore only deal in approximations. The effects of a "full" dose of digitalis or digitoxin

seem to persist, with gradual decline, for one to three weeks, according to the total dosage; but for shorter periods with some of the other digitaloids, especially strophanthin and ouabain.

Clinically, the duration of the actual digitalis action can be judged by the alteration in the T-wave of the electrocardiogram. This persists from 1 to 22 days, averaging about 9 days after discontinuance of the administration (G. C. Robinson, 1919, White and Morris, 1918). The other clinical facts lead to the same conclusion (Eggleston, 1912).

Pardee, 1919, estimates the rate of disappearance in man, after full therapeutic doses, as averaging 0.15 Gm. of Digitalis per day.

The duration of the digitalis-effect can be measured accurately in animals by Hatcher's method (differential fatal dose): In cats, one-half of the original effect of an intravenous injection persists for the following number of days: digitalis, five to twelve days; digitoxin, fourteen (dogs, two days; rabbits less than one day); digitalein, three; digitalin German, three; digitalin true, less than two; ouabain and strophanthin less than one (Hatcher, 1921). Klein, 1914, believes that the action of strophanthin may persist for a month in cats.

The duration is much shorter in dogs and especially in rabbits, as quoted for digitoxin. Apparently, the more resistant a species is to digitalis, the shorter is the action. Both facts perhaps depend on the rate of elimination.

Disappearance in the Body.—The digitaloids disappear from the blood almost immediately after the injection of even much more than fatal doses (Hatcher and Eggleston, 1912; Lhota, 1912).

This rapid disappearance is due to wide distribution in probably all the tissues; for it occurs if the circulation is restricted to limited areas; not, however, if it is restricted to the heart and lungs alone. The liver plays perhaps a larger part than other organs. In rats, the greater part is fixed by the liver (Hatcher and Eggleston, 1919).

The further fate of the digitalis substances is not definitely known. From the duration of their action Cloetta and Fischer, 1906, and Hatcher, 1912, conclude that a part must be stored in the cardiac tissue. Lhota, 1912, claims that digitoxin is found chiefly in the heart and blood vessels, less in the liver and other organs. According to Clark, 1913, there is no evidence that the digitaloids are either fixed or destroyed in the tissues, so that their distribution would be rather one of selective solution-affinity. In proportion to their slow excretion, they would gradually diffuse back into the blood.

Excretion.—The digitaloids are partly destroyed in the body, mainly by the liver, and partly excreted unchanged. The excretion occurs chiefly through the bile, so that the substance may be demonstrated in the feces after intravenous injection. A small fraction is excreted by the kidneys. This increases if the bile duct is tied (Hatcher and Eggleston, 1919).

Cumulative Action.—The effects of digitalis tend to be cumulative; that is, the same doses, continued day by day, tend to produce ever-increasing effects; or more commonly, toxic effects develop suddenly, without warning, after small doses have been continued for some time. In the therapeutic use, the dose must therefore either be diminished, or toxic phenomena result, often quite abruptly. This cumulative action may be explained in part by the slow and uncertain absorption and excretion. The principal factor, however, is probably the slow, persistent and progressive action: Since the effects of a single dose may persist over several days or weeks, the effects of all the doses which are given in the meantime are more or less summed up; and the effects of digitalis are determined by the total dose, and not by the single or even by the daily dose.

Digitalis is usually started when decompensation has occurred. It is then desirable to induce the effects as promptly as may be feasible and safe; and to maintain them as long as necessary.

Intravenous administration would be the promptest method; but it has drawbacks that restrict it mainly to emergencies. Ordinarily, the objects are fully met by proper oral administration. In this, it is necessary to remember the long duration of the digitalis action, and

the consequent cumulative action. It must be emphasized that therefore the total accumulated dosage is of more importance than the single doses; that practically no therapeutic effect is produced until the total dosage approaches the toxic; that the dosage must be reduced when the desired action has developed; that the patient must therefore be closely watched. He should be seen at least daily, while under active medication; and the intensive methods are safest under hospital conditions. If toxic symptoms appear, the administration should be temporarily suspended; *i.e.*, if nausea develops; if the pulse falls below 50; or if any of the characteristic digitalis irregularities arise.

In the intensive methods it is also indispensable to employ digitalis preparations of known activity, tested first on animals, and then checked by cautious observation in the clinic. The dosage should be measured accurately, and not estimated by "drops." Febrile temperature renders the heart more susceptible to digitalis, so that the dosage should be reduced.

Systems of Oral Administration.—These may be grouped into the intensive, the cumulative, the constant dose, and the maintenance methods. The intensive methods aim to give the greater part of the total dosage at once, and practically the whole within a day. The cumulative methods accumulate the effective dosage by divided doses in two or three days. The constant dose methods tend to err on the side of safety, and often do not reach the effective dosage at all. The intensive methods are most effective, and under the best hospital conditions are probably the most satisfactory. The cumulative method occupies a middle ground.

Intensive Method.—Eggleston, 1915, determined the total dosage of standardized digitalis necessary to produce full therapeutic or minor toxic effects, as 0.15 "cat-units" per pound of body weight. With tincture so adjusted that 1 c.c. kills 1 kilogram of cat, and this is about the effect of a good 10 per cent. tincture, this would mean 15 c.c. of tincture per 100 pounds of body weight ($1\frac{1}{3}$ c.c. per Kg.). Eggleston therefore proposed to give half of this dose at once (*i.e.*, 7.5 c.c. of standardized tincture per 100 pounds or $1\frac{1}{2}$ minims per pound); followed in six hours by one-fourth of the total dose, then smaller fractions (*f.i.*, dividing the dose each time successively by $\frac{1}{2}$), every 4th to 6th hour till the total dosage or full response is reached.

The advantages of this method have been confirmed by White and Morris, 1918; G. C. Robinson, 1919, and others. The response starts definitely in 2 to 5 hours after the first dose; reaching its maximum within 24 hours; and continuing without further administration for 4 to 15 days.

Relation of Therapeutic Effects to Dosage.—This has been worked out by Eggleston, 1915, in terms of "cat-units;" a "cat-unit" corresponding to the quantity of the drug per kilogram of cat, that is just fatal by intravenous injection under suitable conditions (Hatcher, 1910). Eggleston found that the relation of effect to dose (cat-units) is remarkably uniform, for a given drug, regardless of the presence or nature of cardiac disease. Whatever the condition, the total dose of digitalis by mouth, to the appearance of the first improvement averages 0.09 cat-units per pound of body-weight (about 0.9 Gm. of good digitalis per 100 pounds); for full therapeutic or minor toxic effects, 0.146 cat-units per pound (about 1.5 Gm. per 100 pounds). With digitoxin, the corresponding doses are: first improvement, 0.04 cat-units per pound (1.4 mg. per 100 pounds; full therapeutic effect, 0.066 cat-units per pound (2.3 mg. per 100 pounds). The other digitaloids give variable results, by mouth, because of uncertain absorption. They are therefore unsuited for the intensive method.

Cumulative Methods.—These start with a daily dose equivalent to 3 to 6 c.c. of the Tincture of Digitalis (MacKenzie and Cushny), divided into

3 or 4 portions, and continued until the desired effect is obtained, when the dose is reduced to the maintenance dosage.

Maintenance Dosage.—When decompensation is only temporary the improvement is often lasting, and the digitalis may be discontinued when compensation has been restored. In auricular fibrillation, however, it is necessary to keep up a continuous digitalis effect. Clinical experience has shown that this should not exceed the daily dosage of 1 c.c. of Digitalis Tincture (A. Frankel, 1907). This is not quite equivalent to the capacity of destroying digitalis, which Pardee, 1919, calculated to average 1.5 c.c. of Tincture (1 c.c. = 1 cat unit). There is therefore little danger of cumulation.

Continuous Methods.—The older methods of using digitalis employed a dosage approximating the maintenance dosage. This would be unsuccessful, except when employing preparations stronger than the standard.

FIG. 15.—DIAGRAM OF DIGITALIS ADMINISTRATION.

This diagram aims to show graphically the quantity of digitalis present in the body at various times and the period when the full effective and minimum toxic dosage is reached with the various methods of administration. This "critical dosage" corresponds to the presence in the body of about 20 c.c. of standard tincture for the 150 lb. patient. The destruction of digitalis is assumed as equivalent to 1.5 c.c. of tincture per day (Pardee). The intensive method is taken as 11 c.c. of tincture reduced progressively by one-half, every 6 hours (i.e., $5\frac{1}{2}$, $2\frac{3}{4}$, $1\frac{1}{2}$, $\frac{3}{4}$, $\frac{1}{2}$ c.c.). The cumulative method is taken as 1 c.c. and $1\frac{1}{2}$ c.c. of the tincture every six hours i.e., 4 c.c. and 6 c.c. per day.

Quantity of Digitalis Present in the Body.—This is important since it determines the response. It may be calculated by subtracting the total quantity destroyed (estimated at 1.5 c.c. of the tincture per day, multiplied by the number of days since the administration started) from the *total* quantity of tincture administered. The result is only a rough approximation, since the rate of destruction is not constant: but it furnishes the best available estimate of cumulation. This is shown graphically in Figure 15. The student will profit by working out the following problems:

Problems of Digitalis Retention.—1. A patient has received by the cumulative method, 4 c.c. of tincture per day for the first week; 3 c.c. of tincture per day for the second week, none for the third week.

Assuming that Digitalis disappears from the body at the average rate of 1.5 c.c. of Tincture per day; and assuming the "toxic dose" at 22 c.c. of Tincture (actually present in the body), what percentage of this amount is present at the end of the 1st, 2nd and 3rd week?

2. If he received 6 c.c. per day, and destroyed it at the above rate, how soon would he reach the toxic dose?

3. How long must it then be withheld before the quantity retained falls to $\frac{1}{3}$ of the toxic dose?

Choice of Digitalis Preparations.—Of the various preparations of Digitalis, a good tincture, physiologically standardized, has many advantages.

The infusion is uncertain and unstable. It was formerly considered as more active than the tincture, but this was generally due to the administration of larger doses. Fluidextracts are unreliable (Haskell and Eckler, 1913). The powder may be used, but has no advantage, and is apt to be more irritant. The pill of Digitalis, Squill and Calomel ("Guy's Hospital Pill") seems needlessly complex. Digipuratum seems to be a good preparation (Boos, Newburgh and Marks, 1911); but as has been stated, a good Tincture is as satisfactory as any.

It may often seem that one preparation, or one digitaloid drug, gives results where another has failed. This is scarcely a conclusive demonstration of its superiority, even in that particular patient, since the cardiac condition, and therefore the response to digitalis, is apt to vary from day to day. Differences in clinical results are often due to differences in the disease, rather than in the drug. The same is true of the gastric effects.

Cushny, 1911, considers that 1 part of Digitalis is clinically equivalent to $\frac{1}{2}$ part of Strophanthus, or 3 to 4 parts of Squills.

Rectal Administration.—This may be used when oral administration is not feasible, for instance, because of emesis. The absorption is at least as rapid as with the oral route, and the dosage is the same. The alcoholic tincture is too irritant to be retained, so that an aqueous extract must be employed (R. L. Levy, 1924; Zondek, 1925).

Intravenous Administration.—The intravenous injection of full doses of strophanthin or ouabain avoids the delay incident to the oral administration, and may produce very striking results. Safe doses, however, do not act more promptly than the oral (Pardee, 1925), and the stormy reactions of the effective doses are distinctly dangerous, especially if the heart has not been thoroughly studied (A. M. A. Committee; G. C. Robinson, 1924); if this has been done, the patient would generally be already digitalized. Intravenous administration should therefore not be considered unless it is imperative that the effect be secured in less than two hours; beyond that time the intensive oral method would be adequate. It is also necessary to have the history of any digitalis administration within the three preceding weeks, and to reduce the dosage accordingly. If full data are not available, at least two or three days free from digitalis should intervene, the dose of strophanthin should be reduced to one-half, and this should be divided into three or four fractions, injected several hours apart; but if these necessary precautions are taken, the results will be no more speedy than with oral administration, and the latter should be preferred.

Strophanthin or Ouabain are more suitable for intravenous injection than any digitalis preparation, because the greatest obtainable uniformity is essential. The dosage for digitalis-free patients is 0.5 mg. ($\frac{1}{20}$ grain) of strophanthin U.S.P. in 3 to 5 c.c. of normal saline; rarely 2 or 3 such doses are repeated six hours apart; it would be safer to follow the single dose by the oral administration of 3 c.c. of digitalis tincture every four hours, till the therapeutic effect occurs. The following would be equivalent to 0.5 mg. of U.S.P. Strophanthin: Ouabain, 0.3 mg.; digitoxin, 1 mg.; digitalis 300 mg. (according to the intravenous toxicity for cats; Hatcher and Bailey, 1910). *Hypodermic or intramuscular injection* (Bailey, 1900)

causes considerable irritation and is not sufficiently superior in rapidity to oral, or in safety to the intravenous administration.

Clinical Response.—Intravenous digitalis therapy was tried clinically by Kottman and by Mendel in 1905; but the preparations which they employed were not satisfactory. The method has been put on a better basis by the introduction of strophanthin (A. Fraenkel and Schwartz, 1907; Krehl, 1907).

The therapeutic events correspond with those of digitalis administration, but occur much more rapidly: The first change is the increased amplitude of the pulse wave, which can be observed in three or four minutes. The pulse then becomes fuller and less irregular, and the symptoms of cardiac failure (dyspnea, cardiac distress, etc.) are improved. The slowing of the rhythm sets in somewhat later: its maximum is only reached after several hours, when the rate may become slower than that of the normal heart. The blood pressure is not altered—or rather it tends to remain or return to the normal. The diuresis also begins in a few hours. The increased amplitude outlasts the slowing.

A. E. Cohn and Levy, 1920, compared the effects of intravenous ouabain and oral digipuratum on patients. The response to ouabain was naturally more prompt and less persistent. Ouabain led less often to alteration of the T wave, but more frequently to toxic effects.

Intravenous injection sometimes produces cyanosis, chills and slight fever (Seifert, 1909).

Recapitulation of Other Digitaloid Drugs.—These present quantitative differences, which might be of some therapeutic value if they were better understood. At present they possess no serious advantage over digitalis for oral, and the strophanthins for venous administration. These accomplish all that can be done by any digitaloid drug. Many of the substitutes are inferior in solubility and absorbability.

Isolated Digitalis Principles.—These have proven disappointing, since the only one which can be obtained pure, digitoxin, is undesirable.

Digitoxin.—This has the undesirable features of producing excessive irritation, and of being nearly insoluble in water. It may be dissolved in 25 per cent. of alcohol. It has been used clinically, especially by Masius, 1894, Corin, 1895, and Eggleston, 1915 (*cf.* Intensive Oral Digitalis Medication). It is better absorbed than Digitalis. The usual *daily dose* by mouth is 1 to 3 mg., largely diluted; hypodermically, 0.5 mg. (1 c.c. of 0.05 per cent. in 25 per cent. alcohol; Unverricht, 1895; it produces irritation).

Digitalin "True."—This is also insoluble and emetic, but non-irritant and not greatly cumulative. Clinically, it has proved too feeble, a variable quantity being probably decomposed in the stomach (Deucher, 1896). It has been used in *doses* of 1 to 3 mg. up to 8 to 16 mg. per day; even 50 mg. have been given without toxic effects (Pfaff, 1892). It is administered in pills or dissolved in dilute alcohol.

Commercial Digitalins.—These have no advantage over the galenic preparations. The uncertain composition of these mixtures, and the danger of confusing the similarly named but very different preparations, should preclude their use. At least, "digitalin" should never be prescribed without specifying the variety (verum, German, French, etc.).

Digitalin German.—This contains considerable digitonin. Soluble in water or alcohol. *Daily dose*, 6 to 30 mg., $\frac{1}{16}$ to $\frac{1}{2}$ gr. (Beates, 1907).

Commercial Specialties.—These are also indefinite mixtures of the same impure principles. The most important are:

Digipuratum (Gottlieb).—This is a purified solid extract, freed from digitonin, and standardized to the same activity as digitalis leaves. It contains all the cardiac glucosides, is uniform, reliable and stable (Hale, 1910) and is relatively non-irritant; but all these features are possessed by a good tincture (Dixon, 1912; Cow, 1912). It is insoluble in cold water, but dissolves on the addition of a little alkali. Its dosage is that of digitalis leaves.

Digalen ("Digitoxin soluble," Cloetta, 1904).—This has been widely advertised as an amorphous and soluble isomer of digitoxin. Kiliani, 1907, states that it consists

mainly of digitalein Schm.; his opinion should carry weight. It was said to be free from the disadvantages of digitoxin; but it is of variable activity, unstable (Hale, 1910), produces considerable irritation, is not suitable for hypodermic injection, and causes cumulative effects (Fraenkel, 1907; Westenrijk, 1908). It therefore possesses no real advantage over a good tincture (Dixon, Cow, 1912), except for venous injections, and these cause pain and sometimes thrombosis. It is marketed as a solution (1 c.c. = 0.3 mg. of the glucosides). The intravenous dose is 1 c.c., repeated in one-half to one hour if necessary.

Strophanthins.—These have the advantages of being less irritant and less cumulative than digitalis; but the absorption is so uncertain that their use by mouth is not advisable (Hatcher and Bailey, 1909). This is reflected in the very different doses of strophanthus used by various clinicians. It is also liable to produce diarrhea. The main field of the strophanthins is for intravenous injection. Ouabain has the advantage that its identity is assured.

Apocynum (Canadian Hemp) is an effective member of the group, but without serious advantages.

Active Constituents.—These were isolated independently by Finnemore, 1909, and Moore, 1909. The principal constituent of Apoc. cannabinum is a neutral crystalline bitter principle, Cynotoxin; that of Apoc. androsaemifolium is Apocynamarin. They are identical pharmacologically and perhaps chemically. They are destroyed by boiling with acids or alkalis, although they are not glucosidal. They are believed to be dilactones of Kiliani's digitogenic acid. Impens, 1913, affirms that the active principle (which he calls "*Cymarin*") is the same for both species, and that apocynamarin is probably a decomposition product. The chemistry and cleavage products of cymarin are described by Windaus and Hermann, 1915. Apocynin and apocynein of Schmiedeberg were impure mixtures. Commercial apocynin is acetovanillin (Finnemore, 1908), and is practically inactive (Wood, 1904).

Actions.—These agree with digitalis (Dale and Laidlaw, 1909, who studied the pure principles). The cardiac action, therapeutic and toxic, of cymarin (frog, Kuroda, 1914); electrocardiograph, v. Hecht, 1915) is somewhat weaker than that of strophanthin. It produces practically no irritation, but relatively strong vasoconstrictor effect. Kuroda claims that the cumulation and emetic effects are weak; but Taviani, 1915, finds the serious disadvantages of uncertain absorption, and variable strength of the commercial cymarins. Large doses are also nephritic.

Beco and Dossin, 1919, with intravenous injections in dogs confirm the slowing, by vagus stimulation (central and peripheral); but claim that the cardiac tonus was decreased, and never raised. The blood pressure rose by general vasoconstriction, especially splanchnic (direct action on vessels). The urine flow was hindered, the renal vessels being constricted even by minute doses.

Cymarin has been used clinically like strophanthin, by vein or muscle, 0.1 to 0.5 mg.; hypodermic injection is too irritant. It is difficultly soluble in water, easily in alcohol. It has also been given by mouth, 0.3 mg., three to five times daily (von Noorden, 1916; bibliography). Gaisböck, 1915, on the basis of his clinical and experimental studies, emphasizes the need of caution in its use. The drug could probably be spared.

Scilla (Squills).—This produces the same effects as digitalis, experimentally and clinically (in auricular fibrillation). The dosage required to produce the typical response of heart-block and reversal of T-wave is from 24 to 48 c.c. of tincture per day (Viko, 1920), *i.e.*, considerably larger than the official dose. Toxic symptoms are rare. The milder action and larger dosage are due to poor absorption, for the intravenous dose is about the same as for digitalis (Eggleston). The poor absorption renders it undesirable as a digitalis substitute (Dixon, 1906); although it was advocated by Haynes, 1906.

Scilla was formerly used as expectorant (nauseant) and general diuretic. It is not well suited to either purpose. There are much safer

expectorants; and diuresis occurs only when cardiac edema is relieved (Viko).

Active Constituents.—The activity was attributed to two amorphous glucosides, scillipicrin and scillitoxin; but Ewins, 1911, found these to be impure mixtures. Kopaczewski, 1914, claims to have isolated two active principles: Scillitin, the toxic constituent, a nitrogen-free glucoside; and Scillidiuretin, water soluble, markedly diuretic; but of low toxicity.

Adonis resembles scilla more closely than digitalis (Chevalier, 1913). Roch and Cramer, 1914, find even large doses inefficient in cardiac diseases. Tuckermann, 1913, claims that "adonidin" is a mixture of an acid and neutral glucoside, both possessing digitaloid effects, the acid being also hemolytic.

Convallaria (Root of Lily of the Valley); active constituent, the glucoside convallamarin; is considered rather uncertain (Roch and Cramer, 1914).

Helleborein is a glucoside from the rhizome of *Helleborus niger* (*Hellebore*). Its digitalis action depends on the presence of an acetyl group (Sieburg, 1913). It is not absorbed from the human intestinal tract and therefore produces only diarrhea clinically (Cushny, etc., 1912).

Erythrophloeine is an alkaloid with digitalis action, obtained from "Sassy Bark" (Chemistry, Power and Salway, 1912).

Bio-Assay of Digitaloid Drugs.—The potent effects of these drugs makes variations in their activity very serious. Considerable variations occur in the crude drugs, and still more in their preparations. It is therefore essential that they be standardized. Since their activity is not due to a single principle, chemic assay is out of the question; and recourse must be had to bio-assays. It has been objected to these assays that they standardize the toxic and not the therapeutic effect. The objection is not well founded, since both actions are produced by the same substances and must therefore bear a definite ratio to each other. Clinical experience has borne out the great practical value of the bio-assay (Rowntree and Macht, 1916).

The U.S.P. directs standardization by the "one hour frog-method," i.e., by the quantity required to produce systolic arrest of the heart in intact frogs, in one hour under standard conditions. Several other frog-methods have also been used. The "intravenous cat-method" of Hatcher and Brody, 1910, which determines the acutely fatal dose, gives more precise results, but takes no account of absorption. The frog-methods also fail to reproduce clinical absorption; but when the activity with frogs and cats is fairly parallel, the absorption may be considered as normal; whilst wide divergence is usually associated with abnormality in the clinical response (Kruse, 1923). It would therefore be safest to assay the preparations by both methods, and to reject those that do not give concordant results. Those which agree should be adjusted to the U.S.P. standard.

Curiously, a chemical colorimetric method with an alkaline picrate solution, similar to the creatinine reaction, gives results that compare quite closely with those of the cat-method, both for digitalis and strophanthus (Knudsen and Dresbach, 1923). It remains to be seen whether this is more than a coincidence.

Fatal-dose Methods.—These determine the fatal dose, i.e., the smallest dose which kills a given weight of animal in a given time. The most convenient is the twelve- or twenty-four-hour frog method (suggested by Cushny, and elaborated by Houghton, 1898; being the first commercial bio-assay process). Guinea pigs may also be used for determining the fatal dose (Reed and Vanderkleed), but have no serious advantage. The chief objection to the lethal dose methods is that the results are not characteristic for digitalis, but might be due to any toxic constituent. On the other hand, according to the tests of the American Drug Manufacturers Association, 1923, they gave more con-

sistent results, both for frogs and guinea pigs, in the hands of different workers, than did the one-hour frog or the cat methods.

The average *M.F.D.* (minimum fatal dose) of some of the drugs is as follows (expressed as milligrams of drug per gram of frog-weight; the data are taken from Houghton and others):

Crude Drugs	Principles	Commercial Preparations
Digitalis..... 1.5	Strophanthin cryst. Kombé..... 0.001	Digitalin German.... 0.05
Squill..... 1.2	Strophanthin amorph. Merck..... 0.00094	
Strophanthus... 0.0075	Ouabain..... 0.00048	
Convallaria.... 0.25		

Houghton, 1909 and 1912, and Hamilton suggest expressing the strength as Heart Tonic Units (H.T.U.), based on the toxicity of crystalline Kombéstrophanthin.

For guinea pigs, the *M.F.D.* of digitalis is 0.06 to 0.1 Gm. per 240 Gm. pig (Reed). Pittenger and Vanderkleed, 1915, propose the use of gold-fish.

The Frog-standstill Methods.—These determine the smallest dose which produces the typical systolic arrest of the heart. They are thus theoretically superior to the fatal-dose method; practically, the results are fairly parallel. Various modifications are in use. The simplest of all the assay methods is the *one-hour frog method* of Famulener and Lyon.

The *M.S.D.* (minimum systolic dose) is as follows (milligram per gram; Hale and others):

Digitalis..... 0.5-1	Digitoxin..... 0.0085	Digipuratum..... 0.6
Strophanthus... 0.0075	Strophanthin amorph, 0.0011	Digitalin German... 0.07
	Ouabain..... 0.0003-0.001	Digitalin French.... 0.013
		Digitalein..... 0.024

Modifications.—Gottlieb, 1908, 1914, allows only thirty to forty-five minutes for the systolic standstill. This was used by Lehnert and Loeb, 1914. Focke, 1906, uses a fixed dose, and judges the strength by the time required to produce systolic arrest. The method is described by Fuehner, 1911, and Heinz, 1913. The short time does not suffice to secure complete absorption (Schmiedeberg). Objections have also been raised by Lutzkaja, 1908, and Hartung, 1912. Dooley and Higley, 1923, advocate intramuscular injection.

Excised or perfused hearts have been used mainly in scientific investigations (Schmiedeberg, 1910; Hartung, 1912; Gros, 1913; Straub, Santesson, 1915).

Fallacies.—All frog methods, and to a somewhat smaller extent the guinea-pig method, are open to certain errors, depending on the inconstant absorption and inconstant susceptibility of different animals (Vanderkleed and Pittenger, 1913). These must be met by using a sufficient number of test-animals. In addition, there are considerable seasonal and other variations. Each lot of frogs must therefore be standardized by determining their susceptibility to a standard preparation. This opens another fallacy, namely, that a given change of conditions may modify the susceptibility in a different degree for each drug, as has been shown for the influence of temperature (Baker, 1912 and 1913). Alcohol (25 per cent.) is not disturbing for frogs (Haskell, 1913), but is protective for guinea pigs. With guinea pigs, age, sex, and weight are unimportant; but there are considerable individual and marked seasonal variations, and the food also has an influence (Vanderkleed and Pittenger, 1913; Haskell, 1913). Vanderkleed and Pittenger, 1914, believe that the variations of guinea pigs are not great enough to necessitate control animals.

Even with these limitations, practical experience shows that the intact-frog methods, when properly and critically performed, permit the estimation of the relative activity of similar preparations (such as a series of tinctures) with a probable error not exceeding 25 per cent.—a sufficiently close approximation for practical purposes. On the other hand, they are unreliable for comparing the relative activity of dissimilar drugs, *f.i.*, strophanthin and digitoxin. The greater toxicity of strophanthin could be due, at least in part, to more rapid absorption—a factor which might be very different in the human subject. This could be excluded by using the excised heart; even then, however, it would be doubtful whether the same quantitative relations hold for the human heart as for the frog's.

The intravenous cat method of Hatcher avoids most of these objections (Eggleston, 1913). Differences in absorption are excluded by the method of administration; the action is purely cardiac, and thus measures the characteristic digitalis-effect, which is not easily simulated by other toxic principles; and the cat heart must resemble the human in its reactions much more closely than that of the cold-blooded animals.

Indeed, experience indicates that its resemblance is closer than that of other mammals. Even unrelated digitaloid principles may therefore be compared. Another advantage is, that the response of individual cats is remarkably uniform, so that the probable error is much smaller, and the standardization of the individual cats is usually not necessary.

The method is sufficiently simple: it merely determines the fatal Kg.-dose; the solution being injected into the femoral vein at such speed that death occurs in about one and one-half hours. This quantity, expressed as milligrams of drug per kilogram of cat, constitutes a "cat-unit" (Hatcher and Brody, 1910). The intravenous therapeutic dose for man is about 5 cat-units.

With the slower acting digitalis preparations, the death-point can be hastened by using the rapidly acting ouabain to complete the reaction: about 75 per cent. of the fatal dose of the digitaloid are injected in fifteen minutes, and after an interval of ten minutes the reaction is completed with 1:10,000 of ouabain (Hatcher and Brody, 1910). This expedient had also been very useful in ascertaining the absorption and persistence of digitaloids.

The cat-method is probably the best for the investigation of fundamental clinical problems; but it is not necessary for the commercial standardization. The results of Eckler, 1911, enjoin caution against its use without special experience. The following table gives for a number of drugs the milligrams that contain a cat-unit; *i.e.*, that kill 1 Kg. of cat (Hatcher, 1912):

Crude Drugs	Principles	Commercial Preparations
Squill.....	575 Adonidin.....	4.35 Digitalin German.....
Euonymus.....	475 Digitalein.....	3.5 Digitalin cryst. Nativele
Helleborus.....	100 Convallamarin.....	(Levine, 1920).....
Digitalis.....	100 Helleborein.....	0.8 Ouabain Arnaud (Levine).....
Apocynum.....	70 Digitalin true.....	0.06
Convallaria.....	50 Scillitoxin.....	
Strophanthus Kombé.....	3.0 Digitoxin.....	0.3-0.5
Stroph hispidus.....	1.5 Strophanthin	
	amorph.....	0.13-0.17
	Ouabain.....	0.1

Macht and Colson, 1917, state that the Hatcher method gives more uniform results if the vagi are divided; but the toxicity is higher.

Attempts to utilize the blood pressure and pulse reactions have been unsuccessful, since these are too variable.

PREPARATIONS

Apocynum (Canadian Hemp).—The dried rhizome and roots of *Apocynum cannabinum*.

Fldest. Apocyn.—Average dose, 0.75 c.c., 12 minims.

Convallaria (*Lily of the Valley*).—The root of *Convallaria majalis*.

* *Digitalis* (Digit.), U.S.P.; *Digitalis Folia* (Digit. Fol.), B.P.; *Digitalis* (Fox Glove Leaves).—The dried leaves of *Digitalis purpurea*. The B.P. specifies that they must be collected when the plant is beginning to flower. Dose, 0.1 Gm., 1½ gr., U.S.P.; 0.03 to 0.12 Gm., ½ to 2 gr., B.P.; as pills. Maximum dose, 0.2 Gm., 3 gr.¹

¹ Under proper precautions, the "Maximum doses" of the drugs of this group can be temporarily exceeded.

The activity of different samples of digitalis varies considerably, so that they should be standardized by bio-assay. This applies also to the Tincture. If preserved reasonably dry, the leaves keep indefinitely. The leaves of the first-year plants are as good as the second (Sharp and Lancaster; Caesar and Loretz, 1910). Plants cultivated in America (Newcomb, 1912) are as good as the wild European (Hale, 1910; Miller and Baker, 1913; Rowntree and Macht, 1916). Those grown during a wet season are less active (Caesar and Loretz, 1907).

The petioles, ribs and hairs of the leaves are relatively inactive (Newcomb and Rogers, 1918).

Other species of digitalis, *e.g.* *D. Thapsi*, also have the actions of the group (Farwell and Hamilton, 1917).

White and Morris, 1918, claim that *Digitalis lutea* is as effective as *purpurea* on the heart, and appears to be less emetic and less convulsive.

The U.S.P. requires that digitalis, in the form of the tincture, properly diluted and injected into the ventral lymph sac of a frog, has a minimum systolic dose (the minimum dose producing in one hour a stoppage of the heart in systole) of 0.0035 to 0.0065 c.c. of tincture, equivalent to 0.000,000.5 Gm. of ouabain, for each gram of body weight of frog. All digitalis preparations are similarly assayed.

* *Infusum Digitalis* (Inf. Digit.), U.S.P.; Infusion of Digitalis.—1.5 per cent.; flavored with cinnamon; (also contains 10 per cent. of alcohol). Must be freshly prepared from the leaves. *Dose*, 6 c.c., 1½ drachms, U.S.P.

* *Inf. Digitalis*, B.P.—0.7 per cent.; note that this is only half the strength of the U.S.P. *Dose*, 7 to 15 c.c., 2 to 4 drachms, B.P.

* *Tinctura Digitalis* (Tr. Digit.), U.S.P., B.P.—10 per cent. of drug. Miscible with alcohol or water (with slight turbidity due to the fat; tinctures deprived of fat do not become turbid, but have no other advantage). *Incompatible* with acids or tannin. *Dose*, 1 c.c., 15 minims, U.S.P.; 0.3 to 1 c.c., 5 to 15 minims, B.P. Unstandardized tinctures generally vary in activity by 200 to 400 per cent. (Fraenkel; Edmunds, etc.).

Euonymi Cortex, B.P.; (*Wahoo*).—The dried root-bark of *Euonymus atropurpurens*. Contains an amorphous bitter principle. Used mainly as cathartic, similar to podophyllum. *Dose*, 0.5 Gm., 8 gr.

Ext. Euonym., B.P.—A powdered extract. *Dose*, 0.06 to 0.12 Gm., 1 to 2 gr., B.P.

Ouabain.; g-Strophanthin-Crystalline.—Sol. in water (to 1 per cent.), more sol. in hot; sol. in alc.; difficultly in lipid solvents. *Dose*, one-half that of the official Strophanthin.

Ampuls of Ouabain deteriorate rapidly through the alkalinity of the glass (Levy and Cullen, 1920); but may be made stable by using a m/50 phosphate mixture of $P_H = 7$ (Cohn and Levy, 1920).

Scilla, U.S.P., B.P.; Squill.—The dried fleshy scales of the bulb of *Urginea maritima* (*Urginea Scilla*, B.P.). The U.S.P. directs the bio-assay of Squill and its preparations, similarly to Digitalis, and their adjustment to the same activity. *Dose*, 0.1 Gm., 1½ gr., U.S.P.; 0.06 to 0.2 Gm., 1 to 3 gr. B.P. Maximum dose, 0.5 Gm., 8 gr.

Acetum Scillæ (Acet. Scill.), B.P. Vinegar of Squill.—30 per cent. (twice the strength of the old B.P.). *Dose*, 0.3 to 1 c.c., 5 to 15 minims, B.P.

Fldext. Scill., U.S.P.—*Dose*, 0.1 c.c., 1½ minims, U.S.P. This formerly contained acetic acid, but Houghton, 1906, showed that the acid diminished the activity by half. For the same reason, the Vinegars of Squill are unscientific.

Oxymel Scill., B.P.—33 per cent. of Acet. Scill. *Dose*, 2 to 4 c.c., ½ to 1 drachm, B.P.

Pil. Ipecac. c. Scill., B.P.—Contains about 5 per cent. of Opium as Pulv. Ipecac. Co.; Squill and Ammoniac. *Dose*, 0.25 to 0.5 Gm., 4 to 8 gr., B.P.

Pil. Scill. Co., B.P.—25 per cent. of Squill, with Ginger, Ammoniac and Soap. *Dose*, 0.25 to 0.5 Gm., 4 to 8 gr., B.P.

Syr. Scill., U.S.P., B.P.—Prepared from Acet. Scill., representing about 5 per cent. of Squill. *Dose*, 2 c.c., 30 minims, U.S.P.; 2 to 4 c.c., ½ to 1 drachm, B.P.

Syr. Scill. Co., U.S.P. (Coxe's Hive Syrup).—An antiquated cough mixture; the average dose, 2 c.c., 30 minims, U.S.P., representing 0.16 Gm. (2½ gr.) each of Squill and Senega, and 4 mg. (⅙ gr.) of Tartar Emetic.

Tr. Scill., U.S.P.—10 per cent. in 75 per cent. alc. *Dose*, 1 c.c., 15 minims, U.S.P. Maximum dose, 2 c.c., 30 minims.

Tr. Scill., B.P.—20 per cent. *Dose*, 0.3 to 1 c.c., 5 to 15 minims, B.P.

**Strophanthinum* (Strophanthin.), U.S.P.; (Amorphous) Strophanthin.—A glucoside or mixture of glucosides from *Kombè Strophanthus*. White or yellowish powder. Very sol. in water or diluted alc.; nearly insol. in lipid solvents. *Dose* (daily), intravenous (or muscular), 0.5 mg., ⅓₂₀ gr., U.S.P. Maximum dose, 1 mg., ⅓₆₀ gr.

Strophanthus, U.S.P.; *Strophanth. Sem.*, B.P.—The dried ripe seeds of *Strophanthus Kombè* (also of *Strophanthus hispidus*, U.S.P.); obtained from central and western Africa. *Dose*, 0.06 Gm., 1 gr., U.S.P. The U.S.P. directs the *Strophanthus* preparations to be adjusted by bio-assay to one-hundredth of the activity of Digitalis.

Ext. Strophanth., B.P.—A powdered extract, representing 50 per cent. of drug. *Dose*, 16 to 60 mg., ¼ to 1 gr., B.P.

Tinctura Strophanthi, U.S.P., B.P.—10 per cent. (This is the same strength as the U.S.P. VIII, but four times as strong as the old B.P.). *Dose*, 0.5 c.c., 8 minims, U.S.P.; 0.12 to 0.5 c.c., 2 to 8 minims, B.P. Maximum dose, 0.5 c.c., 8 minims. However, the absorption is so uncertain that no reliable dose can be stated. Unstandardized tinctures are about as variable as digitalis.

Urginea (*Urgin.*), B.P.; (*Indian Squill.*)—The dried young bulbs of *Urginea indica*. The preparations correspond in title, strength and dose to the B.P. preparations of Squill.

BARIUM

This stimulates all muscle, striped, unstriped and cardiac, irrespective of innervation. It is mutually antagonistic with all muscular depressants, regardless of whether these act on the receptive or on the responsive mechanism.

Unlike the other elements of its group, Ca and Sr, barium is very toxic. Its chief effects resemble those of the digitalis group: It produces a similar action on the cardiac muscle; a strong vasoconstriction by direct stimulation of the arterial muscle (occurring therefore after apocodeine, Dixon, 1903); violent stimulation of peristalsis, even on intravenous injection; and a stimulation and later paralysis of the central nervous system. It also produces local irritation, and is inimical to the lower forms of life such as yeast cells.

The soluble barium salts, and the carbonate and sulphide, are sufficiently absorbed from the alimentary canal to produce the systemic effects. The sulphate, which is used in Roentgen work, is insoluble and non-toxic; and sodium or magnesium sulphate are antidotes for barium poisoning.

Barium is but little used in therapeutics, for fear of toxic effects. However, A. E. Cohn and Levine, 1925, found it very useful in the syncopal attacks of the Adams-Stokes syndrome. These are due to temporary suspension of ventricular contractions; and barium removes the condition by increasing the excitability of the ventricular muscle. For this purpose, barium chloride, 30 mg. ($\frac{1}{2}$ grain) well diluted, is administered by mouth, three or four times per day. The attacks usually disappear within two days, and the barium may then be stopped, without recurrence of the syncope. Epinephrine is relatively ineffective, and atropine quite ineffective. Barium, in the same dosage, has also been tried as a general substitute for digitalis (Pesci, 1904), but appeared unsatisfactory.

Cardiac Action.—Ba, like digitalis, increases the excitability of the cardiac muscle, and the force of the contractions (Wertheimer and Boulet, 1911). The rate is slowed even after atropine, so that this effect is muscular (Fillipi). Intracardiac application causes systolic arrest; dilute solutions, or exocardiac application, produce diastolic arrest, just as does digitalis (Poulssohn, 1910; Werschlin, 1911; Weyland, 1913). The effects in complete heart-block are similar to those of calcium (van Egmond, 1913).

Auricular strips of the turtle heart respond to the barium stimulation by increase of rate, tone and tonus waves. The effects are partly antagonized by epinephrine (Gruber, 1921).

Arterial Muscle.—The high rise of blood pressure under barium is due mainly to vasoconstriction. The effect is directly on the arterial muscle, and involves all arteries, regardless of their innervation (Dixon and Halliburton, 1910; Cow, 1911). This might suggest its use in pulmonary hemorrhage; the lung vessels being strongly constricted (Baehr and Pick, 1913; Berezin, 1914). However, the increase of the general blood pressure more than offsets the local constriction, so that the bleeding becomes more profuse (E. Frey, 1909). The liver veins are constricted in the guinea pig, not in the frog (Berezin, 1914).

Intestines.—Barium chloride produces violent peristalsis, culminating in intestinal spasm, which may be removed by magnesium (Sollmann and Rademackers, 1925). The purgative effect may also be produced by intravenous injection in dogs (3 mg. per Kg.); but 7 to 8 mg. are rapidly fatal by the circulatory effects, without purgation. Rabbits are not purged by any dose, although 18 mg. per Kg. is fatal (Chistoni, 1918). The intravenous injection of 0.5 to 1.25 Gm. was used on horses, to remove tympanites; but there were so many fatalities, that it was generally abandoned (Dieckerhoff, 1895).

Skeletal Muscle.—Barium has two distinct actions on frog's gastrocnemius muscle (Zoethout, 1919):

(a) Direct stimulation, persisting as long as the muscle remains in the solution. This requires the presence of Na ions, and is therefore abolished by isotonic sugar solution.

(b) Contact irritability, seen only when the muscle is immersed or removed from the solution, being produced by the inward or outward passage of Ba ions. It is antagonized by certain Na salts.

Both irritations are antagonized by K, Ca and Mg ions.

Fowl's Muscle.—Injection of BaCl_2 produces only an increase of muscular tonus in the normal leg, but after denervation, it causes a strong contraction. The degenerating muscle has therefore become more susceptible to Ba. A similar result can be secured by preliminary injection of nicotine. Curare does not influence this contraction; indicating that Ba acts more peripherally than curare, nicotine or physostigmine.

Bronchial Muscle.—This is also constricted (Trendelenburg, 1912; Titone, 1913; Baehr and Pick, 1913).

Gall-bladder.—The isolated organ is constricted (Lieb and McWhorter, 1915).

Cerebral Stimulation.—Direct application of barium salts of the cerebral cortex stimulates the white matter, and increases the irritability of the gray matter (Maxwell, 1906).

Excretion.—The main channel is by the intestine, only traces appearing in the urine even after parenteral administration (G. M. Meyer, 1909). A small amount may be deposited in the bones. Barium lessens the elimination of uric acid (Abl, 1913).

Symptoms of Barium Poisoning.—These consist in vomiting, colic, violent diarrhea; convulsive tremors; slow hard pulse and high blood pressure; hemorrhages into the stomach, intestines and kidneys. Death occurs after a few hours or days. The fatal dose is probably 0.8 to 0.9 Gm. Barium carbonate and sulphide are also toxic, but act more slowly, and the sulphide requires relatively large doses (Stedem, 1920). Crawford, 1908, attributed "Loco poisoning" to the Ba contained in the Western plants. This could not be confirmed (Alsberg, Black and Marsh, 1912).

X-ray Diagnosis.—The insoluble BaSO_4 is used in x-ray diagnosis. It is tasteless, inexpensive, and does not delay the gastric movements, as does Bismuth. If pure, 100 to 150 Gm. (boiled with two and one-half to five times its weight of corn-meal, and flavored with cocoa) may be given without any bad results; but it is essential that it should not be contaminated with soluble barium compounds (Guenther and Bachem, 1911; Merck's Report, 27: 43).

Barii Sulphas, U.S.P.; Barium Sulphate.—Caution: In prescribing Barium Sulphate the title should never be abbreviated, to avoid confusion with the poisonous barium sulphide or sulphite.

A fine, white, odorless, tasteless powder; free from grittiness. Insol. in practically all solvents.

CACTUS

Preparations from Cactus (*Cereus grandiflorus*) have been used as substitutes for digitalis, particularly in functional cardiac neuroses. Proprietary preparations have been widely advertised. Experiments on animals and men have shown that these are devoid of digitalis and strychnine actions and are indeed absolutely inert. The clinical testimony is not conclusive. Careful observers have failed to find any clinical effects; those who describe positive results have perhaps undervalued the element of suggestion in the treatment of functional neuroses (Report, Coun. Pharm. Chem., 1910; J.A.M.A., 54: 888).

Uncertain Origin.—Some of the discordant statements are probably due to confusion with other cacti, some of which contain alkaloids with marked narcotic, tetanic, and possibly some cardiac actions. No alkaloid or other definite principle has been certainly isolated from the *grandiflorus*.

Experimental Results.—The drug was introduced in 1864 by Rubini, a homeopathic physician. Boinet and Teissier, 1891, described a weak digitalis action on the frog's heart, produced by an alkaloid, which they considered derived from *Cactus grandiflorus*. They were evidently working with some other substance. No serious attempts were made to check the extreme claims for the cactus preparations, until Hatcher, 1907; Matthews, 1908; Lyon, 1910; and Hatcher and Bailey, 1911, showed that even enormous doses of the best-known preparations are practically inert—entirely so when given by mouth—in animals and in man, in health and in disease. Groeber, 1913, again affirms

the presence of a glucoside with digitaloid action, but so weak that it would be therapeutically inactive. He does not state whether his drug was properly identified. This precaution was taken by Hatcher and Bailey. Gordon Sharp, 1894, also found the clinical results negative when the genuine drug was used. The favorable clinical literature (summarized by Hatcher and Bailey, 1911) does not bear stringent criticism.

Other Cactus Varieties.—Alkaloids have been isolated from a number of cacti (Heffter, 1898): mescaline, anhalonidine, pellostine, pectenine, pilocereine, etc. Mogil-ewa, 1903, investigated their action on the heart, and found that they produce slowing, but without increase of pulse volume (in contrast to digitalis).

MESCAL

"*Peyote*," misnamed "mescal buttons," consists of the tops of a small cactus, *Lophophora williamsii* (formerly *Anhalonium lewinii*). It has been used for centuries by the Indian tribes of the Southwest in religious ceremonies, to promote trances and hallucinations. Blair, 1921, claims that the Indians are also using it as a habitual narcotic, but Safford, 1921, states that its usage is still entirely ceremonial. Lewin, 1888, demonstrated principles with narcotic and strychnine effects. It contains four alkaloids which agree qualitatively in their actions. The latter are quite numerous: a slowing of the heart, a curare action on striped muscles, a specific depression of the respiratory center, and a stimulation of other parts of the central nervous system. The stimulation is shown mainly in certain special senses, most conspicuously in vision, the effect appearing as a loss of coordination. It produces hallucination of all the special senses, but particularly of sight. There are flashes and lines of ever-changing colors. Since they are the same in both eyes, they must be central (Dixon, 1899). A psychologic study of mescaline hallucinations has been made by Knauer and Maloney, 1913. Waeber, 1912, failed to find the described visual and auditory effects and double personality, but observed other psychic and physical disturbances. Bresler, 1905, experimented with its action on mentally affected patients. *Pellostine*, one of the alkaloids, has been investigated by Pincussohn, 1907. Mescal is not used therapeutically.

Anhaline seems to be identical with hordenine (Spath, 1919).

CAMPHOR

Camphor, $C_{10}H_{16}O$, is a solid derivative of terpene, $C_{10}H_{16}$, allied to the volatile oils. It is prepared by the distillation of the wood of the camphor-tree. This natural camphor polarizes to the right. A synthetic camphor has been prepared, which is racemic. A levorotatory camphor is also known. The three isomers agree qualitatively in their actions. The l-form is somewhat more active on the nervous system. Therapeutically, they seem to be equivalent; but only the natural is official.

Camphor is a mild irritant and antiseptic, often employed as a counter-irritant in the form of camphor liniment or spirits. It is also used as a protective against moths. Systemically, the effects are very inconstant, owing perhaps to its uncertain absorption and rapid destruction. It is used intramuscularly to stimulate the circulation in collapse conditions, apparently with good results; the mechanism has not been satisfactorily explained. Toxic doses produce convulsions. In frogs it exerts a curare action.

Local Actions.—Externally camphor acts similarly to the volatile oils, producing mild analgesia and rubefaction, with little sensory irritation. It is applied in neuralgia, inflammations, etc.

The irritant action of small doses of camphor on the digestive canal is used against *dyspepsia*. Large doses produce vomiting.

Antiseptic Action.—Camphor is feebly antiseptic, the isomers being about equivalent (Joachimoglu, 1917). A saturated solution is used as stimulant mouth-wash and gargle. A bit of camphor is a good preservative for hypodermic solutions, proteins, etc. (Romanelli, 1917).

Camphor has been employed as *intestinal antiseptic* (0.3 Gm., three times daily), but its usefulness is doubtful.

Diffuse Peritonitis.—Intraperitoneal injections of the camphorated oil were advocated by Vignaud and Arnaud, 1912.

Pneumonia.—Seibert, 1912, claimed that camphor reduces the toxemia and prevents the crisis, but the benefits are doubtful and the treatment has not obtained wide acceptance. Seibert advised 12 c.c. of 20 per cent. oil solution, hypodermically, every 12 hours. Good results were also reported by Weintraud, 1913, and Leo, 1913. Leo preferred *intravenous injection* of the saturated watery solution (about 1:5,000).

E. Stein, 1915, tried camphor against experimental pneumococcus pneumonia. He found that the different races of organisms differ in susceptibility.

Absorption, Fate and Excretion.—Camphor is quite readily absorbed from the mucous membranes and subcutaneous tissue. Hatcher and Eggleston, 1914, find the absorption more rapid from oral than from intramuscular administration. It is rapidly oxidized to campherol $C_{10}H_{15}O.OH$; and this excreted in combination with glycuronic acid, $C_{10}H_{15}O.O.C_6H_9O_6$ (Schmiedeberg and Meyer, 1879).

This destroys the activity of the camphor; and accordingly, Happich, 1912, claims that the toxicity is higher when glycosuric acid formation is disturbed through starvation or deprivation of oxygen. Similarly, he states that intraarterial injections are more than twice as toxic as intravenous.

Experimental Effects of Camphor on the Circulation.—These are inconstant, different investigators reporting divergent results and conclusions. Generally there is no definite response if the circulation is normal. When the heart muscle is depressed in various ways, camphor may, under favorable conditions, improve the cardiac contractions and remove arrhythmias. The response is, however, uncertain; and gives only doubtful support of the claimed therapeutic action.

Perfused Rat Heart.—This has been found an especially suitable object for demonstrating the improvement. After being injured by cooling, electric stimulation, phosphorus, digitalis, yohimbine, or chloroform, the addition of camphor (natural or synthetic) usually increased the rate and removed arrhythmias; the tonus was generally improved; so also the coronary flow. The effects on the excursions were inconstant. These favorable results did not always follow; indeed, the heart sometimes became worse (Froehlich and Pollak, 1920.)

Combination with Vasodilators.—The improvement of the perfused rat heart was increased by the addition of dilators of the coronary vessels, *i.e.*, caffeine or papaverine (Froehlich and Pick).

Heart of Other Mammals.—These have given more confusing results:

No definite effects have been demonstrated in normal hearts, *in situ* or isolated. Winterberg, 1903; Klemperer, 1907; Plant, 1914; and Richards, 1914, obtained purely negative results. Seligman, 1905, sometimes observed strengthening, but by no means always. He claimed, however, that camphor tends to prevent or recover fibrillation; and Gottlieb, 1905 and 1906, found that the heart of intact animals is also rendered more resistant to fibrillation. This was contradicted by Winterberg. Richards found no definite effect of camphor on the isolated heart in fibrillation or asphyxia; nor Plant after chloral or phosphorus. Heard, 1915, worked with the heart *in situ*, but isolated from its nerves, with the pressure kept constant by a compensator; camphor had no effect. Isaak, 1913, claims a rise of blood pressure from intravenous injection of camphor, in animals with their hearts weakened by phosphorus, but no effect after chloral. During complete heart-block, in dogs, van Egmond, 1913, could generally observe no effect from camphor. The coronary blood flow increases, if the pressure rises (F. Meyer, 1912). The *coronary vessels* (as also the ear-vessels) of rabbits are also dilated directly by perfusion with camphor (1:2,500 to 5,000); still more by borneol and menthol. With a tenth of these concentrations, the dilation is preceded by constriction (Likhatcheva, 1916).

Heathcote, 1923, confirmed the coronary dilation from camphor, menthol and thymol.

Frog's Heart.—The effects of applying camphor solutions were studied by Heubner, 1870; Oehm, 1870, and by Leyden and van den Velden, 1917. Those of perfusion by

Plant, 1914 (bibliography). They are slight and inconstant with normal hearts, but camphor restores the beat of frog hearts arrested by muscarine (Harnack and Witkowski, 1876) or by chloral (Boehm, 1905). The restoration is only transient (Plant, 1914). Joachimoglu, 1917, found a similar response to all kinds of local irritants, so that it does not appear to be characteristic for camphor. Analogous restorations are produced by the various camphor derivatives on *turiles* (Lippens, 1911); camphoric acid being somewhat more stimulant.

The direct effects on the ventricular muscle (Straub's method) were studied by Joachimoglu, 1917. Very weak solutions (1:4000) increased the amplitude slightly; depression occurred with concentrations above 1:2500; and arrest above 1:1250; the hearts may recover spontaneously. The three isomers act quantitatively alike; except that with the racemic the arrest lasts only 15 minutes, whereas the others recover only after $1\frac{1}{2}$ to 3 hours. Menthol also stopped the heart, but weak concentrations did not accelerate.

Sasaki, 1921, studying the phenomena on the apex of the ventricle, found little effect on normal hearts; but the camphor restored depressed irritability, contractility and rhythmicity; for instance, after muscarine, chloral or exhaustion. The increased rhythmicity makes it more difficult to throw the muscle into fibrillation and tetanus. Froehlich and Grossmann, 1921 confirm that camphor restores the regular rhythm to perfused frog hearts that have been thrown into fibrillation by electric stimulation or by aconitine. Heat also produces a similar restoration. These investigators report that camphor also restores the beat of hearts thrown into systolic standstill by perfusion with strophanthin.

With *ventricular strips* of turtle hearts, Plant observed slight quickening, not modified by chloral. The ultimate effects of strong solutions of camphor are depressant, weakening and slowing the beats.

Blood Pressure and Vascular System.—According to Liebmann, 1912, the most frequent result of moderate doses is a peripheral dilator effect, first on the pulmonary then on the systemic blood vessels. The blood pressure, therefore generally falls; but this may be preceded by brief central vasoconstriction. Large doses occasionally produce periodic variations in the blood pressure, through the vasomotor center. Large rises of blood pressure may occur during convulsions.

The earlier investigators (Pellacani, 1883; Alexander-Lewin, 1890; Pässler, 1899) generally described a rise of blood pressure from vasomotor stimulation. Wiedemann, 1877, and Stockmann, 1888, observed rhythmic rises of blood pressure, attributed to heightened reflex irritability. Stimulation of the vasomotor center, however, does not occur with therapeutic doses, but only as the convulsant effects are approached; and especially during the convulsions proper (Pilcher and Sollmann, 1915). Often the blood pressure is not changed by moderate doses. The most frequent result, according to Winterberg, 1903, and Liebmann, 1912, consists in persistent fall of blood pressure occasionally preceded by a slight and short rise. The rise is attributed to central vasomotor stimulation; but the fall is produced by peripheral action on the vessels. Heard and Brooks, 1913, obtained quite negative results. Liebmann finds that the pulmonary vessels dilate before the systemic. The widespread vasodilation results in lowering the pressure in the right heart. Frey, 1909, found no effect on pulmonary hemorrhage. The cerebral vessels are also dilated (Berezin, 1916).

Lieb and Herrick, 1917, report that the *hypodermic injection of irritants*, including camphor, into decrebrated animals often produces a slight and transient rise of blood pressure but that they fail entirely in anesthesia, shock, or hemorrhage.

Heathcote, 1923, found no rise of blood pressure in anesthetized animals, unless convulsions occurred. When these were prevented by removal of the cerebral hemispheres, doses up to 1 Gm. per Kg. did not raise the blood pressure.

Excised Vessels.—Lichatcheff, 1916, reports that camphor, borneol and menthol, in 1:2,500 to 1,500 dilution, produce a strong dilation of coronary and other vessels; this being strongest with borneol and weakest with camphor.

More dilute solutions (1:10,000 to 50,000) have no effect on the coronary. Other arteries are temporarily constricted.

Clinical Effects on Circulation.—Camphor is used clinically as a temporary cardiac stimulant. Opinions are divided as to its usefulness. The effects, if they occur, are inconstant and unreliable. However, its employment is harmless.

In normal individuals and in cardiovascular disease, camphor (even up to 3 Gm. hypodermically—Heard and Brooks, 1913) does not alter the blood pressure, or the rate

or quality of the pulse. In collapse conditions, especially in febrile toxemias, most clinicians believe that hypodermic injections improve the volume, tension and regularity of the pulse temporarily. G. Schwartz, 1906, generally found a rise of blood pressure of 10 to 20 mm., too slight to explain the improvement. It is possible but not certain that the weakened human heart responds better to camphor than experiments on animals would indicate. It is also conceivable that the stimulation is reflex, since the injections produce considerable local reaction (Heard and Brooks). The regulating influence on delirium cordis might be beneficial in auricular fibrillation, but the action would probably be too brief.

Hewlett, 1917, failed to find any change in the blood flow of the human arm after hypodermic injection of 0.3 to 0.7 Gm. of camphor in oil.

Administration.—The camphor is employed intramuscularly, dissolved in sterile olive oil, 1 to 2 c.c. of the 10 per cent. solution being repeated in ten- to fifteen-minute intervals as needed. For babies of one year, A. Jacobi advised $\frac{1}{10}$ to $\frac{1}{4}$ grain every two hours. Intravenous injection (250 to 350 c.c. of 0.1 per cent. in saline) is safe, but less effective (Weintraud, 1913).

Liquid Petrolatum should not be used as solvent for intramuscular injections. It is not absorbed, becomes encapsulated, and forms sensitive tumors (Mook and Wander, 1919).

Other Uses.—Camphor Spirit is a household remedy in colds, bronchitis, etc. It is probably somewhat expectorant, diaphoretic and antipyretic (Binz, 1875 and 1877). The skin vessels are dilated. It was also advised in *tuberculosis*, but has not found much support. Camphor has been used as a nervous depressant in hysteria, epilepsy, chorea, and convulsions, and as an anaphrodisiac. This rests on no rational basis.

Respiration.—The effects of non-convulsant doses are slight and inconstant, practically negative.

Edsall and Means, 1914, and Higgins and Means, 1915, studied the effects on man, using 0.4 to 0.5 Gm. hypodermically. They found the center sometimes slightly stimulated by bronchodilation and slight increase of carbon metabolism. The rate was often slowed; the volume, single or minute, was unchanged.

In animals, the respiration is somewhat slowed but deepened, so that the minute volume is increased. Wieland, 1915, claims lowering of the threshold for CO_2 . Isaac found it especially effective after morphine. Voegtlin and Wiggers, 1918, obtained rather uncertain stimulation after morphine and other depressants.

On the other hand, Hanzlik, 1923, observed a fair increase of respiration after hypodermic injection of camphorated oil (20 per cent.) in anesthetized rabbits; even during rather deep morphine depression.

Excised Ureter.—This is stimulated by the l isomer; the d being indifferent (Macht, 1918).

Skeletal Muscle.—Direct application produces a curare effect in frogs, not in mammals. Other camphors derived from various volatile oils also produce this effect (Hildebrandt, 1902).

Invertebrates.—Newly hatched squid, placed in $\frac{1}{10}$ saturated solution of camphor in seawater, responds by spasm of the mantle and contraction of the chromatophores. The stimulation appears to be in the ganglia. It is followed by paralysis, which may be overcome by nicotine (Moore, 1919).

Lecch-muscle.—Joachimoglu, 1920, found that the three isomers produce quantitatively identical effects: *i.e.*, strong increase of tonus and rhythmic contractions with concentrations of 1:1000 to 5000. Thymol acts similarly.

Toxic Effects.—These are similar in man and animals, consisting in stimulation and then depression and paralysis of the central nervous system.

The *treatment* would consist in evacuation and stimulation. Alcohol and oils should be avoided since they favor absorption.

Symptoms in Man.—These consist in *nausea*, vomiting, colic, vertigo, disturbed vision, tipsiness, *excitement*, *impulsive movements*, *delirium*, *loss*

of consciousness, face flushed then pale; *epileptiform convulsions* are a constant feature in animals, and sometimes occur in man (after 1.5 Gm.; Austragesillo, 1915); often anuria (illustrative reports, Stanley, 1903; F. Baker, 1910; Koppang, 1912). *Death* is rare in man, occurring by asphyxia and collapse. *Convalescence* may last several days or weeks; the gastric disturbance is especially persistent.

Benz, 1919, reported the poisoning of twenty children by the oral administration of 30 to 45 c.c. of camphorated oil. All were more or less convulsed, with blue-black lips, but otherwise fair color. The severe cases had locked jaw. Emesis was induced by mustard water, and all recovered promptly (20 min. to 4 hours).

Convulsions.—In mammals, these are located mainly in the hemispheres; for removal of the hemispheres with section below the optic thalami diminishes (Albertoni, 1882) or abolishes (Morita, 1915) the convulsions.

The *spinal cord* also shows some stimulation, and finally paralysis, but this does not come on until late, and is not important in mammals.

In *frogs*, on the other hand, the action on the spinal cord is *very pronounced*, and consists in a *paralysis*. This entirely obscures other actions which the drug may have higher up in the nervous system in these animals. It appears that the path for reflex impulses is blocked before that for impulses coming from the higher brain (Wiedemann, 1877; Binz, 1878). The symptoms are described by Grove, 1910.

Toxic Dose.—This varies greatly: 0.7 to 1 Gm. has been fatal to children and toxic to adults; 2 Gm. generally produced dangerous effects; but 15 Gm. have been survived (Koppang); and in an infant of eighteen months, 1 Gm. produced little if any symptoms (Miller, 1914).

The *minimal fatal dose* for cats, on intraperitoneal injection, is 0.4 Gm. per Kg. (Joachimoglu).

Solvent and Place of Administration on Toxicity.—Cairis, 1914, and Carnot and Cairis, 1914, have studied these on guinea pigs. With oral administration the toxicity of camphor is greatly decreased by oil. Hypodermically, oil solutions are also less toxic than alcoholic, ethereal or even watery solutions. Intraperitoneal are more toxic than hypodermic injection. Oral administration is more effective than intramuscular (Hatcher and Eggleston, 1914).

Camphor Isomers.—The structure of camphor is nearly related to p-cymol and to carvacrol (Bredt, 1893). It is asymmetric; the natural camphor being dextro-rotatory; the synthetic racemic; and "matricaria-camphor" levorotatory.

The actions of the three isomers appear to be qualitatively identical, and of the same order of magnitude, as to general toxicity and the response of the frog-heart (Joachimoglu, 1916); and of the mammalian heart (Frochlich and Pollak, 1920, etc.). Clinical reports (C. Leitz, 1916; J. Anderson, 1916), indicate that synthetic camphor may be used orally, hypodermically and intravenously. It appears advisable, however, to confine the clinical use to the one variety, *i.e.*, the natural camphor, since this has been more extensively investigated.

Borneol (Borneo-Camphor, $C_{10}H_{18}O$), is used in the orient. It acts similarly to camphor.

Camphoric Acid.—This was introduced by Fuebinger, 1888, an anhydrotic against the night-sweats of phthisis. It aroused some enthusiasm at first (literature, Fujitani, 1906); but experimental investigations have given entirely negative results (Dressmann, 1880; Fujitani; Tyrode, 1908; Roth, 1911); and the clinical effects were also disappointing (Tyrode). The drug is therefore going out of use.

Other Actions.—Tyrode, 1908, could discover no effects of any kind. Fujitani and Roth described central and peripheral stimulant and depressant effects, somewhat different from camphor. It produces a rather marked stimulation of the respiratory center in mammals. Kobert, 1897, ascribes to this the alleged benefits in tuberculosis.

PREPARATIONS

Camphora (Camph.), U.S.P., B.P.; Camphor.—A ketone, $C_9H_{16}CO$, obtained from *Cinnamomum Camphora*. White translucent masses of crystalline structure. Its pulverization requires the addition of a little alcohol. It has a characteristic odor and warm aromatic taste. It is slightly sol. in water, but freely in alc., fixed and volatile oils and fat-solvents. Dry camphor volatilizes readily, but its solutions are practically stable, even in open bottles (La Wall, 1909). *Dose*, 0.2 Gm., 3 gr. by mouth or, hypodermically, U.S.P.; 0.12 to 0.3 Gm., 2 to 5 gr., B.P.

The solubility of camphor at ordinary temperature is 1:598 of water; 1:577 of Ringer's solution (Leo and Rimbach, 1919).

Its use in the Orient antedates history; but it does not seem to have been known by the Greeks and came into use in Europe in the Mediaeval period. At present, 70 per cent. of all the camphor produced is used in the manufacture of celluloid.

Aq. Camph., U.S.P.—A saturated watery solution containing not less than 0.8 per cent. Very little therapeutic action. *Dose*, 10 c.c., 2½ drachms, U.S.P.

Aq. Camph., B.P.—0.1 per cent.

**Linimentum Camphoræ* (Lin. Camph.), U.S.P., B.P.; Camphor Liniment (Camphorated Oil).—20 per cent. of camphor in Cottonseed oil, U.S.P.; in Olive oil, B.P.

**Spiritus Camphoræ* (Sp. Camph.), U.S.P., B.P.—10 per cent. *Dose*, 1 c.c., 15 minims, U.S.P.; 0.3 to 1.2 c.c., 5 to 20 minims, B.P.

(*Tr. Camph. Co.*, B.P.—See Index.)

Camphora Monobromata (Camph. Monobrom.), Monobromated Camphor, $C_9H_{15}Br$ CO.—Colorless prismatic needles or scales, or as powder having a mild but characteristic, camphoraceous odor and taste. Freely sol. in alc. (1:56.); almost insol. in water *Dose*, 0.125 Gm., 2 gr. Action similar to camphor.

Acidum Camphoricum; Camphoric Acid, $C_8H_{14}(CO_2H)_2$.—Obtained by oxidation of camphor. Colorless crystals. Slightly sol. in water (1:125); readily sol. in alc., fats and alkalies. Used with doubtful results as anhydrotic. *Dose*, 0.6 to 2 Gm., 8 to 30 gr.

Oxycamphor (camphor with H replaced by OH) has been recommended as respiratory sedative in cough. The aqueous solution decomposes, and it is marketed as a 50 per cent. alcoholic solution (Oxaphor, N.N.R.), of which the *dose* is 2 c.c. (30 drops).

Fenchon, the characteristic constituent of fennel oil, is isomeric with camphor; it is also used as counterirritant. It is a fluid, and may be applied as such, or diluted to 10 per cent. with alcohol or oil (I. Schlesinger, 1914).

MENTHOL

This is prepared from the volatile oils of various mints. It acts similarly to camphor, and is used especially locally against headache, neuralgia, itching, etc. Applied to the skin, it produces at first a cool sensation, followed by slight pricking and a burning. The cooling effect is not physical, the temperature of the skin being normal or even increased. It is explained by specific stimulation of the nerve-endings for cold (Goldscheider). Alcoholic solutions are antiseptic.

Menthol has a purely depressant effect on the frog-heart (Joachinglu, 1917).

PREPARATIONS

**Menthol*, U.S.P., B.P., $C_{10}H_{19}OH$.—A secondary alcohol obtained from peppermint oil. Colorless crystals of peculiar odor and warm aromatic taste. Only slightly sol. in water, freely in alc. *Dose*, 0.06 Gm., 1 gr., U.S.P.; 0.03 to 0.12 Gm. ½ to 2 gr., B.P.; as carminative, etc. Externally, in alcohol, oils or ointments, 1 to 5 per cent., on mucous membranes, 10 to 25 per cent. on skin.

Emp. Menthol, B.P., Menthol Plaster.—15 per cent.

SAPONINS (SAPOTOXINS; SAPO-GLUCOSIDES)

These comprise a series of related compounds, generally non-nitrogenous glucosides, which occur in many plants. The actions are somewhat related to the bacterial and other toxins, and to the soaps and bile salts. The saponins lower surface tension, and therefore concentrate on the surface. They form a solid and resistant pellicle, and when even very dilute watery saponin solutions (1:10,000) are shaken, each air bubble becomes coated with this tough surface-film, producing a very persistent foam. When shaken with oil or powders, the saponin film prevents the droplets or

fine particles from coalescing, so that permanent emulsions or suspensions are easily formed. Saponin tends to displace other substances or absorbates from the surfaces; for instance it liberates rennin that has been adsorbed by charcoal. In these ways the saponins tend to alter the permeability of the protoplasmic surface of cells, and are general protoplasmic poisons. They have a particular affinity for cholesterol. They hemolyze blood cells, even in isotonic or hypertonic salt solutions.

Fish are killed by high dilutions (1:200,000). In higher animals, they are but little absorbed, so that they act mainly as local irritants to the mucous membranes. A few, however, are absorbable and toxic. Their interest is mainly scientific. Senega is somewhat used as nauseant and emetic. Sarsaparilla and guaiac were formerly employed as alteratives in syphilis. Quillaja (soap bark) and saponaria (soap root) are used technically for cleansing.

Chemical Properties.—Many of the typical members of the group respond to the formula, $C_nH_{2n-8}O_{10}$. They are glucosides and give a purple color with concentrated sulphuric acid. They are generally not attacked by animal ferments. Physically, they possess the characters of colloids: They do not dialyze; most are soluble in water, and are not precipitated by moderate amounts of alcohol; but they do not dissolve in pure alcohol or in fat-solvents. Many are precipitated by saturation with neutral salts, especially ammonium sulphate; by basic lead acetate, etc. Some behave as acids, others are neutral. When heated with dilute mineral acids they are decomposed into sugars (differing for the individual saponins) and a *sapogenin*. Schmiedeberg calls these decomposition products "saponins," and all the original substances "sapotoxins." Others apply this name to the more toxic saponins (Review, Kobert, 1914).

Occurrence.—Sapo-glucosides are very widely distributed through the vegetable kingdom, occurring in at least 400 plants, belonging to 50 different families. They are probably formed in the leaves, but are found in all parts of the plants. The foaming is so conspicuous that many of these drugs have received characteristic popular names, soap-bark, soap-root, etc. They are employed, even by non-civilized peoples, for cleaning; and on account of their high toxicity to fish, as fish-poisons. Ophiotoxin, a definite principle of isolated snake-venom, is believed to be closely related to the saponins (Faust).

Crocus bulbs contain a saponin that is toxic to young animals, but not to old, (Kobert, 1917).

Local Actions.—Most of the sapo-glucosides are markedly irritant to *mucous membranes*. They have an *acid taste* and provoke a flow of saliva (sialogogue action), nausea, vomiting and diarrhea; if inhaled, they cause *sneezing*; if injected hypodermically, they cause *subcutaneous inflammation*.

Therapeutic Uses.—The local actions resemble those of ipecac and are similarly employed. Senega is used as nauseant expectorant, especially in chronic cough; and as emetic. Its non-absorption constitutes an advantage. The emulsifying action determines the use of quillaja as detergent, especially for the cleansing of articles which are injured by alkalies. The use of quillaja in medicinal emulsions, or for producing foam in soda water, etc., is not admissible.

Some of the less toxic saponins might be used for this purpose (Kobert, 1904), but they have not been sufficiently studied to be entirely safe.

A certain number of these drugs have some importance on account of stock-poisoning (*Vaccaria*, Raw Potatoes).

Sarsaparilla, which owes its activity entirely to the sapotoxin or saponin which it contains, formerly enjoyed considerable reputation as an *alterative*. This is no longer accepted (H. C. Wood, Jr., 1916); if it possesses any action at all it is simply that of a very mild nauseant and cathartic.

Systemic Actions.—If sapo-glucosides are injected directly into the circulation they produce hemolysis, diuresis (B. MacCallum, 1905; Asher, 1908); and direct actions,

especially on the central nervous system, which may be rapidly fatal. At first there are violent convulsions; then paralysis, especially of the respiratory center. The effect on fish is also paralytic. Rapid absorption through the gills makes even small doses effective.

Smaller doses given by the blood cause especially *intestinal symptoms*, and death after several days by collapse. Why the symptoms are so largely intestinal is unexplained. Given subcutaneously, they produce these same symptoms, but much more slowly. If they are applied directly to skeletal or cardiac muscle or to nerve-trunks, these lose their irritability at once, and if the solution is fairly strong (1 per cent.), there is rigor. The addition of saponin increases the toxicity of digitoxin for the frog's heart (Postojeff, 1911). Nearly all saponins are toxic to the frog heart (I. Traube, 1919). Saponins act on amebæ, but apparently not on bacteria (Bacon and Marshall, 1906).

Effects of Hemolysis.—Hemolysis liberates potassium and other toxic substances from the corpuscles (Gottlieb and Lefmann, 1907; W. H. Brown, and Loevenhart, 1913); but these are not concerned in the systemic saponin actions: The latter occur with doses which are not hemolytic; nor are the systemic saponin effects avoided by cholesterin which prevents the hemolysis. Presumably the permeability of the nerve cells is directly affected by the saponin.

Poisoning.—Most saapo-glucosides are absorbed so poorly that they produce only local effects: gastroenteritis, vomiting, persistent diarrhea, etc. However, the violent local action may lead to corrosion and this to absorption (*f.i.*, with quillaja). Agrostemma, the common corn-cockle (chemistry, Brandt, 1906) is absorbed fairly readily and thus produces systemic poisoning. This is important since its seed may be admixed with grain. The systemic symptoms agree with those of intravenous injection. On the other hand, certain vegetables, *f.i.*, spinach, contain saponins which seem harmless to man. Incidentally, some saponins show a different toxicity for different species (Kobert, 1914). The toxicity is not simply proportional to the hemolytic power.

Hemolytic Action.—Saponins luke blood even in an isotonic medium. The phenomenon depends on their affinity for the lipoids of the cell envelope and stroma. It is prevented by the addition of cholesterin or other lipoids which combine or bind the saponin.

Hemolytic Concentration.—The limital concentrations 1:400,000 to 1:10, vary enormously but are characteristic for the different saponins (Kobert, 1914).

Phenomena of Laking.—Saponin hemolysis occurs in two stages, which are practically distinct: The liberation of hemoglobin; and increased permeability of the envelope (G. N. Stewart, 1899 to 1909; Woelfel, 1908). The latter occurs even in formaldehyde-fixed corpuscles. The action is probably both on the stroma and on the envelope; dissociating the former from its combination with hemoglobin, and rendering the latter more permeable, thus leading to the entrance of water, swelling, and "water-lacking." Saponin does not cause the complete disappearance of the stromata; bile salts do (Neuberg and Haendel, 1908).

Solution of Lipoids.—The integrity of the corpuscles is intimately connected with their lipid content. The stroma and envelope consist of about one-third of lipoids, chiefly cholesterin and lecithin, and two-thirds of protein (Pascucci 1905). Many hemolytic agents are lipid solvents; such as the saponins, bile salts, soaps and fatty acids, aliphatic narcotics, heat, etc. Their action is generally proportional to their lipid-affinity. Saponins also increase the permeability of artificial cholesterin-lecithin membranes (Pascucci, 1905). The hemolytic serums and toxins probably also act on these lipoids, but perhaps likewise on the protein. It is perhaps not necessary that the lipoids are actually dissolved; they need merely be altered. Hypoisotonic solutions probably disorganize the entire structure of the corpuscles.

The hemolytic activity of different saponins has no relation to their effect on *surface tension* (Woodward and Alsberg, 1916).

Specific Resistance of the Corpuscles.—The blood of different animals shows specific differences. It is noteworthy that the resistance of species varies inversely for saponin and water-laking (Rywoesch, 1907 and 1911). Normal serum is somewhat protective, perhaps by its cholesterin; and this protection is slightly increased by habituation.

Acquired Resistance.—Repeated injections of saponin and other hemolytic agents raise the general resistance of the corpuscles (Kobert; R. Weil, 1910; contradicted by Kagan, 1913). No true antibodies occur. Prolonged saponin feeding increases the resistance, both of the corpuscles proper and of the serum (Alsberg and Smith, 1914).

A similar increase of resistance occurs also in certain diseases in which hemolytic poisons are probably produced, *f.i.*, in syphilis, advanced cancer, etc. (Weil; McNeil, 1910).

Mixed Hemolysis.—Fuehner and Greb, 1912, found that the combination of various hemolytic agents (aliphatic, alkaloidal and glucosidal) gave complex results; the summation of the effects being sometimes simple, excessive or deficient.

Protective Action of Cholesterol.—Ransom, 1901, showed that the addition of cholesterol prevents the hemolytic effect of saponins (also of toluidine compounds, Hildebrandt, 1911; of colbra lysin, and of some bacterial lysins, *f.i.*, staphylo-, tetanus-; of sodium oleate; of the immune-serum hemolysins); but not of some other hemolytic agents. Serum, which contains cholesterol, also exerts this protective action. The phenomenon is explained by a chemic combination between cholesterol and saponin. The protection does not extend to the central saponin actions. The OH group seems essential to all these protections. Lecithin and other lipoids, which do not form chemical compounds, afford a much weaker protection, probably by binding the saponin physically. These effects extend also to other lipid-solvent hemolytic agents (Pilcher, 1913). Cholesterol also protects the heart against digitoxin, but not against the digitaloids (Karaulow, 1912). It prevents not only the hemolytic but also the systemic toxicity of sodium oleate (Klotz and Bothwell, 1915).

Combination of Cholesterol with Saponins.—Cholesterol precipitates saponins from their solutions. Windaus, 1909, showed that definite, crystalline, non-hemolytic compounds are formed. Those with digitonin and cyclamin have been especially studied (Yagi, 1910).

Protective Action of Serum.—Washed corpuscles are laked by saponins in one-fourth the concentrations required in defibrinated blood (Laube, 1911). This is probably due to the cholesterol content. The injection of saponin into animals lessens this protective action for two or three days, by binding the cholesterol (Wacker and Heuck, 1913).

The hemolytic action of watery solution of saponin is rapidly destroyed by the addition of fluorescent substances, eosin and erythrosin (Noguchi, 1906).

Infusion of tea also has an inhibiting effect on saponin hemolysis; this has been proposed as a test for genuine tea (Maggiora and Ferron, 1914); but is probably due merely to the tannin.

PREPARATIONS

Caulophyllum; Blue Cohosh; the rhizome and roots of *Caulophyllum thalictroides*. (Chemistry, Power and Salway, 1913.) Used as diuretic, emmenagogue and antelmintic. (See article under Nicotine and Ergot.) *Dose*, 0.3 to 2 Gm., 5 to 30 gr.

Guaiaci Lignum, B.P.; Guaiac Wood.—The heart-wood of *Guaiacum officinale* or *sanctum*. Contains 20 to 25 per cent. of the Resin and some saponin (a trace of the latter is also contained in the resin). There is some reason to believe that the saponin is the bearer of the action, which is nauseant and purgative. Guaiac is an almost obsolete remedy for syphilis, gout, rheumatism, tuberculosis, etc. It was introduced soon after the discovery of America.

Guaiaci Resina, B.P.; Guaiac Resin (Gum Guaiac).—The resin obtained from *Guaiac Wood*. It contains a number of resinous acids, especially guaiaconic acid, which is colored blue by oxidation. *Dose*, 0.3 to 1 Gm., 5 to 15 gr., B.P.

Guaiac resin is commonly used as a reagent for oxidative ferments. Schaer, 1913, finds the best results with resin extracted from the wood by chloroform; then the natural resin; then alcoholic extract of the wood. Solutions lose their sensitiveness with age.

Mist. Guaiac., B.P., Guaiacum Mixture.—2.5 per cent. suspension of the resin. *Dose*, 15 to 30 c.c., $\frac{1}{2}$ to 1 ounce, B.P.

Tr. Guaiac. Ammon., B.P.; Ammoniated Tincture of Guaiac.—20 per cent. with aromatics and ammonia. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm., B.P.

Troch. Guaiac. Res., B.P.—0.2 Gm., 3 gr.

Hemidesmi Rad.—The root of the *Hemidesmus indicus*.

Quillaia Cortex, B.P.; Quillaia (Soap Bark).—The dried inner bark of *Quillaia*

Saponaria.

Tr. Quill., B.P.—5 per cent. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Saponaria; Soap-root.—The root or leaves of *Saponaria officinalis*.

Sarsaparilla, U.S.P.—The dried root of *Smilax* species. The Jamaica variety contains a single saponin glucoside, "sarsasaponin" (Power and Salway, 1914).

Fldext. Sarsap., U.S.P.—*Dose*, 2 c.c., 30 minims, U.S.P.

Syr. Sarsap. Co., U.S.P.—20 per cent. *Sarsaparilla*; 1.5 per cent *Senna*; flavored with licorice, sassafras, anise and wintergreen. *Dose*, 15 c.c., 4 drachms, U.S.P.

Senega, U.S.P.; *Seneg. Rad.*, B.P. (*Senega Snakeroot*).—The dried roots of *Polygala Senega*. *Dose*, 1 Gm., 15 gr., U.S.P.

Fldext. Seneg., U.S.P.—Contains some ammonia. *Dose*, 1 c.c., 15 minims, U.S.P.

Inf. Seneg., B.P.—5 per cent. *Dose*, 15 to 30 c.c., $\frac{1}{2}$ to 1 ounce, B.P.

Syr. Seneg., U.S.P.—20 per cent. *Dose*, 4 c.c., 1 drachm, U.S.P.

Tr. Seneg., B.P.—20 per cent. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

SOLANINE

The glucosidal alkaloids, solanine, solaneine, and solanidine, which occur in plants of the potato-genus (*Solanum nigrum*, *dulcamara*, *tuberosum* (Potato), *Carolinense*, and *Tomato*), possess a typical sapotoxin action. In certain species, particularly in *S. dulcamara*, they are associated with a small quantity of atropine-like alkaloid and with a saponin (*dulcamarin*). The latter plant is sometimes used as a nauseant. Solanine has the formula, $C_{52}H_{93}NO_{18}$; it splits into sugar and solanidine $C_{40}H_{61}NO_2$. The solanine literature is reviewed by Meyer and Schmiedeberg, 1895.

Tulip bulbs contain an alkaloid, tulipine, that is closely related to solanine and colchicine (Kobert, 1917).

Solanum Dulcamara.—Bittersweet.—The young branches are used. *Dose*, 4 c.c. of the fluidextract.

Potato (Solanum Tuberosum).—The toxic principles are distributed throughout the plant, but only very small quantities are found in the pulp of the tuber—too small to produce any action. The quantity is larger in the peel, and especially in very young and in sprouting potatoes, but it is not increased by storage. The amount in potato is ordinarily too small to be harmful (less than 0.01 per cent.) and it was doubted whether "potato poisoning" could be due to solanine (Droste, 1915). However, under conditions that are not understood the solanine may occasionally rise to 4 or 5 times this quantity. Since 0.2 Gm. of isolated solanine provoke untoward symptoms in man, potatoes containing this high quantity of solanine are poisonous, as shown in the outbreaks of Leipzig (Rothe, 1919) and Glasgow (Harris and Cockburn, 1918). In both, the suspected potatoes contained over 0.4 Gm. of solanine per kilogram.

The symptoms pointed to gastrointestinal irritation: vomiting, diarrhea, colic, headache, depression, etc.

Solanum Carolinense.—The berries have been recommended in epilepsy. They are always given with bromides, and the therapeutic effects of the mixture are probably due entirely to the latter. *Dose*, 4 to 5 c.c. of the fluidextract.

SNAKE VENOM

Actions.—The effects of snake venom are partly local, partly central. The *local effects* consist especially in an intense cellulitis at the site of the bite. This is accompanied by swelling and progresses to gangrene. The *blood* is also deeply affected. Its coagulability is altered, as with albumoses. The red blood corpuscles are dissolved. There is considerable tendency to extravasation and thrombosis. The leucocytes sink to 25 per cent. of their normal number.

Snake venoms have no effect on infusoria, bacteria, or on plants, but they are toxic to all animals above the hydra.

The *systemic actions* are nervous, and mainly central. The most conspicuous is a bulbar paralysis. There is a period of incubation (in man, of about four hours' duration); the patient then becomes drowsy, and then presents an ascending paralysis of the cord—*i.e.*, in the order of legs, arms, larynx, and tongue. This may be preceded by convulsive movements. There is also salivation and vomiting. The respiration becomes dyspneic, giving rise to asphyxial convulsions and forming the cause of death. The heart beats for some time after the respiration stops. Vascular paralysis leads to fall of blood pressure. There is also some curare action.

These actions are common to all snake venoms; with certain snakes, however, the local actions predominate, with others the systemic.

The danger depends on many conditions. For rattlesnake venom, the fatal hypodermic dose would perhaps be 0.15 to 0.3 Gm. The actual mortality in America is probably about 10.5 per cent. for all snake bites, 11.7 per cent. for rattlesnakes (Willson, 1908).

Cobra Venom.—This has been reexamined by Cushny and Yagi, 1916. Frogs showed mainly a slow curare action. This was also the cause of death in mammals. Super-lethal doses also act directly on all forms of muscle, producing first stimulation, then depression.

Autonomic nerves, ganglia and myoneural junctions were not affected; nor was there any direct action on the central nervous system.

Hemolytic Principle.—This is probably a toxalbumin (Kyes and Sachs). Cobra venom lyses washed human and guinea-pig corpuscles directly, in the absence of serum whereas washed sheep and ox corpuscles are highly resistant, but are rendered susceptible by the addition of serum or lecithin. Kyes, 1910, therefore considered the venom as amboceptor and lecithin as complement. The existence of this toxic "cobralecithid" was discredited by Manwaring, 1910, and others. Von Dungern and Coca showed that venom contains a lipoid-splitting ferment, which liberates hemolytic cleavage products. Noguchi believes that soaps of unsaturated fatty acids may act as "complement."

Ophiotoxin and Crotalotoxin.—These, according to Faust, 1910 and 1911, are the chief toxic constituents of cobra and rattlesnake venom respectively; being responsible for the central actions. They are definite, non-nitrogenous principles, not glucosidal, but otherwise very closely related in their physical, chemical and pharmacological characters to the saponins; and probably related to the toad poison, and hence to cholesterin. They produce practically all the effects of the whole snake venom, except agglutination.

Rattlesnake venom is not toxic to rattlesnakes. The serum of these snakes, however, is not antitoxic. It, as also the bile, has only a low toxicity (Walker and Marshall, 1915).

Treatment of Snake Bite.—This must be very prompt. The wound should be ligated, expressed, excised or cauterized. Crystals of potassium permanganate should be rubbed in, or a solution of this, of chlorinated lime or of iodine, should be freely injected into or about the wound. Medullary stimulants and large doses of strychnine, are useful. The popular treatment with large doses of alcohol is empirical. Immunization by antivenoms has been tried extensively.

Other Animal Poisons.—Various animals contain toxic substances belonging to different groups. They are reviewed by Faust, 1910; and the animal hemolytic poisons by Sachs, 1906. The toxins of *Intestinal Parasites* are discussed by Paulian, 1914.

J. Coughlin, 1917, describes *scorpion*, *tarantula* and *centipede* bites, which were not fatal. Garcia, 1917, discusses the effects and treatment of *spider* bites.

Bee-poison.—Flury, 1920, confirms that this is not a protein. It appears to be a sapotoxin-like complex of lecithin and basic components.

Ascaris Poison.—*Ascaris* and other intestinal parasites yield a propeptone that is extremely toxic. The symptoms resemble those of peptone injection. Local application to the conjunctiva produces irritation. This substance is not hemolytic (Torai and Hajime, 1917).

Ascaris lumbricoides also contains a *hemolytic* substance. This is confined to the digestive tract of the worms and is probably used for the digestion of blood by the parasites. Its action is inhibited by serum, so that it is probably not concerned in anemia.

ACONITE

Aconite owes its activity to the rather unstable alkaloid aconitine. This is a peripheral and central stimulant and depressant. Locally, the peculiar stimulation (tingling) and anesthesia (numbness) of sensory nerves, without inflammatory phenomena, is used against neuralgic and rheumatic pains. Systemically, therapeutic doses produce mainly a slowing of the heart (central vagus stimulation) which is employed to some extent in sthenic fevers. Larger doses are highly toxic; producing great general depression, extreme irregularity of the heart (mainly by

direct action on the cardiac muscle), and death by arrest of the respiration or heart.

It is very doubtful whether the systemic use of aconite is advisable. Effective doses are practically toxic; and safe doses are practically ineffective.

The difficulty is increased by the variability and instability of aconite preparations.

The tincture, the most commonly used preparation, now contains 10 per cent. of aconite, in both the U.S.P. and B.P. (Formerly the strength was 35 per cent. U.S.P., 5 per cent. B.P. These differences must be remembered in connection with older clinical papers.)

Historical.—The toxic properties of aconite were known to the ancients; however there is considerable confusion, since the Roman poets used "Aconite" to denote vegetable poisons generally (Fleming). Various species, most of which are toxic, grow in different parts of the world. They were used as arrow-poisons by the ancient Chinese and Gauls. The therapeutic use dates from Anton Stoeck (Observations on the Use of Conium, Stramonium, Aconite, and Colchicum," 1763), who described the tingling without reddening or corrosion, the salivation and sweating, and proposed its use against rheumatic and neuralgic pain, and for "dissipating" swellings and healing ulcers. Alexander Fleming, of Edinburgh, 1845, published a comprehensive experimental and clinical "inquiry" of Aconitum Napellus, which is still a good model for therapeutic observation. Aconite is a favorite remedy of the homeopathic school.

Chemistry of Aconitine.—The chief active constituent of Aconitum Napellus is the alkaloid *Aconitine*, which occurs in a crystalline and amorphous form. It is chemically an acetyl-benzoyl-ester of *aconine*, a base derived from quinine (Ehrenberg and Purfürst). It decomposes readily, even on boiling, with water, into benzoyl aconine (Picroaconitine, Iso-aconitine) and this again into aconine (Freund and Beck, 1894). They have the same actions as aconitine, but picroaconitine is only about $\frac{1}{50}$ as strong as aconitine, aconine $\frac{1}{2000}$. These and probably other decomposition products preëxist in the drug, and are probably formed in its extraction and especially in the manufacture of the alkaloid.

Commercial "Aconitines" therefore may represent mixtures of varying strength, some being a hundred times more active than others. This enormous variability is most unfortunate in a substance of so great a toxicity; and several fatal accidents, to which it gave rise, have led to the practical abandonment of the internal use of aconitine in therapeutics.

Other species of aconite contain related alkaloids, with similar actions: pseudo-aconitine or nepaline; indaconitine; bikhaconitine; japaconitine, etc.

T. R. Fraser, 1873, showed that the effects of aconitine and pseudoaconitine are qualitatively alike; but that aconitine acts much more on the heart, pseudoaconitine on the respiration. He further reports in 1916 on some East Indian species.

Assay, Variability and Instability.—The chemical estimation of the total alkaloid content of aconite preparations is of no value, since the various alkaloids differ enormously in activity: a tincture of good alcohol content may be practically inactive therapeutically (Robinson, 1915). A satisfactory assay may be readily made according to the U.S.P., by the toxic dose for guinea pigs. This shows that the alcoholic tincture deteriorates materially within a year, and is practically inactive in 3 years after manufacture. The deterioration is said to be prevented by acidification (Swanson and Walters, 1923). Commercial tinctures were found by Haskell et al., 1915 to vary 1,000 per cent.; and commercial solid extracts differ even more widely, some being 5,000 times more active than others (A. R. L. Dohme, 1918). It may be expected that there is now much less variation in the United States, since the bioassay is compulsory.

Local Actions.—*In the mouth*, aconite, even a small quantity of dilute solutions, produces a peculiar warm and tingling sensation, a sour rather than bitter taste, followed by numbness and anesthesia. The lips, tongue, and mucous membrane of the mouth and throat feel as if swollen. The flow of saliva is increased reflexly. The apparent irritation is not accompanied by redness, pain, objective swelling, or other sign of inflammation. It is therefore purely sensory.

Analogous effects—heat, tingling and succeeding numbness, without inflammation, are produced in any other situation to which the drug may be applied; and even on the systemic administration of large doses.

From the *skin*, watery solutions are but slightly absorbed, and friction must be employed to secure the local effect. Oily solutions and ointments are absorbed readily.

Bio-assay.—The tingling sensation in the mouth was proposed by Squibb for the identification and estimation of aconite, and is still one of the most satisfactory methods. Perfusion of the isolated frog's heart is sensitive to aconitine in dilution of two in a million (G. B. Roth, 1913). The fatal dose for guinea pigs has been adopted by the U.S.P. as the most practical test.

Eye.—Fleming claimed that the application to one of the temples or one side of the forehead may produce more or less (temporary) *blindness* on that side. The *pupils* are then dilated, presumably to admit more light. The application to the conjunctiva constricts the pupils. In systemic poisoning, they are also constricted until the final asphyxial dilation.

Therapeutic Use of the Local Action.—This is used for the relief of toothache, neuralgia, migraine, rheumatic and other similar pain. For this purpose it may be employed by thorough friction of the tincture, undiluted or with the addition of 1 to 10 parts of soap liniment. This is probably as effective as the expensive Unguentum Aconitinæ (2 per cent.).

Fleming claimed that the internal use of the tincture is often more effective in neuralgia. He started with about 1 c.c. of the U.S.P. tincture, three times daily and increased the dosage until the full therapeutic effect (pulse of 54, lethargy, etc.) is obtained.

Systemic Effects of Therapeutic Doses.—These consist mainly in a more or less pronounced *slowing of the heart rate*, to 60 or 54 beats per minute, according to the dose and the susceptibility of the individual. The pulse is also softer and weaker, but remains regular as long as the dosage of slowing is not surpassed. The blood pressure falls slightly.

The therapeutic slowing (which is often absent in anesthetized dogs) is due mainly to stimulation of the vagus center, for it is practically absent if the vagi have been divided (S. A. Matthews, 1897).

The typical slowing, which occurs in one and one-half to two hours if the tincture has been taken by the mouth, is preceded by *subjective sensations* of evanescent warmth, and persistent numbness, and *tingling*, beginning in the finger tips, and extending along the arm, as the dosage is increased. The *respiration* is moderately slowed, and more or less labored. With the full therapeutic dosage, the patient is weak, giddy, confused, lethargic and cold. These phenomena last for three to five hours, and are as far as the therapeutic action should be carried. They are produced by doses corresponding to 0.15 to 0.3 gm. of aconite (Fleming), *i.e.* by 1.5 to 3 c.c. (20 to 45 minims) of the 10 per cent. U.S.P. or B.P. tincture.

Sweating may occur but is not constant. The *urine* is not increased. The *temperature* is not markedly affected by the therapeutic doses. *Digestion* and *peristalsis* are not disturbed. There is *no cumulative action*.

Vasomotor Center.—This is not affected by non-toxic doses. Toxic doses, however, produce a maximal stimulation, more intense than can be obtained from stimulation of sensory nerves (Pilcher and Sollmann, 1915).

Inactive Tinctures.—Several recent observers (Price, 1911; Rudolph and Cole, 1912) have been unable to obtain effects on the pulse and blood pressure, from small and fairly large doses, in a variety of clinical conditions. These negative results are probably ascribable to inactive preparations of the drug, as with Robinson, 1915.

Therapeutic Uses.—The slowing of the circulation has been utilized in heart disease, in hypertension, and in sthenic fevers, but is of doubtful value, especially in view of the total inefficiency of the dose ordinarily given.

Sthenic Fevers.—In these, it is supposed to “calm” the overactive heart, and to promote the action of mild diaphoretic agents (spirits of niter, ammonium acetate, etc.). It is used in this way during the sthenic stage of acute fevers; especially in children, for the “abortion” of colds. According to Ringer, it is administered in small and frequent doses (3 to 5 drops of the 10 per cent. tincture for adults, at first every fifteen minutes for two hours, then every hour, until the pulse returns to normal), and only for the first day of the fever, to avoid depression. It is difficult to judge its usefulness under such conditions.

Cardiac Conditions.—Aconite is plainly *contraindicated* in uncompensated valvular lesions, since it would reduce the already defective mass-movement of the blood. Theoretically, it might be indicated in functional overactivity of the heart, in excessive hypertrophy, and in acute inflammatory conditions of the heart. In all of these, a slowing of the beats is desirable. In fact, however, the same effect can be obtained by the more desirable expedient of simple rest in bed. The use of “cardiac depressants” is now almost obsolete. Other drugs which have been employed for this purpose are: Sparteine, Veratrum, Colchicine and Potassium salts.

Hypertension.—Fairly large doses of the tincture (15 to 25 drops, four times daily) have been tried, but with doubtful results. Thomson, 1914, claims that it lowers blood pressure and increases the elimination of urea in interstitial nephritis. Pierson, 1913, obtained very little result.

Effects of Larger (Toxic) Doses of Aconite; Mammalian Circulation.—If the therapeutic dosage is exceeded, the primary slowing of the heart rate turns rather suddenly into quickening, accompanied by arrhythmia, which finally becomes extreme.

Toxic doses greatly increase the force and especially the rate of the heart, at the same time rendering it extremely arrhythmic. The beats may occur in groups, as with digitalis. The heart finally goes quite suddenly into delirium cordis, and stops. During the earlier stages of this action the blood pressure is extremely variable, according to the varying force of the heart, and the successive stimulation and depression of the vasomotor center. Toward the later stages, the pressure drops severely (Matthews, 1897; for further details of the interesting cardiac irregularities consult Fleming, page 31; and Cushny, 1909).

The cardiac effects are due partly to stimulation and depression of the vagus and accelerator mechanisms, but mainly to direct action on the cardiac muscle. The excitability of the latter is greatly increased, somewhat as with digitalis (which see). The quickening occurs in the nerve-free heart of the embryonal chick; in mammals also it is seen after all the nerve endings in the heart have been paralyzed by apocodeine.

The *isolated mammalian heart* (Hedbom-Langendorff) shows the following: The first effects are inconstant; the frequency is then enormously increased and the amplitude lessened below what is accounted for by the quickening (increased irritability and weakened muscle). Then follows a transient increase of amplitude (muscular stimulation), and sudden stoppage of the left ventricle (paralysis of automatic property). The right ventricle and the auricles make a few more contractions. Caffeine may start a few beats.

Perfusion of Medulla in Turtle.—Aconitine stimulates the cardio-inhibitory center (Bush, 1920).

Actions of Aconite on the Frog's Heart.—These are practically identical in the intact frog and in perfused excised heart. They are therefore peripheral. They consist essentially in heightened irritability of the auricular, and especially of the ventricular muscle; disturbed conduction; lessened contraction intensity, and finally paralysis. The successive effects are described as follows (Boehm, 1871; Hartung, 1911; Fuehner, 1911).

1. *Preliminary slowing* is sometimes observed. It is probably due to stimulation of the vagus endings.

2. *Acceleration.*—Rather suddenly the beats become quickened and at first strengthened. The acceleration is attributed to heightened irritability of the cardiac muscle. The time of contraction and the refractory phase are shortened

3. *Incoördination*.—Ventricular extra-systoles appear (even when the auricles are removed). The rate of the ventricle increases above that of the auricle, at first in a regular ratio. The combination of the two rates results in "periodic dissociation" or grouped beats. As the rate continues to increase, the contractions can not be maintained regular, and become extremely incoordinated, resulting in the characteristic "*perisistalsis*" of the heart-muscle. This begins in the auricles, but soon extends to the ventricle. It consists in vermicular movements, in which the blood, instead of being propelled, is merely moved about in the heart. The localized contractions may lead to a mulberry appearance, etc. Sometimes the contraction sequence is reversed so that the ventricular contraction initiates the auricular beat. These irregularities may alternate with periods of quite normal beats. The regular rhythm can often be restored by stimulating the accelerator nerve.

4. *Standstill*.—The extreme irregularity always passes off after a time, and is succeeded by slow and weak, but fairly regular contractions, except that the ventricles beat much slower than the auricles. Eventually the ventricles stop relaxed, and then the auricles, usually rather suddenly. Atropine, accelerator stimulation, or direct stimulation may start a few rhythmic beats, but the contractility is soon lost completely.

Heart-test for Aconitine.—The peculiar heart "*peristalsis*" is the most delicate and characteristic test for aconitine. Fuehner, 1911, could thereby detect $\frac{1}{100}$ mg. in intact frogs and $\frac{1}{1,000}$ mg. in excised hearts. Similar effects are produced by the related Delphinine. The Digitalis group also produces peristalsis, but this is of short duration and followed by systolic standstill.

Skeletal Muscles and Motor Nerves.—Strong concentrations of aconitine at first stimulate and then paralyze the motor nerves peripherally. The stimulation is manifested by *fibrillary twitching*, occurring in muscle-nerve preparation, spontaneously or especially after stimulation of the nerve. The threshold of stimulation is lowered. The twitches do not occur after curare, and must therefore be in the endings. They may be seen in living animals. The subsequent paralysis of the nerve, and eventually of the muscle substance, can not occur during life, since the dose and the time required are greater than what would paralyze the heart (Hartung, 1911). The allied delphinine, however, has been recommended as a substitute for curare in frog work (Schiller, 1904).

Infusoria and plants are also killed by aconite (Fleming).

Respiration.—This is progressively slowed in proportion to the dose (Fleming). It is also labored and the later stages become irregular. The slowing bears a superficial resemblance to that of vagus stimulation; but since it occurs also after section of the vagi (Boehm and Wartmann, 1873), it must be due to direct depression of the respiratory center. It is characterized by longer expiratory pauses. Primary increase of respiration has been claimed (Cash and Dunstan; Anrep); but it is small and inconstant, and probably due to other factors (Hartung, 1912).

Temperature.—This falls in severe poisoning, because of the collapse and consequent paralysis of heat regulation. The temperature of the animal falls and rises with the external temperature (Brunton and Cash, 1886).

Summation of Dose.—This influence of this on temperature has been studied by Cash, 1906. He found an imperfect summation of effect if the dose is repeated at sufficiently close interval. But if this exceeds two hours, the later doses may produce actually less effect, *i.e.*, the temperature may not fall as low as with the first dose. *Repeated administration* produces some tolerance in rabbits (Hartung, 1912).

Reflexes.—These are diminished, on account of the sensory paralysis.

Symptoms of Aconite Poisoning in Man.—With very large doses death may occur almost instantly—probably from paralysis of the heart. With moderately toxic doses the following picture is seen: *Tingling* in mouth, stomach, and skin (the *most important diagnostic feature*); excessive salivation; nausea, retching, *vomiting*, and *diarrhea* (the mechanism of the emesis is central; Eggleston and Hatcher, 1915). The burning passes into anesthesia. There is great restlessness. The *pulse* is slow and feeble, later arrhythmic and very rapid. *Respiration* is dyspneic. There are muscular weakness, incoördination, vertigo. The *skin* is cold and livid. The *pupils* are first constricted, then dilated from the asphyxia and convulsions. The *intelligence* does not usually suffer, but there may be stupor and even unconsciousness. The *special senses and speech* may be impaired. *Convulsions* are common. *Death* may occur by heart paralysis or by paralysis of the respiratory center (the heart beating after death; Fleming). The

symptoms may appear almost instantly, and are rarely delayed beyond an hour. In fatal poisoning death occurs usually in two to six hours. There are no constant *postmortem changes*.

Etiology.—*Accidental poisoning* from the fresh plants—which as monk's-hood and the related larkspur are quite common in gardens—as also from liniments, etc., is fairly frequent. On account of the small dose, the absence of postmortem signs, and the difficulty of chemic proof, aconitine became quite a favorite for *suicidal* purposes. The use of the plant for *criminal poisoning* is widely spread in the East. The symptoms are so unmistakable—especially the tingling—that it has not found many users in civilized countries.

Subtoxic Effects in Man.—According to Fleming, 0.5 Gm. of Aconite produces aggravation of the therapeutic effects, of the subjective symptoms, and lethargy with anxiety. The pulse may either be very slow (to 36) and regular, or more often increases suddenly to 70 or 80, and becomes small, weak, and more or less irregular. The quickening may occur without any preliminary slowing. Robinson, 1915, observed extrasystoles without other effects. The respiration is also irregular. The temperature falls further. There is generally vomiting. These symptoms do not entirely subside for one or two days.

Dangerous Effects.—With doses of 0.67 Gm. of Aconite, the collapse becomes pronounced, with pale sunken face, froth at mouth, and extreme prostration. Consciousness remains, perhaps with slight delirium. The voice is weak or lost. The pulse is very small, weak, and irregular; the respiration very imperfect. The skin is cold and clammy. The patient may recover with treatment.

Fatal Effects.—The patient is either conscious or mildly delirious, and becomes entirely blind, deaf and speechless. The pupils are dilated. There are general muscular tremors or slight convulsions; the heart beat becomes imperceptible. The temperature continues to fall. Finally, the heart stops, more or less abruptly.

The fatal dose is uncertain: According to Lewin, death has occurred from 2 to 4 Gm. of Aconite; recovery from 7 Gm.; with aconitine, death has occurred with 4 mg., recovery with 12 mg. Fothergill states that it is more fatal for young rabbits than for adults.

Absorption and Excretion.—The absorption occurs readily from mucous membranes; alcoholic and oily solutions are absorbed from the skin. Lewin states that it is excreted promptly by the urine, feces, saliva and intestinal mucosa.

Treatment of Aconite Poisoning.—The common alkaloidal antidotes and evacuations should be employed. The symptomatic treatment should be mainly stimulating: warmth, ammonia, brandy, strychnine, atropine. Artificial respiration is often life-saving (Lewin, 1875). In extremis, cardiac stimulants (epinephrine or stropanthin) should be used intravenously.

Antagonism of Aconite and Digitalis.—This was proven by Fothergill, 1871; but he also showed that the effects of digitalis with ordinary administration are too slow to be of practical value.

PREPARATIONS

Aconitina, U.S.P., B.P.; *Aconitine*, $C_{34}H_{47}NO_{11}$.—The most active "crystalline" aconitine, assayed on guinea pigs, U.S.P. Very slightly sol. in water, sol. in alc. (1:28). *Dose*, 0.15 mg., $\frac{1}{400}$ gr., U.S.P.; *maximal dose*, 0.3 mg., $\frac{1}{200}$ gr. *Its internal use is not advisable*.

Ung. Aconitine, B.P.—2 per cent.

Aconitum, U.S.P., *Acon.*, *Rad.* B.P.; Aconite (Wolfsbane, Monkshood).—The dried tuberous root of *Aconitum Napellus*, yielding not less than 0.4 per cent. of alkaloids, B.P.; assayed on guinea pigs, U.S.P. Frequently cultivated in gardens. All parts of the plant are poisonous. *Dose*, 0.06 Gm., 1 gr., U.S.P.

Tinctura Aconiti (Tr. Aconit.) U.S.P.; Tr. Acon., B.P.—10 per cent. of drug, 0.04 per cent. of alkaloid., B.P.; assayed on guinea pigs, U.S.P. Miscible with water or alc. *Dose*, 0.6 c.c., 10 minims., U.S.P.; 0.12 to 0.3 c.c., 2 to 5 minims., B.P. The tinctures of the older pharmacopœias were of different strength: 35 per cent. in U.S.P. until 1890; 5 per cent. in B.P. until 1915.

Lin. Acon., B.P.—0.2 per cent. of alkaloids, 3 per cent. of camphor, in alcohol.

Delphinium.—The various species of Larkspurs contain alkaloids, which are closely related to Aconitine, chemically and pharmacologically.

They were used for the destruction of body-parasites since antiquity. They have often caused poisoning in children, and in cattle and horses (Marsh and Clawson, 1916).

Staphisagriae Semina, B.P. (Stavesacre).—The ripe seeds of *Delphinium Staphisagria*. Dose, 0.06 Gm., 1 gr. It is used locally against pediculosis capitis or pubis, in the form of the 10 per cent. Ointment (B.P.), or as the Fluid-extract diluted with 8 to 10 parts of soap liniment or bay rum. It must not be used if the skin is broken. It causes considerable local irritation, and sometimes eczema (Lewin).

Ung. Staphisag., B.P.—20 per cent.

VERATRINE (CEVADINE)

Various species of veratrum (green and white hellebore), cevadilla, zygadenus, and other liliaceous plants contain mixtures of related alkaloids. These are esters of definite bases and acids, related to aconitine both in structure and action.

"Veratrine" is a mixture of alkaloids, extracted from "cevadilla" seeds, which owes its activity mainly to cevadine. It must not be confused with veratrum and its active constituent, protoveratrine, since their actions differ in important particulars.

Veratrine produces a characteristic prolongation of muscular contraction of considerable physiologic interest. Therapeutically it is rarely used as a counterirritant in neuralgic conditions, and as a parasiticide against pediculi capitis.

Composition of Veratrine.—This has been studied especially by Wright and Luff, 1878; and Allen, 1896.

The principal constituent, both in quantity and action, is the crystalline *Cevadine* $C_{32}H_{49}NO_9$, the methylcrotonic ester of the base cevine. It is *not* present in *Veratrum album*; traces are said to occur in *Veratrum viride*, but this is doubtful.

The second important alkaloids of "veratrine" is the amorphous *Veratridine*, $C_{37}H_{43}NO_{11}$, the veratric ester of verine. This is the "veratrine of Wright and Luff." Its effects agree qualitatively with those of cevadine (Boehm and Lissauer).

The commercial "veratrine" contains small quantities of at least three other alkaloids: Cevadiline, Sabadine, and Sabadinine. All these are but weakly active.

Zygadenus (Death Camas), Liliaceæ, a poison plant of Western stock-ranges, owes its toxicity to veratrine bases. It contains at least sabadine, sabadinine and veratralbine (Slade, 1905). The actions of the *Zygadenus* alkaloids have been studied by Mitchell and Smith, 1911. A comprehensive literature is given by Marsh and Clawson, 1915.

Action on Striped Muscle.—This consists in a characteristic modification of the muscle substance, so that it responds by a prolonged contraction, even to a single stimulus.

Phenomena in Intact Frogs.—When an animal, and especially a frog, has been poisoned with veratrine, it shows very striking peculiarities in its movements. It can contract its muscles with ordinary quickness, but it cannot recover its former position for some little time (v. Bezold, 1866).

Form of the Muscle Curve.—The reason for this behavior can be demonstrated on isolated muscle. Frogs are most convenient for this purpose, but identical phenomena occur in mammalian muscle (Quagliariello, 1913): If a veratrinized muscle is stimulated with a single shock, the ascent of the muscle curve is as abrupt as usual, but the relaxation is enormously prolonged (Fig. 16). The muscle remains in what appears to be complete tetanus, but further analysis reveals that the phenomenon is not an ordinary tetanus.

The Contracture is Not an Ordinary Tetanus.—If the nerve of a normal muscle-nerve preparation is laid on the veratrine muscle, a single shock sent into the latter causes a single twitch of the normal muscle, and not a tetanus as would be the case if the veratrine muscle were in ordinary tetanus (Fick and Boehm, 1872). However, if the veratrine stimulated the whole length of the muscle fibers at once, (in contrast to ordinary tetanus, where the stimulation originates from the motor end plates) there would be no difference of potential, and therefore the nerve of the second muscle would not be stimulated, once the shortening of the veratrine muscle is completed. It is therefor not excluded that

the veratrine contracture may be a tetanus, but with the site of stimulus production distributed throughout the length of the muscle. Observations on the development of the contracture in dilute solutions (Lamm, 1911) point in this direction.

The Contracture is Active.—The muscle is able to sustain a considerable weight throughout its contraction; the prolongation of the curve is therefore not due to a mere loss of elasticity, but is an active process. This is also shown by the fact that the formation of heat and the use of material is increased (Fick and Boehm).

If a muscle is prevented from shortening during the application of the stimulus, and then released, before the contracture has passed off, the muscle will shorten to the same

FIG. 16.—Normal veratrine curves, showing primary (*a*) and secondary (*b*) contractions. Gastrocnemii of different frogs, air temperature.

point that it would have reached at the period, if it had been permitted to shorten during the stimulation (Sollmann and Brody). The tension, the height and quickness of contraction, the irritability, the lifting and sustaining power of the muscle are all raised by veratrine (Dreser, 1890), so that we must look upon its action as an increase of functional activity. It also lessens the effects of fatigue.

Influence of Conditions.—The effect of veratrine is enhanced by agencies which stimulate the muscle, such as moderate heat.

It is diminished by depression of the muscle, produced by cold or excessive heat; by fatigue (Fig. 17); or by muscular depressants, such as potassium or ether.

FIG. 17.—Effect of fatigue on veratrine curve: *a*, normal veratrine tracing; *b*, after partial fatigue.

(If the veratrine action is weak, cold increases the contracture, probably by adding its own contracture to that of the veratrine; Sollmann.)

Double Peak Curve.—A careful inspection of veratrine-curves generally reveals two contractions (Fig. 16): a primary contraction (*a*), which occurs with the normal rapidity, but is somewhat higher than normal, and which tends to relax quickly; and a secondary contraction (*b*), which occurs more slowly and lasts longer. The two contractions are more or less fused (*v. Bezold*), but the form varies with conditions (*Mostinski*, 1904). Overend, 1889, attributed this phenomenon to the different contraction velocity of the white and red muscle fibers. *Cervello* and *Weiss*, 1899, showed, however, that uniform muscles exhibit the same phenomenon. *Riesser*, 1921, found material differences in the

response of the slow red and rapid white muscles of the rabbit, but this does not explain the double-peak phenomenon.

Bottazzi, 1901, suggested that the veratrine curve is due to the fusion of two contractions; the first peak representing the normal contraction of the fibrils, and the further portion of the curve the contraction of the sarcoplasmic substance, which he assumes has the properties of smooth muscle. According to this the veratrine action would consist essentially in raising the excitability of the sarcoplasmic substance above the threshold. There is, however, no direct evidence that the sarcoplasm has contractile functions (*Mueller*, 1908); and the modern theories of muscle contraction render this very improbable. *Woebbecke*, 1913, has modified the theory somewhat. He believes that muscle has two distinct functions, but that these are not specifically connected with the histologic constituents. *Verzar* and *Felter*, 1914, attribute the action to increased sensitiveness to normal stimuli.

Veratrine acts directly on the muscle substance, for the effects occur after curare (*Prevost*, 1867), and in the nerve-free end of the sartorius muscle. When a muscle is immersed in a dilute solution, a single stimulus produces at first a normal contraction, then fibrillary twitching (*Lamm*, 1912). The excitability of curarized muscle to direct electric stimulation is not increased; it is diminished by large doses (*Boehm*, 1913). Large doses of veratrine, however, *paralyze the motor endings* without previous stimulation.

Spontaneous Contraction of Muscle.—The immersion of a muscle in veratrine causes a slowly developing contracture, even in the absence of extraneous stimulation. High concentrations *paralyze all forms of muscle* completely (*Koellicker*, 1856, *Lamm*, 1911).

Other Substances Producing Veratrine Effects.—The prolonged contracture which is so characteristic of veratrine, is by no means confined to this alkaloid, but is also produced by digitalin, helleborein, muscarine, strychnine, by aldehydes (*Verzar* and *Felter* 1915), etc., by cold, and by very strong electric stimulation, *Kruse*, 1922. This *wide occurrence* signifies that the phenomenon is of fundamental physiologic importance. These measures also prolong the contraction of *cardiac and smooth muscles*.

The Action of Glycerin on Muscle.—The muscles of frogs poisoned with *glycerin* respond to single stimuli by prolonged contraction, the curve having a superficial resemblance to that of veratrine, but being rather more irregular. The glycerine contraction is, however, a true tetanus, due to greater irritability of the muscle substance; the action-current of each contraction sufficing to start another contraction. The phenomenon occurs also after curarization (*Santesson*, 1903).

Nerve Trunks.—Direct application of veratrine lessens their excitability (*Boehm*, 1913).

Circulation.—The effects are complex. Those on excised hearts resemble aconite and digitalis (slowing with increased systole). In intact animals, stimulation of the vagus center (Fig. 18) predominates at first (marked slowing); later, the fall of pressure from vasomotor paralysis becomes prominent.

Mammalian Circulation.—Small doses sometimes cause primary quickening of the heart. With larger doses (0.025–0.05 mg. per Kg.) there is sudden and marked slowing with corresponding fall of blood pressure (*Bezold* and *Hirt*, 1874; *Lissauer*, 1887; *Pilcher* and *Sollmann*, 1915). The slowing is greatest soon after the injection, often with marked arrhythmia or temporary arrest. This acute effect is due to stimulation of the vagus center (see, however, under *Veratrum*), for section of the vagi largely abolishes it, and stimulation of the vagus trunk does not produce further slowing (*Busquet*, 1907). With divided vagi, large doses may cause primary quickening and generally moderate rise of blood pressure (*Bezold*; *Pilcher* and *Sollmann*). The fall of blood pressure is mainly due to the slowing, although some fall may occur independently (*Lissauer*). The vasomotor center is moderately stimulated by the respiratory embarrassment, even when the vagi are cut. The stimulation does not occur if artificial respiration is maintained (*Pilcher* and *Sollmann*, 1915). Reflex stimulation causes vasoconstriction.

Late Effects.—The acute effect soon passes off. The heart then beats with a steady, moderately slowed rate. This slowing is not removed by atropine and is therefore cardiac.

The blood pressure falls progressively, occasionally interrupted by spasmodic rise from central vasomotor stimulation. The strength of the heart is not impaired, for it reacts well to compression of the aorta, and beats efficiently just before death. The fall must therefore be vasomotor; and accordingly, sciatic stimulation or asphyxia fails to

raise the pressure (Lissauer, 1887). The vagus remains excitable. The cerebral vessels are constricted (Dixon and Halliburton, 1910).

The isolated mammalian heart (Hedbom-Langendorff) shows a primary slowing from stimulation of the peripheral vagus mechanism; then irregularity, and finally paralysis of the cardiac muscle. The tone is increased.

Frog's Heart.—The effects resemble aconite and digitalis. They involve mainly the ventricle and consist in slowing (no further slowing on vagus stimulation; Busquet, 1907); prolonged systole and increased tonus; sudden change in the rate to one-half; "peristaltic" contractions; and final median standstill. High concentrations cause prompt systolic standstill, with continued shortening. The auricles continue much longer. The same effects occur on the excised and perfused heart (Lissauer, 1887; Boehm, 1913).

De Boer, 1917, attributes the slowing and halved rhythm to increase of the refractory period of the ventricle.

Peripheral Action on Blood-vessels.—Veratrine produces powerful constriction, which may be removed by atropine or quinine. These antagonists do not prevent contracture by barium, (Kondo, 1919).

FIG. 18.—Cevadine (veratrine) on blood pressure; showing the stimulation of the vagus center. Intravenous injection of 0.02 mg. per Kg. into anesthetized dog; artificial respiration.

Collapse Action.—The impairment of circulation, combined with the emetic action, result in varying degrees of collapse, and thereby fall of temperature, analogous to veratrum.

Respiration.—This is influenced by the circulatory and convulsive actions, and also directly. It is temporarily arrested during the acute fall of blood pressure, but may be depressed without any change of blood pressure. The respiratory embarrassment is generally diminished by atropine or division of the vagi (Pilcher and Sollmann, 1915).

Bronchial Muscles.—These constrict in intact animals (Dixon and Brodie), but not in the excised trachea (Trendelenburg, 1912). Titone, 1913, observed that veratrine relaxed isolated bronchial muscles.

Convulsions.—These are commonly present in mammals and frogs, and are probably medullary. Rabbits and guinea pigs show convulsive "bucking."

Cerebral Functions.—These are scarcely affected.

Local Action.—Cevadine is a strong irritant, resembling aconite. Applied to the skin, it produces burning, later a cold sensation and partial anesthesia, with reddening and sometimes discrete vesication. The irritation is especially strong on the abraded skin; 1:100,000 solution producing

tingling and "shooting" pain (Sollmann and Pilcher, 1916). On mucous membranes it causes acute catarrh—sneezing, coryza, gastroenteritis, vomiting, diarrhea, etc.; sometimes with corrosive lesions. The *vomiting*, however, is mainly central (Eggleston and Hatcher, 1915). In frogs, the secretion of *mucus* from the skin is greatly increased.

Therapeutic Uses.—Veratrine is used locally as counterirritant, in neuralgias and similar conditions, as 2 to 4 per cent. ointment. Sabadilla seeds are employed against pediculosis capitis (Salve, 1:4; Decoction, 5:200). The irritation is severe, and absorption has caused serious symptoms. The internal use of veratrine (against fever), even in mg. doses, has produced gastroenteritis.

Absorption is rapid; little is known about the *excretion*, but it probably occurs by the kidneys.

Symptoms of Poisoning in Man.—These resemble aconite poisoning.

They consist in: Burning in mouth, spreading to stomach; increased salivation, vomiting, diarrhea, abdominal pain; anxiety, headache, giddiness; pupils dilated; pulse slow and feeble, later irregular; weakness, twitchings in muscles. Death by respiratory and circulatory collapse. Consciousness preserved till the end. Postmortem, often intestinal ecchymoses.

In *non-fatal doses*, the symptoms are very slow in disappearing, and a double case of *slow poisoning* by continued small doses is on record: The two patients became very weak and thin, suffered from bloody diarrhea, insomnia, disturbance of the intellect, and delirium.

The *treatment* is the same as in aconite-poisoning. As the veratrine is believed to be rapidly excreted through the urine, it is well to administer hot tea as a diuretic.

Veratrina.—A mixture of alkaloids obtained from the seeds of *Asagrea officinalis*. Very slightly sol. in water (1:1760); freely sol. in alc (1:2.8). Its internal use is not advisable, but it has been given in doses of 2 mg., $\frac{1}{30}$ gr. Externally, it is applied as ointments of 2 to 4 per cent. *Maximum dose*, 5 mg., $\frac{1}{12}$ gr.

Insect Powder.—The flowers of *Chrysanthemum Cinnerariaefolium* contain as active principle Pyrethron (Fujitani, 1909), a neutral N-free syrupy substance, with actions apparently resembling veratrine.

Andromedotoxin.—This is an N-free neutral principle, isolated by Plugge from *rhododendron* and similar plants. It seems to belong to this group (Mountain Laurel-Kalmia-poisoning; Crawford, 1908).

VERATRUM

Veratrum viride and *album* (Green and White Hellebore) seem to be mere varieties (the green American, the white European), with practically identical actions and composition (Salzberger, 1885-1890). They owe their activity mainly to the alkaloid, *protoveratrine*. A number of other related but less active alkaloids are present. There are, however, wide differences of opinion as to the constituents of *Veratrum viride* (Cramer, 1915).

The effects of protoveratrine, and therefore of veratrum, are qualitatively similar to those of cevadine, but they differ very materially in their relative significance: The characteristic muscular and irritant actions of cevadine are insignificant in protoveratrine. The most important effects of veratrum are on the medulla, and especially on the circulation, resulting in vagus stimulation, slowed pulse, fall of blood pressure, sweating, "collapse-action," and reduction of temperature. It is therefore employed as a "cardiac depressant." Protoveratrine is more toxic than cevadine, approaching aconitine; but the prompt evacuation of overdoses by emesis (central) renders veratrum practically safe.

Constituents.—The most important alkaloid of *Veratrum album*, although not the most abundant (0.03 to 0.08 per cent.), is *Protoveratrine*, $C_{32}H_{51}NO_{11}$. It occurs in a crystalline and amorphous form (Salzberger, 1890). The other alkaloids are: *Jervine*, 0.1 per cent., weakly active; traces of *Rubijervine* (almost inactive); the inactive *pseudojervine* or protoveratridine, which is probably a decomposition product; the glycoside veratramine; and veratroidine and veratrabline, which are probably mixtures of amorphous bases (Bull. Am. Pharm. Assoc., 1911, p. 162; Kobert). Traces of cevadine have been reported in *V. viride*, but are doubtful.

Black Hellebore, *Helleborus niger* is in no way related to the above veratrum species. Its active principle, Helleborein, belongs to the Digitalis group.

Experimental Effects on Respiration and Circulation.—The typical effects of intravenous injection of veratrum viride consist in brief but marked depression of the respiration, slowing of the pulse, and lowering of blood pressure. These effects are largely prevented by section of the vagi, and do not recur if further doses of the veratrum are injected. The repeated injections generally produce marked rise of blood pressure, especially if the vagi are intact.

The effects are probably due to protoveratrine.

Cramer, 1915, believes that the effects are produced by the stimulation of the afferent vagus endings, producing reflex inhibition of the respiratory center, and radiating from there to stimulate the vasodilator and the cardioinhibitory centers; these afferent endings being then paralyzed, so that subsequent injections become ineffective. Cramer's doses are so different from those found necessary by other investigators, that comparison of the results is difficult. His explanation is probably correct as to the respiration; but requires confirmation as to the circulatory changes. At present, it is simpler to suppose direct stimulation of the vagus center, slowing the heart rate and thus lowering the blood pressure. At least Pilcher and Sollmann, 1915, did not observe any significant changes in the vasomotor center. The rise of blood pressure on repeated injection is probably due to paralysis of the cardiac vagus endings, resulting from large doses.

Respiration.—Moderate doses of veratrum viride (2.5 to 5 mg. per kilogram) injected intravenously into dogs produce brief but marked slowing or arrest of the respiration. This effect is generally absent if the vagi have been divided, and may therefore be attributed to stimulation of the afferent vagus endings (Cramer, 1915; Pilcher and Sollmann, 1915). Cramer finds that this does not occur on repeating the injection, and therefore believes that the stimulation of these endings is followed by their paralysis. He also finds veratrum ineffective after atropine, which would indicate that atropine also paralyzes the afferent vagus endings. Very large doses of veratrum depress the respiration after any of these conditions, presumably by a direct action on the respiratory center.

Moderate Doses on Mammalian Circulation.—In dogs with intact vagi, the intravenous injection of veratrum viride, 2.5 to 10 mg. per kilogram, produces a prompt sharp fall of blood pressure and marked slowing of the heart, with prompt return to normal. The fall of blood pressure is due essentially to the cardiac slowing through stimulation of the vagus center, for if the vagi have been divided, the pressure falls but slightly. The efferent vagus endings are not stimulated. The vasomotor center is not directly affected, but is sometimes moderately stimulated by the fall of blood pressure and especially by the respiratory embarrassment (Pilcher and Sollmann, 1915).

Wood, Jr., 1906, also describes moderate fall of pressure and distinct slowing, but apparently more persistent. Both disappear on section of the vagi. Cramer, 1915, does not believe that the fall of pressure depends chiefly on the slowing, but rather on vasodilation; for he states that the fall starts first; that cats may show the fall without the slowing; that the fall occurs after atropine; and that it is accompanied by intestinal vasodilation. He confirms that the depression of the circulation and respiration are prevented by section of the vagi; and assumes that veratrum acts by stimulating the afferent depressant vagus endings. The effect does not involve the depressor nerve, for the vasodilation occurs in rabbits after section of the depressor trunks, but not after the vagi were divided.

Cavazzani, 1909, observed that epinephrine prevents the fall of pressure after veratrum viride (just as it does that of depressor stimulation). On the contrary, there results usually a rise of pressure.

Repeated Doses on the Circulation.—These produce considerable rise of pressure, especially if the vagi are intact; less if they are divided (Pilcher and Sollmann). Wood found that this occurs also after section of the cord. It is partly explained by quickened heart rate, from paralysis of the vagus endings. Cramer obtained no effect whatever from the second injection, and believes that the first dose, after first stimulating, paralyzed the vagus endings.

Toxic Doses on the Circulation.—These produce at first exaggeration of the vagus stimulation (marked slowing, irregularity, arrest) with corresponding fall of blood pressure. This is followed by sudden extreme acceleration and rise of pressure (partly asphyxial, partly spasmodic). The rise may last for several minutes, and is succeeded by rapid progressive fall and death. In man, excessive doses also quicken the pulse rate.

Cramer found the results inconstant; due, as he believes, to an intermixture of the stimulant and depressant effects on the afferent vagus endings. The blood pressure may fall to zero, remain normal, or rise; or follow the convulsive respiration. The heart rate may be slowed, but is more often quickened. The inhibitory vagus endings are paralyzed. Subsequent injections have but little effect.

Sensory Actions.—Dried veratrum or protoveratrine are irritant, provoking sneezing, etc.; but in solutions, the irritant effects are very slight. These have a marked anesthetic action, lasting forty-eight hours, on the cornea (Eden).

General Symptoms in Mammals.—The first effects are nauseant and emetic, often so severe as to obscure other symptoms. Of these, the respiratory changes are characteristic, especially in rabbits. They consist in periodic dyspneic attacks, culminating in convulsions of a medullary type. The respiratory disturbance is probably due to the combined influence on the respiratory and other medullary centers, circulatory changes and muscular exhaustion. In the intervals the respiration is regular. *Death* occurs late, with the circulation fairly preserved and consciousness present to the end (Eden).

Collapse Action.—The combination of the central, circulatory and muscular depression, nausea and dyspnea, results in more or less collapse. This and the profuse sweating lower the *temperature*, proportional; to the general symptoms (Eden).

Effects of Therapeutic Doses on Man.—Collins, 1915, 1916, has made an extensive clinical study of a 10 per cent. tincture of veratrum album with single doses of 1 to 2 c.c. or divided doses of 1 c.c. every hour, to a total of 4 c.c. Full doses produce constantly a slowing of the pulse to about 62 per minute (irrespective of the original rate); and very generally a fall of systolic and diastolic blood pressure of about 35 mm.

The slowing and fall are proportional to the dose. Electro-cardiograms show no effect (Collins and Hanzlik, 1918).

The blood flow in the arm is markedly lowered by therapeutic doses (Hewlett, 1917).

Respiration is not disturbed. Headache, gastric burning, nausea and vomiting may set in, but come after the depression of the circulation, and are therefore not its cause. The effects last for several hours. Large doses (4 c.c. within half an hour) may produce more serious and lasting collapse, with a pulse rate of 40 or 30, suddenly returning to normal after eight or nine hours.

Veratrum Poisoning.—Although protoveratrine is very highly toxic, veratrum is vomited so promptly that death is rare even with large doses (Wood). It has, however, been reported after 1 to 2 Gm. of the powdered White Hellebore (which is used as insect powder), and in enfeebled patients from a teaspoon of the Tincture.

Symptoms.—These consist in burning, vomiting and diarrhea, dysphagia, collapse, paralysis or light convulsions.

Treatment.—The stomach should be emptied by warm water or lavage, and the collapse treated along the usual lines.

Therapeutic Uses.—Veratrum is probably the most active and reliable *cardiac depressant*, and was formerly much used to slow and soften the pulse, and lower the blood pressure, especially in eclampsia and other

conditions of high blood pressure. Pesci, 1906, *f.i.*, claims that it lowers the blood pressure by 7 to 50 mm., slows the pulse, increases diuresis, and lessens uremia. Haultain, 1914, makes similar claims. It was used for the same purposes, and to lower the temperature, in the early stages of sthenic fevers (pneumonia) and other acute infections. The effects are probably mainly due to the cardiac slowing from vagus stimulation and to the nausea. Veratrum with other cardiac depressants has rather gone out of fashion—perhaps undeservedly. It is contraindicated in asthenic conditions (cardiac weakness, general debility, typhoid, etc.).

Response in Pathologic Conditions.—Collins, 1916, observed the most marked effects in cases of hypertonus, the systolic pressure falling more than the diastolic. Little or no response was obtained in arteriosclerosis, paroxysmal tachycardia, or heart-block.

Diuretic Action.—This is not produced in animals (Cramer, 1915). If it occurs in eclampsia, as claimed, it is probably due to the correction of the circulatory abnormalities.

Administration.—Veratrum is best given in repeated doses—1 c.c., 15 minims, of the Tincture (U.S.P.) every half hour or hour—till the skin becomes moist, the pulse slower and slight nausea is present. It may then be stopped.

The desirable range is 3 to 4 c.c. (Collins and Hanzlik, 1918). Caution is necessary if a total of 4 c.c. is exceeded. If vomiting should appear before the other effects, 5 to 10 drops of Tr. Opii are administered with each dose of veratrum. Repetition of the dosage does not inhibit the action (as occurs with intravenous injections in animals).

Bio-assay.—Commercial preparations vary considerably in activity. As the drug contains a number of active principles, its efficiency cannot be estimated by alkaloidal assay. The determination of the minimum fatal dose for frogs or guinea-pigs is a convenient method. It averages about 2.3 mg. of drug per Gm. of frog, and 0.24 mg. per Gm. of guinea-pig (Pilcher, 1917.) Rowe, 1925, proposed mice, as more rapid and accurate. The M.F.D. is $\frac{1}{4}$ mg. per Gm., intraperitoneally.

PROTOVERATRINE

The effects, as described by Eden, 1892, are similar to veratrum, the reported differences being perhaps explainable by dosage and interpretation. In mammals, moderate doses by vein produce temporary fall of pressure, absent if the vagi were cut. Eden attributes this to reflex depressor stimulation, but vagus stimulation is a more probable explanation. This action is short, the pressure rising rather suddenly 40 to 50 mm. above normal, with increase of pulse rate, and inexcitability of the vagus. The rise is probably due to vagus paralysis. This is also of short duration. With repeated injections, the vagus paralysis becomes permanent, and the primary fall of pressure is absent; there being instead a small rise. *Toxic doses* produce cardiac arrhythmia, with periods of stoppage and corresponding changes of blood pressure. The rate in the intervals is at first rapid, then falls with the blood pressure. The vasomotor center becomes paralyzed.

Frog's Heart.—The effects are mainly depressant: the systoles are somewhat prolonged, but the tone is scarcely increased. Soon the ventricular rate is reduced to half, as with cevadine, aconite or digitalis; but this is interrupted by short periods of total arrest of the ventricle or auricles, apparently due to exhaustion of the muscle. Finally the heart stops in diastole, with relatively small doses (Boehm, 1913).

Motor System.—In frogs poisoned by protoveratrine, the reflexes disappear early. This paralysis is largely *central*, for it occurs also if the poison is excluded from the muscles by ligature. However, there are also *peripheral effects*: the muscles may respond normally to a single stimulus or contract even somewhat more quickly and efficiently; but they fatigue very rapidly (Eden, 1892). The prolonged contraction characteristic of cevadine is indicated very faintly, if at all, under ordinary conditions; but it may be elicited in excised muscles if precautions are taken against fatigue (Boehm, 1913). The nerve trunks are paralyzed only by concentrated solutions; the negative variation is said to be prolonged.

Jervine.—The effects also resemble veratrum, but the quantity of this alkaloid in the drug is too small to have any noticeable effect on circulation (Wood, Jr., 1906). With effective doses, the heart rate is first slowed then rapid. The blood pressure falls progressively, presumably by depression of the cardiac muscle and vasomotor center. The respiration fails simultaneously (Wood, 1874).

Rubijervine.—Wood, 1874, found that “veratroidine,” which was probably an impure rubijervine, acted mainly on the respiratory center, with some cardiac depression. Its quantity is also too small to be important.

PREPARATIONS

Veratrum Viride, U.S.P. (Green Hellebore, American Hellebore).—The dried rhizome and roots of *Veratrum viride*. Dose, 0.1 Gm., 1½ gr., U.S.P.

Veratrum Album (White Hellebore).—This is probably a mere variety of the former, growing in Europe. It is used in the same doses.

* *Tinctura Veratri Viridis* (Tr. Verat. Vir.), U.S.P.—10 per cent. Dose, 1 c.c., 15 minims, U.S.P. Till 1900, the Tincture was of 40 per cent. strength. Norwood's Tincture was supposed to be a saturated solution of the fresh root.

COLCHICUM

Colchicum (Meadow Saffron), and its active alkaloid colchicine, are believed to have a specific effect on acute attacks of gout. Their use is empiric and has no pharmacologic explanation. Toxic doses produce a characteristic late gastro-intestinal irritation, even on hypodermic administration. The action is probably due to conversion into oxydicolchicine. The vomiting, purging, and intestinal congestion may be so violent as to lead to fatal collapse, so that the plant (all parts) is of toxicologic importance. The other actions are relatively insignificant, but are related to aconitine.

Therapeutic Use in Gout.—Colchicum is credited with prompt effects on acute gouty attacks; relieving the pain in one or two hours, the heat and swelling subsiding soon after, and the attack ending in a few days instead of weeks. It must be used early and rather freely. It does not prevent recurrence, soon loses its efficiency, and is often unsuccessful; so that many clinicians are altogether skeptical.

Historical.—The toxic properties of colchicum are mentioned by Dioscorides; it was used against gout or rheumatism by the Arabian school (sixteenth century), and since then in domestic practice; but was abandoned in regular practice on account of its poisonous action, till it was reintroduced by Stoerck, 1763.

Attempted Explanations of Its Use in Gout.—These are all unsatisfactory. It has no definite effect on the elimination of urine, uric acid or urea. The purgation may contribute to the relief; but it is not essential and other purgatives lack the special effect. The changes in the leucocytes have recently been invoked, but are not convincing. Circulatory and analgesic actions are also unsatisfactory suggestions, since they have not been demonstrated directly, and since colchicum has no effect on other inflammations, or on acute or chronic rheumatic pain, neuralgia, etc.

The weakness of the pharmacologic explanations is reflected in the references of S. Loewe, 1920.

Metabolism.—The urine secretion is something slightly increased, sometimes greatly diminished, probably depending on the catharsis. The statements as to uric acid and urea (e.g., Noel Paton, 1886; Maurel and Arnaud, 1910; Abl, 1913) are so contradictory, that they can have little importance. With the modern methods, Denis, 1915, found neither increased elimination of urates in the urine, nor diminished concentration in the blood. The bile flow is slightly increased (Kionka, 1906). For about an hour after administration, the leucocytes in the blood are decreased; this is followed by a remarkable increase, especially of the polymorphous, which reach two to five times the normal in twelve hours (Dixon and Malden, 1908).

Administration.—Tincture or Wine of Colchicum Seed or Corm, have been given in divided doses, 0.5 c.c., 8 minims, every three hours (advantageously with an equal quantity of magnesium carbonate or sodium salicylate), until a therapeutic response or slight gastro-intestinal dis-

turbance and weakness occur. Some disturbance of digestion and soft stools are the rule; and in susceptible patients there may be considerable purging and faintness. This may be lessened by atropine, but if possible should be avoided by proper dosage. A single large dose, 2 to 5 c.c., $\frac{1}{2}$ to $\frac{1}{3}$ of tincture, acts more promptly, but may cause severe nausea, diarrhea and great muscular weakness. Prolonged administration is generally harmful and therefore inadvisable. *Colchicine*, which is readily obtainable, permits more definite dosage. It may be given, 0.5 to 1 mg. $\frac{1}{120}$ to $\frac{1}{60}$ gr., three times daily, for one or at most two days. This usually causes considerable diarrhea, beginning on the second day, and with its appearance the drug should be discontinued. The stools will remain loose for another day.

Symptoms of Colchicum Poisoning.—These set in only after three to six hours, even with large doses. They begin with abdominal discomfort, followed by violent and uncontrollable vomiting and purging and great prostration. The stools are at first normal, but become dysenteric and bloody. They are not especially painful but exhausting; so that the patient passes into collapse, with the nervous and muscular symptoms of cholera. Death occurs in seven to thirty-six hours from exhaustion, consciousness being preserved to the end.

The *fatal dose* varies; $\frac{1}{2}$ ounce of the Tincture has been fatal. This would correspond to about 8 mg. of colchicine; but recovery has occurred from much larger doses, presumably with imperfect absorption.

Treatment.—This involves evacuation by emesis and catharsis, if necessary, and diuresis. Tannin is a chemic antidote, but not very effective. Opium and belladonna are given against the gastroenteritis, and the collapse is treated as usual.

Autopsy reveals intense and often hemorrhagic congestion of the intestines, especially the lower portion.

Gastro-intestinal Irritation.—The mechanism of the intense congestion and violent peristalsis has been variously explained. They occur even on parenteral administration, but this has no special significance, since the colchicine is excreted into the intestines (Speyer, 1870; Laborde and Houde, 1887). The action is not directly on the muscle or its innervation, for excised intestine is depressed in tone and excursions by colchicine or oxydicolchicine (Fuehner and Rehbein, 1915). Roosbach, 1876, stated that the motor response to the intestinal vagus or splanchnic is not affected. The persistence of vagus response has been confirmed by Fuehner and Rehbein. Jacobj, 1890, conducted experiments with intestines exposed under a saline bath. These showed increa-peristalsis of a normal type, inhibited by atropine. He concluded that the action consists in enormously heightened response to the normal peristaltic stimuli. Dixon and Malden, 1908, also described immediate peristalsis, which was arrested by atropine and which they therefore attributed to parasympathetic stimulation. Fuehner and Rehbein, 1915, repeated these experiments, but failed to confirm the results. Increased peristalsis occurred only exceptionally. It appears therefore that the peristaltic increase observed by Jacobj and Dixon was accidental, due to causes other than the colchicum.

Fuehner and Rehbein refer the entire action to an irritative capillary vasodilation analogous to the local actions elsewhere, and produced by contact with the drug, reaching the intestine directly or by excretion. They find this hyperemia of the stomach and intestines even with small doses.

Lipps, 1920 confirmed the occurrence of hemorrhagic gastroenteritis after hypodermic administration. He assumed that a capillary hyperemia occurs in other organs, including inflamed regions, and that this is the basis of the therapeutic results. The assumptions require more evidence.

Local Action.—Strong solutions applied locally to the conjunctiva or subcutaneous tissue, produce hyperemia, irritation and anesthesia.

Central Nervous System.—This is gradually paralyzed from below upward, partly directly and partly by the collapse.

No appreciable direct effect is exerted on the circulation (therapeutically, it is somewhat slowed by the relief of the symptoms¹); nor on the glands, striped muscles, or motor nerves (Rossbach; Dixon and Malden).

Explanation of the Delayed Action.—The long period before the symptoms appear can not be materially shortened by increasing the dose (Schorff and Rossbach, 1896), or by intravenous injection. Colchicine itself has relatively little effect on frogs; but its toxicity for these can be increased 50 times by raising the temperature to 37°C

(Sanno, 1911). The reason for this is, according to Jacoby, 1890, that it is not the colchicine itself which produces the symptoms, but an oxidation product—oxy-di-colchicine,—which is formed from it in the mammalian organism—even by circulating it through excised organs—but does not seem to be capable of formation in the frog's at a low temperature. Once formed, whether in the above manner or artificially by the action of ozone, it is toxic to frogs also.

Bio-assay.—The toxicity of mice or heated frogs may be used (Fuehner, 1910).

Colchicine Derivatives.—The structure of colchicine has been established by Zeisel, 1888, and Windaus (Fuehner, 1913). By treatment with acids, a methyl group is easily split off as methyl alcohol and replaced by OH, yielding *colchicineine*. This and various other derivatives have been studied pharmacologically by Fuehner, 1913. The relative toxicity for various animals shows interesting differences.

PREPARATIONS

Colchici Cormus, U.S.P., B.P.; *Colchicum Corm* (Root).—The dried corm of *Colchicum autumnale* (yielding not less than 0.35 per cent. of colchicine, U.S.P.). *Dose*, 0.25 Gm., 4 gr., U.S.P.

Ext. Colch. Corm., U.S.P.—A powdered extract, 1 Gm. representing 4 Gm. of drug, or about 1.4 per cent. of colchicine. *Dose*, 0.06 Gm., 1 gr., U.S.P.

Ext. Colch., B.P.—The juice expressed from the corm and evaporated to a soft extract. *Dose*, 16 to 60 mg., $\frac{1}{4}$ to 1 gr., B.P.

Vin. Colch., B.P.; Wine of *Colchicum*.—20 per cent. of corm. *Dose*, 0.6 to 1.8 c.c., 10 to 30 minims, B.P.

Colchici Semen, U.S.P.; *Colchici Semina*, B.P.; *Colchicum Seed*. The dried ripe seed of *Colchicum autumnale* (yielding not less than 0.45 per cent. of colchicine, U.S.P.). *Dose*, 0.2 Gm., 3 gr., U.S.P.

Fldext. Colch., U.S.P.—*Dose* 0.2 c.c., 3 minims, U.S.P.

**Tinctura Colchici* (Tr. Colch.), U.S.P., B.P.; Tincture of *Colchicum* (Seed).—10 per cent. *Dose*, 2 c.c., 30 minims, U.S.P.; 0.3 to 1 c.c., 5 to 15 minims, B.P. *Maximum dose*, 2 c.c., 30 minims.

Colchicina, U.S.P.; $C_{22}H_{25}NO_6$.—Pale yellow amorphous scales or pale yellow amorphous powder, turning darker on exposure to light; odorless or nearly so. Sol. in water (1:22); freely sol. in alc. *Dose*, 0.5 mg., $\frac{1}{120}$ gr., U.S.P.

APOMORPHINE

Apomorphine is an artificial alkaloid, formed by dehydrating morphine through the action of concentrated mineral acids:

This causes profound changes in both the structure and actions. The peculiar narcotic effect of morphine is almost completely lost. In its place there appears an excitant effect on the nervous centers. In therapeutic doses, this is confined to the vomiting center, apomorphine being the preëminent centrally acting emetic, useful especially for hypodermic administration, in poisoning, etc. It is not so useful as a nauseant.

The emesis is accompanied by the usual side effects of vomiting. It often causes considerable general depression, and sometimes dangerous cardiac depression.

Smaller doses produce a prompt hypnotic effect under certain conditions (acute alcoholism).

Larger doses cause excitement, convulsions, and death by asphyxia. On direct application it paralyzes the heart and skeletal muscles.

The Emetic Action of Apomorphine is Central.—The specific emetic of apomorphine was announced by Gee 1869, in the same year as the discovery of the substance by Matthieson and Wright. The emesis is

produced by very small doses and is very prompt, with but little preliminary nausea. The fact that there is no evidence of gastric irritation (Gee, 1869), and that apomorphine is more effective hypodermically than by mouth (Siebert, 1871) suggested strongly that its emetic action is not a reflex from irritation of the pharyngeal or gastric mucosa, as is the action of most emetics; but that the apomorphine emesis must result from a central action, a direct stimulation of the hypothetical vomiting center in the medulla. Other evidence also tended strongly to the same conclusion. The absolute proof has been brought by Eggleston and Hatcher, 1912, who found that the typical phenomena of vomiting could be produced by the injection of apomorphine into animals from which the whole alimentary canal had been removed, from the cardia to the anus. These eviscerated animals show the retching, the vomiting movements, and the expulsion of mucus from the mouth and esophagus. Direct application of the apomorphine to the esophagus or pharynx does not produce vomiting.

Emesis also occurs in dogs if a very small quantity of apomorphine (0.0001 mg. per Kg.) is applied directly to the floor of the fourth ventricle, in the region of the Thumas (1891) vomiting center. Most other emetics also produce vomiting when applied to this region, and so does strychnine. (Weiss and Hatcher, 1923). This response does not occur if the sensory nuclei of the vagus have been destroyed. Hatcher and Weiss 1923 believe that apomorphine and presumably the other emetics merely lower the threshold of the center to reflexes which are ordinarily not emetic, *i.e.* that emesis is somewhat analogous to strychnine convulsions. There also appears to be a defecation center in this region.

Other Evidence That Emesis is Central. Absence of Irritant Action.—Siebert, 1871, gave daily emetic doses of apomorphine to dogs for six weeks, and found no signs of any inflammation at autopsy. Reichert, 1879, showed that solutions do not produce acute irritation even on the sensitive conjunctiva.

Greater Efficiency on Hypodermic Administration.—Siebert and all subsequent workers showed that administration by mouth requires larger doses and a longer time to produce vomiting. Eggleston and Hatcher found that dogs require by vein only $\frac{1}{125}$ of the oral dose, and vomiting occurs in one-half the time. The effective doses are (milligrams per kilo); by mouth 5.7 in four to ten minutes; hypodermic, 0.2 in two and one-half to ten minutes; intramuscular, 0.05 to 0.075 in three to seven minutes; intravenous (without anesthesia), 0.05.

Division of Both Vagi.—These constitute the sole afferent paths for the reflex of local emetics (Openchowski, 1889). With locally acting emetics therefore vomiting can not occur if both vagi are divided, but this does not prevent the apomorphine emesis (Siebert, Harnack, and others; the contrary results of some investigations are explained by experimental errors, constrained positions of animals).

Movements of Stomach in Emesis.—This has been investigated in cats by the X-ray method (Cannon, 1898). The same events follow apomorphine and mustard; the first effect is total inhibition of the tone of the cardiac portion, which becomes a flaccid bag. The pyloric end is shut off by a deep contraction ring. The contents are then expelled by sudden contraction of the diaphragm and abdominal muscles. As the expulsions are repeated, the gastric walls tighten around the remaining contents.

Replacing Stomach by Pig's Bladder.—Magendie found apomorphine effective under this condition (Magnus). This would not exclude the possibility of intestinal irritation.

Movements of Excised Stomach.—Schultz 1886, found that apomorphine and other emetics produce strong reversed peristalsis in excised stomach; but Batelli, 1896, finds the same movements without giving any drugs, and they may be attributed to asphyxia.

Cocainization of Pharyngeal Region.—Valenti, 1911, asserts that emesis, by apomorphine as well as by local agents, is prevented by cocainizing a certain pharyngeal area which controls the cardiac sphincter. He suggests that apomorphine increases the excitability of the center so that it responds by vomiting even to the normal impulses which emanate from this pharyngeal region. However, this may merely mean that the

relaxation of the cardiac sphincter, which is controlled from this region, is indispensable to successful emesis (Mellinger, Openschowski, Cannon). Magnus, 1914, discredits the existence of a pharyngeal vomiting center.

Susceptibility of Different Animals to Emetic Action.—Animals which are incapable of vomiting (rabbit, rat, guinea pig, horse, cattle, etc.) do not do so under apomorphine; but many animals which vomit more or less readily in response to local irritants, are also completely insusceptible (pigs, birds, frog) or relatively insusceptible to apomorphine emesis (the cat requires about 50 times more per body-weight, hypodermically, than the dog). Man and dog are the most susceptible. Continued administration does not establish tolerance (Siebert). Insusceptibility to the emetic actions does not imply tolerance of the other central actions of apomorphine, to which all animals are susceptible.

Recalcitrant Stage.—Excessive doses of apomorphine are not as effective as moderate doses in producing emesis, and may render the animal completely recalcitrant to the emetic action (Reichert, Eggleston and Hatcher).

Ant-emetic Drugs.—Apomorphine vomiting is not affected by local sedatives (bismuth, etc.), but is prevented by narcotics. With chloroform and chloral, full narcotic doses are needed; but with morphine and its esters, very small, non-narcotic doses suffice. Papaverine is ineffective (Ruth, 1913); also atropine.

Other Central Actions.—If apomorphine is given in larger doses it produces a series of excitant effects, especially in animals which do not vomit (Harnack, 1874). At first there is great restlessness, gnawing, excitement and terror. These are perhaps due to the nausea and to the unaccustomed sensations. The gnawing is not seen with rabbits, from which the hemispheres have been removed, so that it must be of cerebral origin (Morita, 1915). The respirations are quickened (even under chloral narcosis), but regular. Apomorphine also disturbs heat regulation, so that animals do not respond to fever by polypnea and shivering (Magne, 1914). With larger doses (larger than are ever used in man), there are ataxia and then violent irregular convulsions. These interfere with respiration, and the animal dies in asphyxia. Death occurs also if the convulsions are suppressed by chloral, but then requires a dosage twenty times as high. Frogs exhibit the same phenomena. Hattori, 1910, finds that the reflexes from the spinal cord and brain are increased.

Heat-regulation.—Apomorphine inhibits the polypnea and shivering reactions to experimental fever (Magne, 1914).

Local Application.—Harnack, 1874, showed that this paralyzes cardiac and skeletal muscles in frogs.

Hypnotic Action of Apomorphine and Use in Acute Alcoholism and Hysteria.—C. J. Douglas, 1899, claimed that apomorphine, in, in small, non-emetic doses (2 mg.), acts as a safe and certain hypnotic, effective even in delirium; natural and refreshing sleep occurring usually in five to twenty-five minutes. Coleman and Polk, 1902, experimenting on an extensive series of acute alcoholic patients, confirmed the claim. They employed hypodermic doses of 2 to 6 mg. Other observers (Rosebrugh, 1908) report similar results; the tendency, however, has been to use doses (5 mg.) which produce an emetic action (Rosenwasser, 1907). This perhaps aids the therapeutic effect by breaking into the fixed ideas of such patients. The sleep occurs in a few minutes after emesis. Hypodermic administration secures by far the best results.

Velocity of Action.—In man, the hypodermic injection of 5 to 10 mg. ($\frac{1}{12}$ to $\frac{1}{6}$ gr.) of apomorphine produces severe nausea and vomiting within ten or fifteen minutes, generally without other effects. By mouth, twice this dose is uncertain. The emesis may be repeated several times. The nausea is intense and is apt to persist longer than with the reflex emetics, since the apomorphine is not removed.

Phenomena of Nausea.—These are common to all emetics. They consist in a feeling of sickness, lassitude and weakness; pale skin; increased secretion of sweat, saliva, mucus and tears; sensation of excessive heat; increase of respiration and pulse rate; fall of blood pressure. *During the emesis proper*, the contraction of the abdomen will raise the blood pressure temporarily—a fact which contraindicates emesis in apoplectic patients, etc.

Circulation and Respiration in Nausea and Vomiting.—Traube, 1867, described an initial fall of pressure, with slow vagus pulse, succeeded by quickened pulse toward the

end of the emetic action. The details have been studied by Brooks and Luckhardt, 1915, on unanesthetized animals. Their results were confirmed by Miller, 1915.

They found emesis accompanied by marked disturbances of the circulation and respiration. There is sometimes a period of elevated pressure; but commonly, at the moment of emesis, the heart is inhibited, with sudden severe fall of blood pressure. This is interrupted by periods of great oscillations. These great and sudden changes may rupture blood vessels, which would resist more gradual changes of equal degree.

The changes are somewhat different in the two types of vomiting.

Rapid projectile type, with short nausea: During the nausea, the blood pressure is slightly raised, the pulse rate increased, its amplitude diminished. During the vomiting, the pressure falls sharply with practically complete arrest of the heart, or arrhythmia. The respiration is suspended. After the expulsion, rapid recovery occurs to normal.

Slow, labored type, with more marked nausea, etc.: During the nausea, there is deep breathing and salivation. During violent retching, the blood pressure and the intrathoracic pressure oscillate greatly. The pulse is slow and irregular. During the vomiting, the changes are as described.

The slowing and fall of blood pressure are due to inhibiting vagus stimulation, since they are prevented by atropine. The oscillations are indirect results of the muscular efforts, and are generally eliminated by curare.

The Acceleration of the Heart in Emesis.—Ackermann, 1856, showed that all kinds of emesis are accompanied by this acceleration. Harnack, 1874, observed some acceleration even after atropine, so that there must be a reflex stimulation of the accelerator mechanism; the vagus mechanism is probably also reciprocally inhibited.

The stimulation of the salivary centers has been studied by V. E. Henderson, 1910.

Accidents in the Therapeutic Use of Apomorphine.—The apomorphine nausea may produce considerable depression, varying in degree in different individuals. It is characterized by muscular debility, and rarely collapse (Harnack, 1908). These may precede or follow the emesis, and are especially liable to occur in the rare cases in which the emesis fails; in pulmonary and cardiac disease; in debilitated patients and in children. The collapse is preceded by irregular respiration, anxiety, vertigo, and fainting. During the collapse, the patient may be unconscious, and pass into early death. These cases are quite exceptional, but their possibility should be borne in mind. It is believed by some that the accidents are often due to impurities, so that only freshly made solutions of the crystallized alkaloid should be used, never of the amorphous.

Old solutions of apomorphine acquire a deep green color, indicating decomposition. The emetic action may not be effected by this change in some samples, but it is lost in others (Harnack, 1874).

Chloromorphids.—These are formed in the manufacture of apomorphine, if the action of the hydrochloric acid on the morphine is not carried sufficiently far. They are, therefore, a frequent contamination of commercial apomorphine. They are chemically analogous to acetyl-morphine, being formed by the substitution of Cl for the OH group of morphine. Their pharmacologic actions are also similar to those of acetyl-morphine (heroin), namely exaggerated morphine effects, with greatly increased toxicity, paralysis of respiration, and an antiemetic action (Harnack and Hildebrandt, 1911). These investigators hold these impurities responsible for the failure of emesis and the collapse. They may perhaps also explain the hypnotic action of Douglas.

Dosage.—For emetic effect, 5 mg. ($\frac{1}{12}$ gr.) or at most 10 mg. ($\frac{1}{6}$ gr.) of the crystallized hydrochloride, in $\frac{1}{2}$ to 1 c.c. of water, should be given hypodermically, and repeated in fifteen minutes if necessary. As a nauseant expectorant, it is inferior to ipecac, but may be used by mouth, in syrup of citric acid, in doses of 2 to 10 mg. ($\frac{1}{30}$ to $\frac{1}{6}$ gr.) for adults; $\frac{1}{2}$ to 2 mg. ($\frac{1}{120}$ to $\frac{1}{30}$ gr.) for children. This dosage does not cause depression.

The therapeutic use of emetics will be discussed later.

Absorption.—Apomorphine is readily absorbed from all mucous membranes.

Emesis is produced by applying a few milligrams to the conjunctiva of a dog; also from application to the urethra, vagina, etc. (Macht, 1917).

PREPARATIONS

* *Apomorphinae Hydrochloridum* (Apomorph. Hydrochl.), U.S.P., B.P.; $C_{17}H_{17}NO_2 \cdot HCl$, $\frac{1}{2}H_2O$, U.S.P.; $(C_{17}H_{17}NO_2 \cdot HCl)_2 \cdot H_2O$, B.P.—Prepared from morphine by the abstraction of one molecule of water. The preparations of different manufacturers differ more or less in composition and activity (Harnack, 1909). Minute, white or grayish-white, glistening prisms; odorless; acquiring a greenish tint upon exposure to light and air. Sol. in water (1:50) and in alc. (1:50). *Dose*, Expectorant, 1 mg., $\frac{1}{60}$ gr.; emetic, hypodermic, 5 mg., $\frac{1}{12}$ gr., U.S.P.; 3 to 6 mg., $\frac{1}{20}$ to $\frac{1}{10}$ gr.; by mouth, 6 to 16 mg., $\frac{1}{10}$ to $\frac{1}{4}$ gr., B.P. *Maximum dose*, 20 mg., $\frac{1}{3}$ gr.

Inject. Apomorph. Hyp., B.P.—1 per cent. *Dose*, 0.3 to 0.6 c.c., 5 to 10 minims.

APOCODEINE

This is an analogous derivative of codeine, apparently variable in composition and actions. Dixon, 1903, claims that it paralyzes successively the nerve-endings of the vagus, vasomotors, other smooth muscle, striped muscle, and cardiac accelerator, as well as the nerve-centers, but its action does not seem to be absolutely specific. Magnus, 1905, found both stimulant and paralyzant peripheral effects on peristalsis. It has been used as expectorant, emetic, hypnotic and cathartic (Fraenkel)

ASPIDOSPERMA (QUEBRACHO)

The bark of *Aspidosperma Quebracho-blanco* contains several alkaloids with very similar actions: fall of blood pressure, increased heart rate, clonic convulsions with muscular weakness, and a very great and persistent increase of the rate and depth of respiration. The lungs are markedly hyperemic (Harnack and Hoffmann, 1884; Wood and Hoyt, 1903; Wood, 1910). These actions are partly central, partly peripheral. Wood, 1908, attributes the respiratory effect to intense irritation of local areas of the lung, which is observable at autopsy. The alkaloid quebrachine is mainly responsible for this effect. One of the alkaloids, aspidosamine, produces emesis; the others only nausea, with its usual accompaniments.

Cow, 1914, finds that larger doses paralyze the nerve cells of the autonomic system, brain and spinal cord. Still larger doses paralyze the vagus, sympathetic and motor endings, similarly to nicotine and curare. Death occurs by paralysis of the respiratory center when the motor nerves still respond to stimulation.

Hesse claimed to have isolated six alkaloids; but of these only two are well characterized, namely aspidospermine and quebrachine, the latter identical with yohimbine. The others were probably impure mixtures and cleavage products (Ewans, 1914).

Aspidosperma has been used as a respiratory stimulant in all forms of dyspnea and asthma; but its usefulness is doubtful. Its irritant action on the lungs and the great circulatory depression should be borne in mind. The *dose* of the fluidextract is 1 to 4 c.c.; of the amorphous aspidospermine (a crude mixture), 0.06 to 0.1 Gm.; of the crystalline (true aspidospermine chloride, 5 to 30 mg., at first every hour or two, then less frequently; S. Solis Cohen).

IPECACUANHA AND EMETINE

Ipecac, the root of a Brazilian plant, contains several alkaloids, of which two, emetine and cephaeline, produce local irritation and nausea and emesis, by central and local action, without danger of side effects. The drug is therefore very useful therapeutically. Large doses produce specific effects in amebic dysentery. The systemic actions (central and cardiac depression; stimulation and depression of smooth muscle) do not occur when the drug is administered by mouth, since there is but little absorbed.

Nauseant and Emetic Actions.—These are produced much more slowly than with apomorphine. In man, vomiting occurs only after one-half to one hour. The drug is therefore more useful as a nauseant expectorant than as an emetic. As *expectorant*, the Syrup is employed (1 c.c.). An infusion, used as a gargle, has been recommended to avoid irritation of the stomach. For *emesis*, the powdered ipecac may be administered, 1 to 2 Gm. in warm water, repeated in half an hour if necessary; or the Syrup (teaspoon for adults, teaspoon for infants, especially in spasmodic croup). It has some advantage over the mineral emetics in that it causes less gastric irritation and less general depression.

Location of Emetic Action.—It has generally been stated that this is purely local, mainly because emesis occurs more promptly on gastric than on hypodermic administration; the efficiency of hypodermic administration being explained by excretion of the alkaloids into the stomach (Valenti, 1911) and intestines (d'Ornella, 1873).

However, Eggleston and Hatcher, 1915, found that the emetic dose is nearly the same by either channel; moreover, they observed the occurrence of vomiting movements in eviscerated animals. It is clear therefore that the vomiting is of central origin; but because of the prompter action of the gastric injection, which was confirmed by these observers, it follows that the local action facilitates the emetic response. Emetine and cephaeline act alike, except that cephaeline is twice as active.

Irritant Action.—Ipecac irritates all mucous surfaces, sometimes to an exaggerated degree. It may therefore produce conjunctivitis, bronchitis, skin eruptions, asthma, diarrhea, rectal irritation, etc. Some persons are extremely sensitive to these effects. On the abraded skin, 1 per cent. solution of emetine raises a wheal (Sollmann and Pilcher, 1916). Hypersensitive patients also react with urticaria to systemic administration (Savignac and Alivasatos, 1919) or with eczema or asthma. Widal et al., 1922, claimed that these can be desensitized.

The *subcutaneous tissue* is but little subject to irritation by ipecac (Zepf, 1903), perhaps because the drug is too rapidly absorbed. Renal irritation occurs rarely.

Use in Dyspepsias.—The gastric hyperemia, produced by small doses, is sometimes utilized in dyspepsias (a drop or two of the syrup in a teaspoon of water, every fifteen minutes). The benefits are doubtful.

Use in Amebic Dysentery.—Ipecac, emetine or cephaeline, when administered in adequate doses usually cause the prompt disappearance of all the clinical symptoms, generally with absolute and often permanent disappearance of the *entameba histolytica* from the stools. The most complete and permanent effects are obtained in early acute cases (Ross, 1916). In chronic cases, relapses and carriers, the amebas occur as resistant, encysted forms, against which hypodermic injections appear to be rather ineffective; oral administration is then distinctly more successful, but may also fail.

The response to the ipecac alkaloids has been attributed to a specific amebicidal action. This appears to be incorrect; the dysentery amebae tolerating direct contact with high concentrations of emetine. The mechanism of the clinical action is therefore obscure.

Musgrave, 1912, and some others, have referred the clinical results to the intestinal irritation; and believe ipecac effective in all forms of dysentery, whatever the etiology. This view has not obtained acceptance.

Harris, 1890, claimed that ipecac more or less freed from its alkaloids ("de-emetinized") is equally effective and less disagreeable. This is now generally denied. Vedder found it quite inert.

Formerly, the opinions of the value of ipecac treatment were divided; but the later clinical investigators are practically in agreement. The older failures are probably attributable largely to faulty administration and inadequate dosage.

Experimental Amebic Dysentery.—Cats artificially infected with *E. histolytica*, can be cured by early and energetic treatment with either emetine or quinine, but not with papaverine or narcotine (Sellards and Leiva, 1924); but emetine may fail if the conditions are not suitable (Dale and Dobell, 1917).

Amebicidal Action.—*Entamebæ histolyticæ* in the stools of dysentery patients are quite unaffected by contact with emetine in dilutions of 1 : 2000 for one or 2 hours; and even 1 : 250 often fails to kill in this time (Allan, 1920). Dale and Dobell, 1917, also found that the emetine alkaloids affected the ameba less than quinine, although quinine has much less effect on the disease. The older claims of high efficiency (Vedder, 1911; Wherry, 1911; Rogers, 1912) were doubtless errors due to the undeveloped technic.

The action is quite slow, so that some organisms, especially of the encysted forms, are likely to survive when most have been killed. *Endameba buccalis* often survives on contact with 1 per cent. emetine hydrochloride.

Related Alkaloids.—Pyman and Wenyon, 1917, and Walters, Baker and Koch, 1917 have investigated the efficiency of emetine and its derivatives on cultures, especially of ameba *limax*. Emetine and cephaline were about equal. Psychotrine was much inferior. Some emetine derivatives with higher alkyl esters were more efficient than emetine.

Papaverine and Narcotine.—Emetine is probably an isoquinoline derivative (Windaus) and therefore related to papaverine and narcotine. Pick and Wasicky, 1915, found that these opium alkaloids also kill protozoa.

Bactericidal Action.—Emetine is fairly efficient *in vitro*, but acts very slowly and is therefore, useless *in vivo* (Kolmer and Smith, 1916).

Administration in Dysentery.—The oral administration of adequate doses of soluble preparations of ipecac or emetine is likely to produce vomiting. The emesis often diminishes in two or three days, and can be controlled by 10 or 15 minims of Tr. Opil. The vomiting may be circumvented by the use of salol coated pills or of difficulty soluble preparations, and by hypodermic administration.

Salol-pills.—These constitute probably the most effective and safest method. A careful technic must be followed; such as the method of S. K. Simon (1906, 1918):

The patient is directed to bed during the treatment (which takes about two weeks), and is kept on a light, mainly liquid diet. After an initial castor oil purge, he receives a single dose of ipecac, as salol-coated pills, in the evening, three hours after the last meal. The first dose is of 3 or 4 Gm. This is reduced by 0.3 Gm. daily, until 0.65 Gm. is reached. This last dose is then continued for two weeks, and is supplemented by colon irrigations with salt or borax solution. If ulceration has been extensive, the colon is later washed with a dilute silver nitrate solution. Tonic measures are always necessary.

In normal individuals, 3 Gm. of ipecac, given by this method, produces generally diarrhea, lasting some days; often considerable abdominal pain and slight tenesmus (Musgrave, 1912); no depression and rarely vomiting. A patient took 300 gr. in three days without apparent discomfort (Dock and Lyons, 1910).

Direct Intestinal Administration.—Ipecac has also been administered by the duodenal catheter (Beck, 1912), by rectum, and through the stump of an operated appendix.

Rectal Administration.—Lawson, 1918, claims successful results from an enema of 4 to 8 gms. of ipecac, suspended in a pint and a half of water.

Difficulty Soluble Preparations.—Two types of these have been introduced: Emetine-fuller's earth adsorbate; and emetine-bismuth iodide.

Emetine Adsorbate.—The alkaloids of ipecac are adsorbed by the fuller's earth. The product ("Alkresta ipecac") is insoluble in water and dilute acids and therefore avoids the direct gastric irritation. It was originally claimed that it would be dissolved by the alkalinity of the intestines. This is incorrect (Sollmann, 1919). It is now claimed that some of the emetine is dissolved in the intestines in some other manner, perhaps by the soaps (Clowes and Walters, 1920); but there are no data as to the quantity dissolved and the entire absence of systemic effects, clinically as well as experimentally (Eggleston and Hatcher, 1915) shows that it cannot be large.

Emetine Bismuth Iodide.—This was suggested by Du Mez, 1915. It contains about 20 per cent. of emetine and is but slightly soluble in water or dilute acid; but the emetine is dissolved by dilute alkali (Sollmann, 1919). It causes relatively little gastric disturbance, and is often efficient in chronic cases and in carriers (Report Committee Pharm. and Chem. J.A.M.A. 1918, Vol. 71, page 2013; critical bibliography).

The gastric solubility may be further reduced by making it into pills with mutton tallow (T. J. G. Mayer, 1920).

Hypodermic Treatment with Emetine.—This was introduced by Rogers, 1912, and has been found more promptly effective and less disagreeable

than oral administration (review by Vedder, 1914). A few injections of 0.03 Gm. of emetine usually suppress all symptoms, and cause the living amebæ to disappear from the stools; but unless the full "course" is given they are likely to return in the chronic form, which is much more difficult to treat. The course consists in 0.03 Gm. twice a day for ten days; *i.e.*, a total of 0.6 Gm. Longer courses, introducing more than 1 Gm., may produce cardiac collapse. Even with the shorter courses there is often considerable depression for several days, and the patients should be kept in bed (Chopra and Ghosh, 1922). In the chronic form, with encysted amebæ, the oral administration appears to be more effective, and it may be necessary to give several courses at intervals. Carriers may be treated with rectal irrigations of quinine or silver nitrate. Care must be taken that the emetine solution is not introduced in the eye, for it is very irritant (Blue, 1915).

Side Effects.—The ordinary dose does not produce any gastro-intestinal or general disturbance, and practically no local reaction if the solution is neutral. The larger doses cause some nausea, vomiting, depression and pain—more with intramuscular than hypodermic. Even 0.25 Gm. at one dose produced only persistent nausea (Allan). Cephaline would not be used, because of its greater emetic action.

Emetine Diarrhea.—Bloody diarrhea in consequence of therapeutic hypodermic emetine injection is probably more common than was formerly supposed; it may be mistaken for recrudescence of the dysentery. Kilgore and Liu, 1917, describe several cases of children who received excessive doses under the mistaken notion that they would be more tolerant than adults.

Fatalities.—A number of toxic and a few fatal cases have been reported clinically (Spehl and Collard, 1914; R. L. Levy and Rowntree, 1916; Dalimier, 1917; H. H. Johnson and Murphy, 1917).

They usually exhibit intestinal, paralytic and edemic symptoms. The heart may be depressed. The dangers are greater in diseased subjects (Pellini and Wallace, 1916).

These accidents do not appear to be connected with variability in the commercial preparations (Lake, 1918) but appear to be explained by cumulative action. Walters and Koch, 1917, found in animals that doses only $\frac{1}{10}$ of the minimal single fatal dose, became fatal when repeated daily for three weeks.

Excretion after Hypodermic Injection.—Emetine appears in the urine within 20 to 40 minutes; but the excretion outlasts the treatment by 5 to 9 weeks. It must therefore form stable deposits in the body (Mattei, 1920); perhaps at the side of injection.

Intravenous injection has also been tried, but should be condemned. Vedder rightly cautions against it. Baehrman and Heinemann, 1913, had no bad results with 60 to 200 mg.; whilst 300 to 400 mg. gave severe effects in a few minutes; vascular paralysis, marked dyspnea, unconsciousness, vomiting and diarrhea, very slow pulse. This exceeds the fatal intravenous dose for rabbits (2.5 mg. per kilogram). The fatal hypodermic dose is much higher (20 mg. for rabbits).

Variability of Commercial Emetine Hydrochloride.—The occurrence of two fatal human cases led R. L. Levy and Rowntree, 1916, to investigate the toxic effects. They found wide differences in the toxicity of commercial samples. They describe the toxic phenomena in animals, and the clinical toxic cases.

Emetin in Pyorrhea Alveolaris.—The supposed causation of Rigg's disease by endamebæ prompted the trial of emetine. Many observers reported good results; but neither these, nor the etiology, are beyond dispute (Price and Bensing, 1915).

Smith and Barrett, and others, found endameba buccalis constantly present in the lesions, and introduced the local use of ipecac. Bass and Jones, 1914 and 1915, were especially enthusiastic. They report the amebæ destroyed by hypodermic injections of emetine, 0.03 daily for three to six days; or 2 or 3 Alcresta ipecac tablets (each of 0.65 Gm. powdered ipecac) two or three times daily by mouth, for the same period. This does not produce nausea, but often some abdominal discomfort or diarrhea. The lesions require a long time to heal, and may become reinfected, when the treatment must be repeated. As prophylactic, they recommend a daily mouth wash of 1 or 2 drops of fluidextract ipecac in a half-glass of water. Evans and Middleton, 1915, also report

SUCCESS.

Use in Other Parasitic Conditions.—Emetine has been unsuccessful in syphilis, rabies, trypanosomes and bacillary dysentery. Marked improvement was reported for sprue by Schmitter, 1915.

Malignant Tumors.—It has been reported that these may disappear after local injection of emetine. However, this is due merely to the caustic action (Lewisohn, 1918).

Tuberculosis.—Raeburn, 1914, suggests its use (1.5 mg. hypodermically) to lessen pulmonary congestion, expectoration and congestive hemorrhage. The rationale is not clear and it requires confirmation.

Systemic Effects.—These occur only after very large hypodermic or intravenous doses. They consist in *paralytic symptoms*, among the earliest in mammals being *vaso-motor paralysis* with fall of blood pressure. This is further aided by *weakening of the heart muscle* due to its direct muscle-action (it produces diastolic arrest of the isolated frog heart; Moulinier, 1914). Death occurs mainly by central paralysis.

If the action has lasted any time, the autopsy will show a marked *gastro-enteritis* with ecchymoses and even ulcers. There are also hemorrhages into the lymph glands, spleen, kidneys, etc. (Kilgore and Liu, 1917). However, even fatal doses produce only slight degeneration of the renal parenchyma (De la Paz and Montenegro, 1918).

Circulation.—Notable effects occur only with toxic doses; and these are complex and variable. It is very doubtful whether they could be utilized in therapeutics; but emetine has been tried in *tubercular hemoptysis*, the reports being often favorable, but not very critical. The mechanism is not explained.

Flandin, 1913, claimed immediate arrest after the hypodermic injection of 0.04 Gm. without unpleasant symptoms. The injection may be repeated in intervals of twelve to twenty-four hours. Valassopoulos, 1913, used 0.02 Gm. (also in rectal carcinoma). Nicola, 1914, employing the same dosage as Flandin in hemoptysis, obtained variable results. Apparent success (arrest in forty-eight hours) was obtained mainly in the early stages, with scanty hemorrhage or high blood pressure. Bleeding from venous congestion or with low blood pressure was not influenced.

Systemic and Pulmonary Circulation.—Plumier and Clermont, 1919, found no effect with hypodermic administration. Non-toxic intravenous injections lowered the carotid pressure, but increased the pressure in the pulmonary artery and vein, and also the pulse rate. Larger doses dilated the pulmonary vessels, but generally less than the systemic vessels. The heart was also depressed.

Absence of Hemostatic Effects.—Superficial capillary hemorrhage is increased by the local application of emetine; and is checked by intravenous injection only as this lowers the blood pressure (Hanzek, 1918). The coagulability of the blood is not altered, in dogs or rabbits. Perfusion of the blood vessels in frogs or mammals shows no effect until the concentration of emetine reaches 1:2,000; above this, there is slight constriction.

Smooth Muscle.—Maurel, 1914, describes for the intestines, stomach and blood vessels a primary increase of tonus, large doses paralyzing.

Pick and Wasicky, 1916, point out that emetine is related to papaverine in action as well as in chemical constitution. It paralyzes the smooth muscle of the digestive tract, bronchi, uterus, heart and vessels (but small doses stimulate peristalsis). The depressant action is exerted directly on the muscle substance, emetine being mutually antagonistic with barium.

Uric Acid Excretion.—This is increased by ipecac, as by other gastro-intestinal irritants (Abl, 1913).

Comparative Action of Emetine and Cephaeline.—Emetine is methyl-cephaeline (Carr and Ryman, 1913. They also describe the chemic properties).

The actions of emetine and cephaeline agree qualitatively; but emetine is the stronger amebicide, whilst cephaeline is more irritant, more emetic (about twice, Eggleston and Hatcher, 1915, Meltzer, Eckler and Koch, 1917) and about twice as toxic (Podwyssotzki, 1879; Wild, 1895; Paul and Cowley, 1901; Lowin, 1902). Emetine was said to be more depressant to the heart, and cephaeline is somewhat hemolytic.

Other Cephaeline Esters.—Walters and Koch, 1917, tested a series of derivatives. They found only quantitative differences.

Psychotrine.—The third alkaloid of ipecac is also chemically related to cephaeline. (That is, it contains 2 atoms less of hydrogen.) It has a very low toxicity (Walters and

Koch). The amount in the drug is small and unimportant. Lloyd has announced a colloidal alkaloid ("Kryptonine") is ipecac.

Ipecacuanhic Acid.—A further constituent, ipecacuanhic acid was, until recently, considered a bearer of the action of ipecac in dysentery. It has been shown, however, that this tannin is inactive. The ipecacuanhic acid possesses all the chemic characters of caffeotannic acid (see Index), from which it differs only by one atom of oxygen. The pharmacologic actions of these two tannins also agree perfectly (and differ from ordinary tannin) as they are neither antiseptic nor astringent (Kimura, 1903).

Ipecacuanhin.—Ipecacuanhin is a crystalline glucosidal constituent (Finnemore and Braithwaite, 1912).

PREPARATIONS

**Ipecacuanha* (Ipecac.), U.S.P.; *Ipecac. Rad.*, B.P.—The dried root of *Cephaelis Ipecacuanha* (*Psychotria Ipecacuanha*, B.P.), Rio Ipecac. The U.S.P. also recognizes *Carthagenia Ipecac.* from *Cephaelis acuminata*. Ipecac must yield not less than 1.75 per cent. of alkaloids, U.S.P.; 2 per cent., B.P. Walters and Koch, 1917, find that both varieties contain about twice as much emetine as cephaeline. The drug was introduced into Europe about the end of the seventeenth century. *Dose*, expectorant, 0.06 Gm., 1 gr., U.S.P.; 0.03 to 1.2 Gm., $\frac{1}{2}$ to 2 gr., B.P.; as emetic, 1 Gm., 15 gr., U.S.P.; 1 to 2 Gm., 15 to 30 gr., B.P., of the powder, stirred into warm water.

Fldext. Ipecac., U.S.P.; *Ext. Ipecac. Liq.*, B.P.; about 1.5 per cent. of alkaloids; the U.S.P. also contains 1 per cent. of HCl. *Dose*, as expectorant, 0.06 c.c., 1 minim; U.S.P.; 0.03 to 0.12 c.c., $\frac{1}{2}$ to 2 minims, B.P.

Pulv. Ipecac. et Opii, U.S.P.; *Pulv. Ipecac. Co.*, B.P.; Dovers' Powder.—(See Index.)

**Syr. Ipecac.*, U.S.P.—7 per cent., acidulated with Acid. Acet. *Dose*, as expectorant, 0.75 c.c., 12 minims; as emetic, 15 c.c., 4 drachms, U.S.P.

Ipecac Syrup of the International Protocol is only $\frac{1}{4}$ the strength of the U.S.P.

Troch. Ipecac., B.P.—0.015 Gm., $\frac{1}{5}$ gr.

Vin. Ipecac., B.P.—5 per cent. *Dose*, 0.6 to 0.8 c.c., 10 to 30 minims; as Emetic, 16 to 20 c.c., 4 to 6 drachms, B.P.

**Emetine Hydrochloricum* (Emet. Hydrochl.), U.S.P., $C_{30}H_{44}N_2O_4 \cdot 2HCl$.—Contains variable amounts of water of crystallization. White or yellowish crystalline powder. Freely sol. in water or alc. *Dose*, 20 mg., $\frac{1}{3}$ gr., U.S.P., hypodermic; by mouth, as expectorant, 5 to 10 mg., $\frac{1}{12}$ to $\frac{1}{6}$ gr.; as emetic, 10 to 20 mg., $\frac{1}{6}$ to $\frac{1}{3}$ gr. Care must be used to keep it from contact with the eyes, as it is highly irritant.

Emetine Bismuth Iodide, N.N.R.—Odorless, orange-yellow powder; somewhat bitter taste; but slightly soluble in water or dilute acid; emetine is liberated by dilute alkali. *Dose*, 0.2 Gm. (3 grains), daily for four days, administered in capsules, with meals.

Cephaelina, N.N.R., $C_{14}H_{26}O_2N$.—*Dose*, 5 to 10 mg., $\frac{1}{12}$ to $\frac{1}{6}$ gr., in pills or as powder with sugar.

Chaparro Amargosa (Simarubaceæ), a Mexican plant (*Castela Nickolsonii*) has been used in amebic dysentery, with successful results, and without bad effects. The bitter infusion is used. It kills endamebas (Nixon, 1914, 1916).

It effected cures in cases that had been refractory to emetine (Shepherd and Lillic, 1918).

Sellard and McIver, 1918, isolated a product toxic to small animals, which is apparently glucosidal. They also give an abstract of the early literature.

THERAPEUTIC USE OF NAUSEANT EXPECTORANTS

Small doses of emetics produce only some increase of the bronchial and salivary secretion and sweat, which is useful in the early, congestive ("dry") stage of colds and in "dry" coughs. The dose should be sufficiently small to minimize general depression and noticeable gastric disturbance, although this sometimes can not be avoided. The nauseants should be given every two to four hours.

For the "abortion" of colds, ipecac is often employed in the form of "Dover's Powder," 0.5 Gm. at night. In the congestive stage, the syrup of ipecac may be used. *Tartar Emetic* may be substituted, but is more

depressant, and its continued use may give rise to poisoning. Its expectorant dose is 5 mg. ($\frac{1}{12}$ gr.); or 1 c.c., 15 minims of the Vinum Antimonale (= 4 mg., $\frac{1}{15}$ gr.). This is also one of the constituents of the *Mistura Glycyrrhizæ Composita*.

Viscid, adherent mucus may be thinned by *Ammonium Chloride* or *Carbonate* (0.2 Gm.); or *Potassium Iodide* (0.2 Gm.); or by the irritant saponin of *Syrupus Senegæ* (2 c.c.). The *Compound Syrup of Squill* (1 c.c.) savors of "shot-gun" prescribing.

The reactions of the salivary center have been studied by V. E. Henderson, 1910. He finds that this is readily depressed by *anesthetics* and by *morphine*, even in small doses. *Iodides* and other salts do not cause acute stimulation, but may act reflexly. *Emetine* stimulates both directly and reflexly, also *ammonium salts*, but with these the reflex stimulation is the more important. *Antimony* acts only reflexly, *apomorphine* only centrally.

Bronchial Secretion.—J. L. Miller, 1914, could not demonstrate any effect with therapeutic doses of emetine, ammonium chloride or carbonate. Large doses produced an increase, even when administered by duodenum.

Site of Action of Miscellaneous Emetics.—This has been investigated by Eggleston and Hatcher, 1915. A drug may be considered to act directly on the center if emesis occurs with smaller doses and more rapidly when the drug is given by vein than by mouth; and if the phenomena of nausea and the motions of emesis occur after the whole alimentary tract has been removed. According to these criteria, they found that the emetic action of most alkaloids is central; namely, apomorphine, morphin, nicotine, lobeline, aconitine, veratrine, pilocarpine, quinine and ergot; as also picrotoxin, digitalis and sodium salicylate. With ipecac, the local action probably contributes to the result.

LOCALLY ACTING EMETICS

The afferent paths which may reflexly stimulate the vomiting centers are very numerous; but for practical therapeutic purposes only those of the pharynx and gastric mucosa are available. Not every form of gastric irritation results in vomiting—the kind, rather than the degree, of irritation being important. This, and the necessity of avoiding severe local and systemic effects, limits the number of irritants which may be used as therapeutic emetics. However, there is still a wide choice, adapted to the various indications.

Cupri Sulphas and Zinci Sulphas.—These act practically alike, provoking the vomiting reflex before there is time for any other local irritant action. They are not absorbed (unless the stomach is corroded), and therefore do not lead to any systemic effects. Vomiting occurs with certainty in a very few minutes. The nausea is therefore short, and the after-depression is small, constituting an advantage over apomorphine. They are especially useful to empty the stomach of indigestible food or poisons (provided that these are not corrosive). Copper sulphate is of especial value in *phosphorus poisoning* if any of the poison is still in the stomach, since the metallic copper is precipitated and forms an impermeable coating over the unabsorbed phosphorus particles.

The emetic dose of copper sulphate is about 0.25 Gm. in 1 per cent. solution; that of zinc sulphate is about 1 to 2 Gm. They may be repeated in fifteen minutes if necessary.

Mustard.—A teaspoonful of powdered mustard in a cup of warm (not hot) water, repeated every fifteen minutes is a rather uncertain emetic, but a useful emergency remedy in poisoning, when the patient is already

disposed to vomit. *Salt water*, or even plain warm water, or tickling of the fauces, may be similarly useful.

Antimony.—In the form of Antimony and Potassium Tartrate (Tartar Emetic) antimony acts similar to Copper, mainly by a local effect, but its use should be avoided, since it is very depressing. It is fairly easily absorbed, so that 0.2 Gm. has repeatedly proven fatal. The ordinary emetic dose is 30 mg.; and if this not effective in half an hour, it would be well to give tannin as an antidote.

Emesis as an Undesirable Side Action.—This occurs with *Digitalis*, *Squill*, *Apocynum*, the *Salicylates*, *Senega* and a large number of other drugs. The action may be local or central, often both.

Therapeutic Use of Emetics.—Emetics are employed especially for the following purposes:

In Acute Poisoning.—The need for evacuation of the stomach, and the relative advantages of gastric lavage, has been discussed under the General Treatment of Poisoning (see Index). It must be remembered that *emetics are ineffective in profound narcosis* (by chloral or chloroform, Harnack, 1874; by morphine, bromide, etc.).

In Acute Indigestion.—Here also lavage would deserve the preference. Apomorphine is often very effective in exposing **malingerers**.

To remove solid bodies from esophagus, pharynx, or upper air-passages. However, according to de la Paz and Garcia, 1916, emesis does not dislodge solid bodies from the trachea or bronchi, but may drive them deeper. Plugs of mucus, however, may be displaced by increased secretion of mucus. Emesis may cut short an attack of **asthma** (Hoover and Taylor, 1915). It may also arrest paroxysms of *tachycardia*.

To cause **compression of the liver**, for the removal of bile and small gall-stones from the gall-bladder and ducts: The usefulness of this measure is doubtful; since the intestines are also compressed, the added vis a tergo can not be very effectual, and on the other hand it might rupture a distended gall-bladder.

Contraindications to Emetics.—These are mainly due to increase of pressure and to debility, and are as follows:

1. Severe *heart-defects*, or *aneurism* of the aorta, since the sudden and violent increase of intrathoracic and intraabdominal pressure may result in the rupture of these organs.
2. *Atheroma*. The sudden changes in blood pressure are apt to burst a vessel and produce apoplexy.
3. Similarly, they may lead to hemorrhages in *phthisis*.
4. Abortion may result, in *advanced pregnancy*.
5. Tendency to *hernia*.
6. In all *debilitated conditions* there is danger of collapse.
7. *Caustic poisoning*.

THE PHARMACOLOGY OF TEMPERATURE REGULATION

General Statement.—In warm-blooded animals, any departure from the normal temperature disturbs a variety of functions more or less profoundly. These disturbances tend automatically to restore the normal temperature. Heat production and heat dissipation both have a share in this regulation, and may be brought into play either directly, or through reflexes. The automatic compensation or regulation is very perfect under ordinary conditions and with normal animals. It may become inadequate if any of the factors entering into it are powerfully

altered, whether this alteration be central or peripheral. The temperature may thus rise or fall. The changes usually involve several factors, at least secondarily. These vary with conditions, which are often difficult to analyze. Many of our data are therefore incomplete, confusing and often apparently contradictory.

Thermoregulating Centers.—The constancy of the temperature of warm-blooded animals is obtained through nervous mechanisms; certain portions of the midbrain, the corpora striata and the caudal nuclei being especially important, so that they have been designated as "temperature centers." Destruction of this region interferes markedly with temperature regulation; puncture or irritation produces rise of temperature; the direct application of heat or cold causes the same reactions as fever or chilling. On the other hand, it must not be overlooked that other factors also enter into heat-regulation, and that these "heat-centers" are perhaps only an indispensable link in the mechanism or temperature control. In fever, the heat regulation is adjusted to maintain abnormal temperatures, so that it appears as if the "pitch" of the centers could be altered by pathological conditions, just as the respiratory center may be narcotized to maintain a higher level of carbon dioxide; and the effects of pyretics and antipyretics have been attributed to lowered threshold and narcosis of the temperature centers. The actual phenomena, however, are more important than the hypotheses.

Evidence for Thermoregulating Centers.—High section of the spinal cord destroys heat regulation completely. Ablation of the cerebral hemispheres has little effect. Traumatic or electric irritation of various parts of the midbrain (particularly the corpus striatum, optic thalamus and the ponto-bulbar junction) produces a rise of temperature (Hale White 1890).

Direct Application to Heat Centers.—Heat regulation is markedly affected by the direct application of heat, cold or drugs to the region of the caudate nucleus. The temperature is thus *raised* by cold, corrosive poisons, caffeine or "tetra;" it is *lowered* by heat, chloral, antipyrin or quinine applied to this region (Barbour and Wing, 1913; Cloetta and Waser, 1914; Hashimoto, 1915, Prince and Hahn, 1918). Indeed, the drugs are more effective in this way than intravenously.

Local heat to the corpus striatum of rabbits diminishes the oxidative metabolism and the respiratory volume; local cooling of this region produces the opposite effects, also shivering and fall of body temperature. The oxidative changes are contributory causes, rather than effects of the change of body temperature (Barbour and Prince, 1914).

Heat Centers of Rabbit.—Isenschmidt and Schnitzler, 1914, find the tuber cinereum the most important. The efferent fibers lie in the caudal portion of the midbrain, widely scattered over the ventral and median parts of the cross-section.

The tuber cinereum is not the only center concerned in temperature regulation; but this fails if this portion is destroyed, whilst the preservation of a part of the fibers suffices for the function.

The fever produced by cooling of the corpora striata is accompanied by vasoconstriction in the hind limb, chiefly of the skin vessels. This would diminish heat loss and thus contribute to the fever. Heating of the center produces the opposite effect (Prince and Hahn, 1918).

Direct Heating and Cooling of Center on Response to Drugs.—This has been studied by Hashimoto, 1915. He found that it has no influence on the febrile reaction to tetra, epinephrine or large doses of cocaine (sympathetic stimulants); but that it modifies toxin, salt and anaphylactic fever.

The antipyretic action of antipyrine and salicylate is markedly increased by heat, removed by cold. After quinine heat is effective, cold not. Morphine removed the response to both heat and cold.

The Evidence for the "Temperature Centers" is Not Absolutely Conclusive.—Their existence has been questioned by many investigators. The literature is reviewed by L. M. Moore, 1918. She showed that the puncture and similar fevers are rather the

results of general operative procedures; and that rabbits maintain a normal temperature after the caudate nuclei have been destroyed.

F. Sachs and Green state that faradic stimulation of the caudate nucleus does not produce any temperature changes, in animals or human.

Literature of Heat-Regulation.—Comprehensive bibliographies are found in the reviews of Barbour, 1920; O. Loewi, *Ergeb. Physiol.*, 1904; W. G. MacCallum, *Harvey Lect.*, 1908; and L. Krehl, *Pathologische Physiologie*, 1907.

The Share of Heat Production and Dissipation in Temperature-Regulation.—Heat-production is largely incidental to the ordinary activities of the animal. Voluntary work or involuntary shivering are utilized in the regulation of temperature; but the regulation by changes in heat-dissipation is more rapid and generally less disturbing, and is therefore principally utilized. Heat is lost mainly from the skin and respiratory tract, by radiation and conduction, and by the evaporation from the skin and from the pulmonary surface.

The relative importance of these channels of heat loss differs in different animals and in the same individuals according to circumstances. In man, the skin is the chief means of regulating the heat loss.

Methods of Studying the Mechanism of Heat Regulation.—Calorimetric measurements give the most comprehensive information of the relation of heat loss and heat production. The calorimeter gives directly the quantity of *heat lost*; and from this, and the changes in internal temperature of the animal, the *heat production* can be readily calculated. The *share of the nitrogen and carbon metabolism* in the heat production may be deduced from the nitrogen and carbon dioxide excretion, and from the consumption of oxygen. The changes of the cutaneous vessels and their share in the heat loss may be deduced from direct inspection of the skin, from comparison of the dermal and internal temperature, and from plethysmographic observation. The means for localizing the effects centrally or peripherally will be discussed as occasion arises.

Heat Production.—Heat is evolved in the destructive metabolism of the tissues, particularly the muscles and glands, and this furnishes the “chemical factor” in heat regulation. The production of heat is thus a part of ordinary metabolism. It may be *increased* by greater activity of the organs; especially by muscular work, or even by increased muscular “tone.” The febrile increase of heat-production is due partly to shivering, partly to increased activity of the glands, partly to glycogen mobilization by the liver.

Conversely, the production of heat may be *diminished* by reducing metabolism; by quieting the muscular movements with morphine; by lowering their tone with ether; or paralyzing them with curare; by starvation or by depriving an animal of its glycogen; by reducing nitrogen-metabolism with quinine; by reducing the circulation by vasomotor or cardiac depression (collapse), etc.

The *importance of the chemic regulation* may be judged by the fact that animals become practically poikothermal when they are paralyzed by curare (Pflueger, 1878) or by high section of the cord; that glycogen free animals are not rendered febrile by “heat puncture,” etc.

The “*Specific*” heat production (as distinguished from that incidental to physiological activity) is doubtless under the control of the central nervous system; the muscular tone, for instance depends on the spinal cord. The special relation of the corpora quadrigemina to heat production is seen in “heat puncture.”

Heat Dissipation.—The heat-loss is controlled by three factors:

(1) *Blood-flow* to the surfaces, acting partly by favoring radiation, partly by increasing perspiration and therefore evaporation.

(2) *Air-currents*, especially rapid, shallow breathing, which favors evaporation. This is utilized especially by animals, whose fur interferes with evaporation from the skin.

(3) *The water-affinity of the blood* and eventually of the tissues.

All three mechanisms appear to require the cooperation of the supramedullary (mid-brain) centers for their effective adjustment.

The Role of Evaporation.—Water is vaporized from the lungs, by the evaporation of the sweat, and by direct evaporation from the cutaneous epithelium (Keeton, 1924). The volatilization of 1 c.c. of water abstracts 0.6 calories from the body. In man at rest, evaporation accounts for only the smaller part (one-fourth) of the heat-loss; but it is the most rapid method of heat-regulation and plays the dominant share whenever *extra* heat loss is required; *i.e.*, in compensation against excessive heat production, or against external heat. It is of especial importance in the production and relief of fever.

The Vascularity of the Skin.—This is especially important in man. It plays a conspicuous part in the protection against external heat or cold; against incidental overproduction of heat in muscular work; in the rise and decline of fever, the “chill” and the “crisis;” and in the action of most antipyretic drugs. The vascular reactions may be evoked by direct action on the vessels, by reflexes from the temperature sensations of the skin, and by temperature or other changes in the thermoregulating centers. The sensations that arise in the skin itself often seem the dominant element in evoking and intensifying the regulating mechanisms. The sensation of cold even when it originates in only a limited area of the skin produces general constriction of the cutaneous vessels, as well as shivering. The ischemia of the skin intensifies the sensation of cold and thus causes further constriction. A sensation of heat produces hyperemia of the skin (and diminished muscular tone). The hyperemia feels warm and so produces more hyperemia. The thermoregulating centers, however, appear to be necessary to accelerate or to arrest the reaction at the proper level.

Diaphoresis.—This tends to go parallel to the vascularity of the skin; but it is also influenced by the central innervation of the sweat glands (and by autonomic poisons); and by the water-affinity of the blood and tissues.

The Blood-concentration as a Factor in Temperature Regulation.—Changes of the water-content of the blood would affect heat loss in several directions. Concentration of the blood, for instance, would decrease its volume and increase its viscosity; and thereby diminish the blood flow. It would also increase the affinity of the colloids for the water, and thus decrease the rate of secretion, of perspiration and of evaporation.

The importance of this factor has been emphasized especially by Barbour, who found a marked parallelism between the body temperature and the concentration of the blood (solids or hemoglobin). *i.e.*, the concentration of the blood rises and its water-content diminishes, when the temperature is raised by infective fever, etc. (Barbour and Howard, 1920). The concentration is restored *i.e.*, lowered by antipyretics (salicylates, quinine, antipyrine), which, in the absence of fever, have little effect on either the temperature or the blood concentration (Barbour and Herrmann,

1921). Dilution of the blood by the injection of saline (Barbour and Freedman, 1920) or by the administration of glucose (Barbour and Howard, 1920) also lowers febrile temperature, but does not affect normal temperature. Phlebotomy leads to dilution of the blood, and this may be an effective factor in the old treatment of fevers by bleeding. When it is attempted to change the body temperature by external heat or cold, the animals protect themselves against the heat by dilution; against the cold by concentration of the blood (Barbour, 1924). In this concentration through cold, a considerable part of the water goes into the subcutaneous tissue, and thus adds to the thickness of this heat-insulating layer (Barbour and Hamilton, 1925).

The Changes of Blood-concentration against External Temperature Require the Thermal Centers.—For it does not occur if the animals have been rendered poikilothermal by operations on their central nervous system (Barbour and Tolstoi, 1924). The regulation also fails if the external temperature exceeds a certain degree (for dogs, 42°C. in dry air; 33° in moist air). These extreme temperatures produce fever, and therefore concentration of the blood and dehydration of the tissues (Lozinsky, 1924).

Cause of the Blood-concentration in Fever.—This is not known; but it is reasonable to suppose that toxins alter the colloidal condition and therefore the permeability of cell-membranes and presumably of the protoplasm. This may easily lead to greater imbibition, and hence to concentration of the blood, etc.

Mechanism of the Antipyretics and Role of the Sugar Mobilization.—The antipyretics might be conceived to act:

(a) By restoring the colloidal condition and permeability; this would restore the dilution of the blood; bring more blood to the surface; and release the vasodilator reaction.

(b) The dilution of the blood-volume by antipyretics is accompanied by a considerable increase of blood sugar. This suggests that their mechanism may consist in converting glycogen into sugar and that this sugar then causes dilution of the blood. It is possible, however, that the sugar-increase is a secondary phenomenon; *i.e.* a mechanism for restoring the osmotic balance of the rapidly diluted blood.

REACTIONS WHICH RAISE THE TEMPERATURE (PYRETICS)

Increase of heat production or diminution of heat loss would tend to raise the temperature; but ordinarily, the tendency is offset by compensatory reactions. A significant rise of temperature, *i.e.*, fever, will occur only if the change exceeds the capacity of compensation, either because it is extraordinarily great or because it involves more than one factor. This break in compensation may be caused by a large number of agencies, acting through different mechanisms; only a few of these need to be considered here.

Normal Temperature Variations.—The daily normal variations in man range from 36.2°C. (97.2°F.) at 4 A.M. to 37.5°C. (99.4°F.) at 6 P.M. The temperature is increased by muscular work; for instance by an hour's work, in a normal individual, from 37 to 38.4°C. (from 98.6 to 101°F.). In ill health, the diurnal and work variations are greater.

Heat Puncture.—The essential element of "puncture fever" seems to be increased heat production, by increased carbon metabolism, especially of hepatic glycogen. The compensatory heat loss is not adequate; but it is not known whether this disturbance is direct or indirect.

I. Ott; Richet; and Aronsohn and Sachs, 1884 to 1885, nearly simultaneously discovered that a stab into the corpora striata of rabbits causes a rise of temperature, starting in a few hours, reaching a considerable height, and lasting for some days (Technic in Aronsohn and Sachs). The effect can then be repeated by a fresh puncture but

fails if the destruction is extensive. It can also be evoked by electric stimulation of this region, so that it consists evidently in the stimulation of a function concerned in heat regulation.

Relation of Heat Production and Dissipation.—Calorimetric experiments show that the rise is due to increased heat production (Richet, 1895), with partial compensation by increased heat loss. During the ascent, the heat formation and loss are both increased, but the loss lags behind. When the high level is reached, the heat formation lessens somewhat, and the dissipation increases, so that the temperature runs constant. In the descent, both decrease, but especially the heat formation (Schultze, 1899).

Mechanism of the Increased Heat Production.—This is due to increased carbon metabolism (increased CO_2 excretion). The nitrogen excretion may also be increased, but this is not essential, and is probably secondary to the hyperpyrexia.

The rise occurs in curarized animals (Hirsch and Mueller, 1903) so that the muscular metabolism is not essential, though it may play a part. Glycogen-free animals do not show a rise (Rolly, 1903). The liver temperature is high. These facts indicate that heat puncture acts mainly by increasing the hepatic metabolism. Walbaum, 1913, however, believes that the main factor is central stimulation of the cutaneous vessels.

Regulation.—The uniform course of the temperature shows that the disturbed functions have struck a balance—in other words, that there is some “regulation.” When the temperature is lowered artificially, by external cold or by antipyretics, it soon recovers its former high level (Schultze).

The Ponto-bulbar “Center.”—Tschedschichin, 1866, observed that the temperature rises when a section is made at the junction of the pons and medulla; the same result follows electric stimulation of this region (Heidenhain, 1870) and irritation of various other parts of the midbrain.

The Hyperpyrexia of Infection.—The essential element of infective fever appears to be a disturbance of the central tone of the cutaneous vessels and a concentration of the blood, making the heat loss absolutely or relatively inadequate. The heat production, and particularly the nitrogen metabolism, are generally increased; but this is not essential, and does not exceed the limits which are easily compensated in normal animals.

Heat Production.—In the ascent, this is generally increased; but it may be normal or even diminished. The same holds true for the plateau. In the descent, it is generally diminished, particularly if the fall occurs by lysis.

Increased heat production is therefore a characteristic, though not a constant feature of the rise; but this does not prove that it is the essential cause of the rise. The greatest increase is witnessed in the initial chill, and is largely due to the shivering movements. This cause disappears as the temperature rises; but now the increased activity of the heart and respiration furnish further causes for increased heat production. The higher temperature of the body must also accelerate oxidation. The toxins of the infections undoubtedly cause more or less cell destruction, and this material must be oxidized. A large share—possibly all—of the increased heat production is thus purely incidental; and whilst it doubtless facilitates the rise of temperature, it can not be considered as the essential element.

The site of the heat production is the same as in normal animals; for the temperature of the internal organs show the same relation as in health; the liver, for instance, being the warmest. From this it can be affirmed that the glands and muscles both participate in the increase, but not necessarily in the normal ratio—presumably this would differ according to circumstances.

Oxidation.—The energy for the increased heat production is furnished by oxidative changes; and with adequate food, the main source consists of non-nitrogenous material. The glycogen in particular tends to disappear. However, the nitrogen metabolism shows a characteristic relative increase from a number of causes.

Total Nitrogen Excretion.—Increased nitrogen metabolism is a nearly constant feature of infective fevers. The increase, however, does not run parallel to the fever; it may start before or after the rise; and it generally reaches its maximum after the fever has started to decline. It must therefore be an incidental, rather than an essential feature of the process.

Explanation of the Febrile Increase of Nitrogen Metabolism.—The increased nitrogen excretion denotes increased tissue destruction. Simple overheating also increases the nitrogen excretion, but relatively much less than in fever. A part may be accounted for by the partial inanition, which is so commonly enforced in fever: Indeed, the nitrogen loss can be entirely prevented by an ample diet; but to do this requires more food than

in health. It may therefore be accepted that the nitrogen excretion in fever is always greater than that for the same diet in health. This leaves as the only explanation, direct toxic effects of the infective agents, leading to cell destruction.

Intermediate Nitrogen Metabolism.—Very little is known as to whether this takes the same course as in the normal. Presumably it is somewhat different; for the urea excretion is relatively low (though the absolute value may be high); whilst ammonia, uric acid, purine bases and creatinine are relatively high. The urine often contains creatine, albumen, acetone bodies, oxyacids, etc.

Protein-quotient of Serum.—The albumin-globulin ratio of the serum is not altered by the rate of nitrogen-metabolism; for it undergoes no change after thyroid administration, which accelerates metabolism; not after quinine or sodium cacodylate, which retard it; nor after antipyresis through antipyrine and coal tar antipyretics (Hanson and McQuarrie, 1917).

The Course of Heat Dissipation.—The heat loss is always deficient in infective fevers, absolutely or at least relatively; and this deficiency or failure of the heat loss to compensate the heat production, must be considered the essential factor in the high temperature. In man, these changes run parallel with the cutaneous circulation—a pale, dry, cold skin meaning a diminished heat loss; and the converse (Kraus, 1894; Maragliano, 1888).

In the ascent, the heat loss is conspicuously decreased, leading to the characteristic “chill” (the vasoconstriction cooling the skin, whilst the internal temperature is high). During the continuance of the fever, the loss is generally increased, absolutely, so as partly to balance the increased heat production—but the increase of heat dissipation is small as compared with what would occur if a normal animal were producing the same amount of heat. One may therefore say that the dissipation remains relatively decreased. In the descent of temperature, the heat loss is increased relatively, as well as absolutely. This is the main element of the “fall by crisis.”

Altered Reaction of the Cutaneous Vessels.—The altered behavior of the cutaneous vessels, which seems to be the essential element of fever, finds expression in other directions. They are more easily affected by chemical and mechanical irritation (Baeumler, 1873); they constrict more strongly in response to reflexes (Heidenhain); they are apt to undergo alternate contraction and dilation, with little apparent cause; a slight degree of cooling produces chilliness, etc. These phenomena all indicate that the innervation of these vessels is disturbed.

Anhydremia.—Fever is often paralleled by diminished water content of the blood, as indicated by increased solids and hemoglobin. This would interfere with perspiration and thus with heat dissipation. Conversely, the injection of dextrose tends to be antipyretic by producing hydraemia (Barbour and Howard, 1920). This may be the basis of the old use of alkalies as “refrigerants.”

Heat Regulation in Fever.—The fact that heat regulation is disturbed—because one or more of its factors are disturbed—does not mean that all regulation is abolished. The disturbed functions will eventually find a new level, so that fevers generally run a more or less regular course—which implies an adjustment. Any adventitious change will alter this adjustment, generally in the same direction as in normal animals.

Fevers therefore show the normal daily variations, the rise during the day, and the fall during the night; although these variations may be smaller or larger than normal. Artificial cooling and heating and the administration of antipyretics provoke the same compensatory reactions as in health, though these are less effective. The febrile temperature can therefore be more easily lowered or raised, the changes are more extensive and more lasting; but when left to itself, the temperature will tend to assume its original febrile level. It might therefore be said that the temperature of fever is adjusted to a higher level (Liebermeister); which may mean nothing more, however, than this: that when the altered functions become constant, the resulting temperature must also become constant.

Heat Centers in Anaphylaxis.—In sensitized animals, the injection of the specific serum into the heat-puncture region produces fever. This does not occur in normal or immunized animals. The centers therefore are specifically sensitized in anaphylaxis (Hashimoto, 1915).

Comparison of Heat Puncture and Infective Fevers.—These two forms of fever have considerable resemblance. Both may show increased heat production with inadequate heat loss; but in puncture, the production seems to preponderate; in infections, the disturbance of heat loss. Both forms are central; both react similarly to antipyretic drugs,

Indirect Hyperpyretics.—Quite a large number of substances are apt to set up fever, particularly on subcutaneous injection in rabbits; and in infants, in which the temperature is more labile. To this class belong plain saline solution or plain water, albumose, egg-white and other proteins, irritants, etc. Many of these produce albumosuria (Krehl) and they probably act by causing tissue decomposition, with the formation of products (albumoses, etc.) which act similarly to infections.

Tetra-hydro-beta-naphthylamine.—This substance produces a very considerable rise of temperature, with increased heat production and diminished heat loss. It is not known which is the essential element. The hyperthermia differs from infective fever and heat puncture in that it is not reduced by the ordinary antipyretics, but only by profound narcosis.

Dosage and Efficiency.—The subcutaneous injection of 0.04 to 0.05 Gm. raises the temperature of rabbits several degrees, the rise starting in an hour and persisting over four hours; but it fails completely in some animals. Dogs react similarly. In man, non-toxic doses do not produce a rise.

The pyretic efficiency of various derivatives has been studied by Waser, 1919. The monomethylated base is more active than the ordinary "tetra."

The phenomena have been extensively studied by R. Stern, 1889 and 1890; Hale White, 1892, Sacharoff, 1909; A. Black, 1911; Feri, 1911, and others, but without clearing up the mechanism of its action. Cloetta and Waser, 1913, have investigated its derivatives to compare the structure and actions.

Other Actions.—Aside from the rise of temperature, it produces dyspnea and restlessness, sometimes convulsions. It revives rabbits from light chloral sleep (Airila, 1913). It wakens even decerebrated animals from chloral sleep—whilst cocaine and caffeine have this effect only on normal animals (Morita, 1915). It also has important sympathomimetic actions (Jonescu, 1909): Stimulation of the cervical sympathetic (mydriasis, exophthalmos); a general vasoconstriction involving both cutaneous and systemic vessels (rise of blood pressure), mainly of peripheral origin. It has a moderate peripheral dilator effect on bronchioles (Jackson, 1914). Elliott, 1914, describes the rapid production of gastric ulcers in rabbits from hypodermic injection.

Hyperglycemia occurs only with doses that render the animal restless (Corral, 1918).

Mechanism of Pyresis.—Calorimetric observations show increased heat production and diminished heat loss. The latter is perhaps explained by the vasoconstriction; and the increased heat production may possibly be ascribed entirely to the increased muscular movements. In accordance with this, the carbon dioxide excretion is greatly increased, whilst the nitrogen excretion is but little affected. The heat production is apparently the main element in the rise, for curarized or deeply morphinized or etherized animals do not respond to the drug (Mutsch and Pembrey, 1911). The action must be above the medulla, for no fever occurs if the carotids have been blocked by paraffin (Ott and Scott, 1908).

To this extent therefore the effects resemble those of heat puncture; but whilst the puncture fever is readily lowered by antipyretics, none of these, *i.e.*, quinine, antipyrine, etc. or small doses of morphine, have any marked effect on the terta-fever (Feri, 1911).

Cocaine Hyperthermia.—The effects of cocaine, so far as they have been analyzed, appear to agree with those of Tetra-hydro-naphthylamine.

The rise of temperature is due essentially to increased heat production, mainly from increased movements, for these go parallel (Richet and Langlois); and the rise can be prevented by curare or chloral, but not by the ordinary antipyretics (Mosso). The heat dissipation is slightly increased.

The cocaine fever does not occur after excision of the caudate nuclei, suggesting that its action is at least in part upon the same nervous centers which are concerned in "heat puncture."

Atropine Hyperthermia.—This may fairly be attributed to the muscular excitement, and to the suppression of sweat.

Caffeine Hyperthermia.—Large doses of caffeine produce a slight degree of fever (Binz, 1878; Pilcher, 1911). This could be explained by the increased muscular tone and by the dilation of the intestinal and consequent constriction of the superficial vessels.

Muscular Exercise.—All muscular movement increases the production of heat. In health, this is nearly compensated by increased heat loss (sweating, etc.), so that the temperature is but little increased.

Convulsants.—All convulsant poisons (santonin, picrotoxin, strychnine), produce characteristic changes in heat regulation. Small doses cause increased heat loss and a slightly smaller heat production. Larger doses cause increased metabolism, through muscular action, and hence increased heat production, which is accompanied by a further increase of heat loss. Paralytic doses diminish the heat production very greatly. The temperature is changed accordingly: Small doses tend to lower it; moderate convulsive doses would increase it; paralytic doses lower it greatly. The heat loss is particularly conspicuous in small and young animals, whilst larger animals tend to show a rise of temperature, with moderate doses (Harnack, 1901). In traumatic tetanus, thermic fever, etc., the temperature may rise greatly, usually when there is a general disturbance of heat regulation.

Excessive External Heat.—This diminishes the heat dissipation, and thereby tends to raise the temperature. This calls forth the compensatory reactions—sweating, cutaneous hyperemia, quickened respiration, etc., mainly through the direct action of the heated blood on the centers (e.g., Moorehouse, 1911). This sets in when the internal temperature departs but a fraction of a degree from the normal; about as readily in fevers as in health. The compensation is more or less effective for a time. When it breaks, there result the phenomena of "thermic fever."

REACTIONS WHICH LOWER THE TEMPERATURE (ANTIPYRETICS)

The temperature may be lowered by anything that lessens heat production or increases heat loss. Here again, as the temperature tends to fall below normal, compensatory reactions are set up, which ordinarily suffice to keep the temperature at the normal level. Indeed, it is highly difficult to depress the temperature materially below the normal, except by means which effect profound and extensive changes, such as deep narcosis, general vasomotor paralysis, or other collapse conditions.

On the other hand, it is relatively easy to lower an abnormally high temperature; for this coincides with the natural tendency to return to the normal physiological state—a tendency which must be always present, even in fever, although it is not effective unless supported by extraneous means.

Accordingly, the practical antipyretics become such only when the temperature is excessive. They have very little influence on normal temperature, because their effects would evoke more powerful compensations and partly also because the primary effects themselves are less powerful when they have to overcome a normal state, than when they are assisting an abnormal state to the normal.

Response of Slight Hyperpyrexia.—The increased response to antipyretics is not confined to high temperatures, but occurs also in infections when the temperature averages but little above normal, such as chronic tuberculosis, osteomyelitis and empyema (Barbour, 1919).

Action of Therapeutic Antipyretics.—The therapeutically available antipyretics act in several distinct ways: *The application of cold* (baths, etc.) results in the direct abstraction of heat; *antipyrine*, *acetanilid*, *phenacetin*, etc., increase heat dissipation by dilating the cutaneous vessels; and by restoring the water-content of the blood. Their action is mainly central. *Quinine* also restores the water-content, and it diminishes heat production by a direct (peripheral) depression of nitrogenous metabolism. *Aconite* and *veratrum* probably lessen heat production by slowing the circulation.

Relation to Heat Centers.—All the antipyretics depress temperature very effectively when applied directly to the caudate nuclei. When the central control is excluded,

quinine is still antipyretic, while antipyrine and salicyl tend to raise the temperature (Isenschmidt, 1913; Barbour and Denning, 1913).

External Cold.—Regulation against external temperature is effected, in the first place, by reflex constriction of all the cutaneous vessels. This in itself produces the sensation of chilliness. If this physical regulation is not effective, the chemical regulation sets in, the heat production being increased by involuntary shivering. Indeed, the carbon dioxide and heat production are increased before it comes to visible movements, by a mere increase of "tone."

Vigorous individuals, when the external cold is withdrawn in time, usually present a "reaction," with cutaneous hyperemia, etc.

Febrile patients compensate against cold by the same mechanisms as the normal; put the compensation is not as effective, so that abnormally high temperatures are reduced more readily.

Circulatory Collapse.—Any reduction of the circulation—whether cardiac or vasomotor—lowers heat production, and also tends to lower heat dissipation, since less blood circulates through the skin. The advanced grades of this action correspond to what will be described under anesthetic coma. The slighter grades are produced therapeutically by Aconite, Veratrum, Colchicum, Digitalis, etc., but practically they are not very effective unless the dosage exceeds the safe limit.

The collapse phenomena are particularly important, because febrile patients—especially when weakened by a prolonged infection, with their impaired circulation and poor heat production—are very subject to them. Here collapse may result spontaneously, or by the withdrawal of the stimulant effects of the high temperature, or by antipyretics in doses which would not be dangerous in normal individuals.

Temperature Fall and Blood Pressure Fall.—These run independently, in various types of collapse. In the slowly progressive collapse of dysentery toxin, the central mechanism protecting against overcooling is disturbed when that against overheating it still intact (Diehl, 1920).

THE TREATMENT OF FEVER

The treatment of fever has always been tinged by the views which have successively prevailed concerning its nature. When fever was considered mainly as a subjective condition, attention was directed principally to the sensations of heat and thirst, and there arose the class of *refrigerants*, including the dilute mineral acids. They are still useful, especially carbonated drinks, in conjunction with other treatment. On the other hand, alkalies and organic salts have been used to counteract the tendency to acidosis.

As physical observation came more into fashion, the quickened pulse of fever fixed the attention of the clinicians, and it was attempted to combat all the conditions of fever by slowing the pulse. The so-called class of *cardiac depressants* came into vogue. They include substances acting in various ways:

Aconite and *veratrum*, producing vagus stimulation and general fall of blood pressure. *Digitalis*, producing a slowed heart, but increased blood flow. *Nauseants*, as tartar emetic, acting secondarily through the nausea. *Potassium salts*, which have a direct action on the heart.

When the thermometer was introduced into medicine, and it was recognized that an elevation of temperature was the best index to febrile conditions, *antipyretic measures* came into prominence.

In regard to the application of antipyretic measures in fever, it is essential to bear in mind that they have *no direct effects on fever, except upon the temperature*.

Exceptions to this general statement are the actions of quinine in malaria, of salicylates in acute articular rheumatism, and the analgesic action of the coal-tar products.

For the rest, they strike neither at the cause of the fever nor at any symptoms other than those resulting from the hyperpyrexia. They make the type of the disease neither less severe nor shorter.

In malaria, e.g., antipyretics may prevent the development of a paroxysm of fever; but they do not attack the cause of the disease as does quinine; for their effect is not lasting, nor does their continued administration lead to a reduction in the size of the spleen.

They are a symptomatic and not a specific mode of treatment. And symptomatic treatment must always be carried on with great care, lest more harm than good should result. But where it is not possible to attack the cause, it is often advisable to remove objectionable symptoms. The question then is, *May a reduction of fever temperature be useful?* It must be borne in mind that hyperpyrexia is often a protective mechanism. This is shown by the onset of collapse in certain cases, if the stimulus of the high temperature is removed. Also, bacteriologic research has shown that with most bacteria the optimum temperature for development is confined within very narrow limits, which are exceeded by the temperature of fever. The *tendency* of fever may perhaps be said to be useful in all cases, but as a matter of fact it usually leads to more damage than good. The cells of the mammalian organism are not adjusted to work under the conditions of so high a temperature. It is detrimental to them as well as to the bacteria, and sometimes more so. Its effects consist in lassitude and enervation, in general discomfort, restlessness, irritability, and delirium. The respiration and heart are quickened. The metabolism, and especially the elimination of nitrogen, is greatly increased. This leads to emaciation, diminished alkalinity of blood, degeneration of important organs, etc. All these, joined perhaps to a deleterious action of the increased metabolic waste-products, produce a condition highly detrimental to the patient. These conditions, in so far as they have not already passed into permanent anatomic changes, are promptly and totally removed by restoring the normal temperature. Measures for this purpose are therefore indicated whenever these symptoms arising from hyperpyrexia become very pronounced, and unless there are special contraindications. They should not be used, for instance, if there is ground for suspecting a masked collapse. Nor are they of any use in high continued fevers.

Antipyretic measures of this kind are mainly cold baths and the coal tar antipyretics, and these have their respective drawbacks and advantages. The chief advantage of

Initial period. Fastigium. Amphibolic stage. Defervescence.
Fig. 19.—Antipyretics in typhoid fever. Dotted lines = cold baths; + = antipyretics (Strümpell).

cold baths lies in the fact that there is no danger of a direct collapse action; but there is no need for this danger with antipyretics if their dose be properly adjusted. The latter save the patient the exertion, discomfort, and shock of a cold bath. As, in the case of baths, the temperature-regulating mechanism is not adjusted to normal, the patient experiences all the ordinary effects of an attempt to reduce the temperature below normal: chills, cyanosis, etc.; and the metabolism is increased rather than diminished. The action of the chemic antipyretics is also more pronounced and lasting (Fig. 19) and resembles more closely that of natural defervescences; and their analgesic action is of marked value in influencing the subjective condition of the patient. In regard to this *narcotic action*, antipyrine and acetanilid are about on a level; they are surpassed by phenacetin. This action is especially useful when the fever is associated with delirium.

The objections to cold baths are very greatly lessened if *tepid baths* are used. These are not so much antipyretic as stimulant, improving the blood pressure, digestion, and sleep. They increase the nitrogen excretion. It has been shown that cold baths cause a considerable rise of blood pressure in acute fever, whereas camphor, caffeine, strophanthus, ether, or alcohol are generally ineffectual in this condition. As to the chemical antipyretics, the theory has been advanced that they interfere with the natural protective bodies of the serum. It has been shown, however, that this is not the case, at least as far as the agglutinin of typhoid serum is concerned. In conclusion, it is probable that *the best general treatment of fever consists in a combination of antipyretics and graduated baths.*

QUININE

General Statement.—Quinine, the principal alkaloid of cinchona bark, is a general protoplasmic poison. It is toxic to all cells, and even to unorganized ferments; but it has a specially high toxicity for ameboid cells, and is relatively non-toxic for higher organisms. It exerts a very selective action on the malarial parasites, and is therefore a specific against malarial diseases, provided sufficiently large doses are administered. It is also a fairly effective antipyretic in other fevers, reducing heat production by diminishing nitrogen metabolism. It is useful as an analgesic in colds; and in the form of quinine-urea hydrochloride as a local anesthetic. Through its bitter qualities, it acts as a stomachic tonic. It stimulates the uterus. Full doses produce "cinchonism," characterized especially by auditory and visual disturbances, which may assume grave proportions with excessive doses; but very large quantities have been consumed without serious poisoning.

Cinchona and Its Constituents.—The bark of the cinchona tree (Peruvian or Jesuits' bark) contains a number of alkaloids (cinchonine, cinchonidine, etc.) resembling quinine, but endowed with less of the desired activity, and with more of the undesired side effects (convulsant, etc., Albertoni, 1882). It also contains considerable tannin, which interferes with the systemic actions. (Cinchonine is much more depressant to the heart, and more toxic than cinchonidine.)

The trees yielding cinchona are indigenous to the mountainous district of the Andes in South America. The natives were probably acquainted with the medicinal value of this "tree of health," and the bark was brought to Europe by the early explorers. It received its name, cinchona, from the Countess Chinchon, who was one of the first Europeans to receive its benefits (1638).

At present practically all the barks of commerce are from cultivated trees, the original forests having been largely depleted. This cinchona cultivation is carried on in a number of subtropical mountainous countries possessing a rather moist climate—especially in India and Java.

The U. S. Pharmacopœia does not discriminate between the different species. Between thirty and thirty-six of these are recognized; but many are probably mere variations and hybrids.

The alkaloidal content of the different barks varies greatly. It has been considerably increased by cultivation, some samples yielding to 13 per cent. of quinine. The alkaloids are contained in all parts of the plant, in the parenchymal cells. The root bark contains the most, then comes the ordinary bark.

The *constituents* are: Certain acids (quinic, quinovic, etc.); *Tannin*, as *cinchotannic acid* (2 to 4 per cent.), which gives a green color with iron; *cinchona red*, a derivative of the preceding (both are glucosides); gum, wax, resin, etc.

A large number of alkaloids have been isolated; some of these arise in the course of the manipulations.

Most of the alkaloids are optically active, and occur also as isomers, as follows:

$C_{19}H_{22}N_2O$: Cinchonine, cinchonidine, homocinchonine, cinchonidine (cinchotoxine)

$C_{19}H_{22}N_2O_2$: Cupreine (from cuprea bark)

$C_{19}H_{24}H_2O$: Cinchonamine

$C_{19}H_{24}N_2O_2$: Quinamine, conquinamine

$C_{20}H_{24}N_2O_2$: Quinine, quinidine (= conquinine); quinicine (= quinotoxine)

$C_{20}H_{26}N_2O_2$: Hydroquinine; hydroquinidine (= hydroconquinine)

When the crystallizable alkaloids have been separated from cinchona extracts, evaporation of the mother liquor yields a brown extract, *Chinoidine* (Quinoidine), which contains amorphous alkaloids, mainly di-cinchonidine and di-quinidine.

Structure of the Cinchona Alkaloids.—Quinine is built up from two rings: (1) quinoline; and (2) a piperidine derivative named "loipon" or quinuclidine. These are linked together by a $CH.OH$ group. The quinoline ring bears a methoxyl group, and the loipon a vinyl group. The replacement of these by other alkyl groups forms the various derivatives; which may therefore be derived from the type:

(Quinoline) (Loipon)

 $\text{H.C}_9\text{H}_8\text{N.CHOH.C}_7\text{H}_{13}\text{N.H} = \text{type}$ $\text{CH}_3\text{O.C}_9\text{H}_8\text{N.CHOH.C}_7\text{H}_{13}\text{N.CH:CH}_2 = \text{quinine (methyl cupreine)}$ $\text{HO.C}_9\text{H}_8\text{N.CHOH.C}_7\text{H}_{13}\text{N.CH:CH}_2 = \text{cupreine}$ $\text{H.C}_9\text{H}_8\text{N.CHOH.C}_7\text{H}_{13}\text{N.CH:CH}_2 = \text{cinchonine}$ $\text{CH}_3\text{O.C}_9\text{H}_8\text{N.CHOH.C}_7\text{H}_{13}\text{N.CH}_2\text{.CH}_3 = \text{hydroquinine}$ $\text{HO.C}_9\text{H}_8\text{N.CHOH.C}_7\text{H}_{13}\text{N.CH}_2\text{.CH}_3 = \text{hydrocupreine}$ $\text{C}_2\text{H}_5\text{O.C}_9\text{H}_8\text{N.CHOH.C}_7\text{H}_{13}\text{N.CH}_2\text{:CH}_3 = \text{ethylhydro. cupreine (optochine).}$

Replacement of the methyl in quinine by other alkyl groups does not destroy the antimalarial action, and may even fortify it (Fraenkel, Arzneimittel Synthese). Omission of the alkyl group, as in cinchonine materially weakens the antimalarial efficiency and increases the convulsant action.

Quinicine and Cinchonine.—When quinine or cinchonine are heated with acids, the linking CHOH is hydrolyzed to CO , the two H being transferred to the adjacent C and N of the loipon, forming an imide group, and breaking the benzol ring. These compounds were discovered by Pasteur in 1853 and named by him quinicine and cinchonine.

Chemists, impressed by exaggerated estimates of the toxicity of quinicine, suggested that the toxic actions of quinine are due to the formation of quinicine by the gastric acidity; and that this formation in mixtures of quinine with organic acids would constitute a very dangerous incompatibility. These fears are quite unfounded: quinicine or quinotoxine is not much more toxic than quinine itself; and only insignificant traces of it can be formed at ordinary temperatures.

Miller and Rohde, 1895, proposed to change the names to quinotoxine and cinchotoxine. The change has been largely adopted, but seems confusing and unjustified. The toxicity is not very high; and practically the same name, *quinatoxine*, had previously been applied by Ostermayer, 1884, to a quite different substance, diquinoline dimethylsulphate. This produces curare actions (Hoppe-Seyler, 1880; Durdafi, 1889).

Formation of Quinicine and Cinchonine by Acids.—Pasteur prepared quinicine by heating quinine with dilute sulphuric acid at 120°C . At 100° , however, Biddle, 1912, found that dilute mineral acids (to $\frac{\text{N}}{\text{I}}$) convert only 2 to 3 per cent. of the cinchonine;

whilst weak organic acid (acetic etc., $\frac{\text{N}}{10,000}$) transform 95 per cent. The conversion is independent of the dilution or dissociation. Similar results were obtained independently by Rabe, 1910.

At 36 to 38°C ., however, the conversion proceeds very slowly, even with organic acids; so that at most 0.2 to 1 per cent. are converted in 48 hours. The concentration of cinchotoxine probably does not increase with longer heating; for there is a parallel transformation of cinchonine into an insoluble resin (Biddle, Ad Kaufmann).

Some conversion into cinchonine occurs also in sunlight, and more slowly in diffused light; but this also is converted into resin. The formation of cinchonine or quinicine may be judged by the dark discoloration (Biddle).

Quinine behaves in all these respects essentially like cinchonine. It will be seen that under no conditions of the body could significant quantities of quinicine be produced by the action of acid, as supposed by Kaufmann and by Biddle. These overlooked incidentally that quinine is also toxic when administered in other ways. Nor need any bad effects be feared from prescribing acid quinine mixtures. Discolored and precipitated solutions should naturally not be used therapeutically, since they would lack the desired actions of quinine.

Actions of Quinicine (Quinotoxine).—Hildebrandt claimed that this is not convulsive; that it has a digitoxin effect on the frog-heart, and that it raises the blood-pressure slightly. Biberfeld found the toxicity for mammals quite low (lethal dose, 15 mg. per Kg. by vein; 200 mg. hypodermically, corresponding to about $\frac{1}{2}$ ounce in man). In this large dose it produced convulsions. It did not have a digitoxin effect on the

exposed frog heart, but depressed it like quinine. It also depressed other smooth muscle, produced local anesthesia similar to quinine, but was not antipyretic.

Actions of Cinchonine (Cinchotoxine).—The toxicity of this is also low. Hildebrandt found the hypodermic lethal dose as 150 mg. per Kg. for mice (equivalent to 10 Gm. for a man. The same dose of cinchonine was not toxic. Hunt obtained about the same number for cinchotoxine (310 mg.) as for quinine (370 mg.). Rabbits seem considerably more susceptible (Biberfeld, M.F.D. hypodermic, 10 mg. per Kg., Fraenkel, F. D. hypodermic, 30 mg. per Kg.; Hildebrandt, cat, F.D. hypodermic, 20 mg. per Kg.). Death is preceded by violent convulsions.

Hildebrandt described a slight rise of blood-pressure. Biberfeld found depression of the circulation. Fraenkel observed on the exposed heart, first very strong contractions, then diastolic arrest.

Colloids and Surface Phenomena.—Quinine, like saponin and proteins, tends to concentrate at the surface of solutions, to such a degree that it forms rather rigid films (Ramsden; quoted from Bayliss). These interfere with the condensation of other substances at the surface, and therefore hinder catalytic phenomena, inorganic as well as organic. This results in decreased metabolism. The surface action is also shown by arrest of Brownian movement; and there is a tendency to precipitate colloidal solutions, such as the proteins. Quinine may therefore produce anaphylactoid phenomena. The quinine film presumably diminishes the permeability of the cell, and would thereby lead to a narcotic action, which is seen on local application to nerves and muscles. Quinine tends to arrest cell movements, for instance of the white blood cells, infusoria, cilia, spermatozoa, etc., presumably through the rigidity of its film. All these effects render quinine a "general protoplasmic poison" toxic to all kinds of cells; but its toxicity to vertebrates is relatively low; probably because it is largely bound and deposited in insoluble and harmless form.

Ferments.—Interference with ferment action may be seen in many directions. The most important are: the *oxydases of blood* and of protoplasm autolysis (Laqueur, 1906); slowed acidification of shed blood; lessening of the amount of hippuric acid formed when benzoic acid is circulated through the excised kidney. The various digestive ferments are hindered, but not to the same degree. It also lessens the glycogenetic function of the liver; *i.e.*, the postmortem transformation of the glycogen into sugar (Hoffmann, 1877).

In the therapeutic administration of quinine, the concentration does not rise sufficiently high to hinder the action of *oxydase* (Johannessohn, 1919). The effects on *invertase* and on *paramecia* have been studied by Rona and Bloch, 1920.

Hemoglobin.—This shows a characteristic change with strong quinine solutions (Marx, 1906); no methemoglobin is formed (Lewin, 1909).

Action on Leucocytes.—A solution of 0.5 to 1 in 1000 is sufficient to inhibit the movements of *leucocytes* on the warmed slide, and a somewhat larger dose causes their disintegration. Phagocytosis is hindered by 0.001 per cent. (Hamburger and Hekma, 1908), but stimulated by very low concentrations (Manwaring and Ruh, 1907).

The depressant action is also observed in *intact frogs*. When the mesentery of this animal is exposed, leucocytes in active motion are seen inside and outside of the vessel. If quinine is now applied, the movement of the cells outside of the blood will be arrested, whilst those in the blood stream still emigrate. The result is an accumulation of cells about the vessel wall. If the quinine is injected into the vessel, the reverse takes place. The movement of the cells in the blood is arrested, preventing emigration, whilst those outside do not come into contact with the poison, continue to move away, and leave a clear zone about the vessel (Binz, 1867; Ikeda, 1916). This action does not occur in mammals, since the necessary dose would kill the animal.

In *man and mammals*, it causes at first an increase of the lymphocytes, these being pressed into the circulation by the muscular contraction of the spleen and lymph glands. This is followed after an hour by a decrease, and this is again succeeded by rather marked leucocytosis. Continuous administration leads to leucopenia followed by leucocytosis (G. B. Roth, 1912; Johannessohn, 1919). The *opsonic index* is slightly increased in man by doses of 15 gr. (T. B. Wilson, 1907).

Antiseptic Action.—Bacteria and yeasts are also killed by quinine, but require a higher concentration (2 to 8:1000) than do the protozoa. The efficiency is not materially hindered by serum or pus (K. Taylor, 1915).

McDonald, 1915, considers its germicidal efficiency about half that of phenol; whilst as an antiseptic it approaches mercuric chloride. He recommends 1:2000 for bladder irrigation, especially as prophylactic in cystoscopy. This concentration does not cause noticeable irritation.

Concentrations Used for Antiseptic Irrigations.—The following are usually employed: Cystitis, 0.05 to 0.5 per cent.; conjunctivitis, dysentery, 0.5 per cent.; gonorrhea, to 5 per cent.; hay fever, spray, 1 to 2 per cent. (hydrochloride).

Wound Infection by Gas-bacillus.—K. Taylor, 1915, recommends dressing with 0.1 per cent. of the acid hydrochloride.

Local Actions.—Quinine produces some local irritation and anesthesia.

When given hypodermically it occasions severe pain, and may lead to *abscess formation*. When given by the stomach, large doses cause *gastralgia*, *nausea*, vomiting, and diarrhea. It also retards the *absorption* of salts, and probably of food. Its excretion through the kidneys may give rise, with large doses, to *albuminuria* and *hemoglobinuria*. The hemoglobinuria of severe malaria (black-water fever) may be partly due to increased sensitiveness to quinine.

Ulcers.—The sulphate has been used as antiseptic, styptic and stimulant dusting powder on ulcers.

Quinine as Anesthetic.—Quinine and its derivatives, when brought in contact with sensory nerves, produce local anesthesia. This is used clinically in the form of the more soluble and less irritant double salts, especially urea hydrochloride. The anesthesia is more lasting than with other local anesthetics; it may persist for several days (Hertzler *et al.* 1909). However, the concentrations above $\frac{1}{4}$ per cent. sometimes produce considerable irritation, edema and fibrous indurations and above 1 per cent. there may be sloughing. Its employment has therefore greatly diminished (E. Mayer *et al.*, 1920); although some clinicians consider these fears as exaggerated (E. J. Brown, 1920).

Quinine-urea hydrochloride is injected hypodermically, generally as $\frac{1}{4}$ per cent., sometimes 1 to 3 per cent. Solutions of 10 to 20 per cent. may be used on mucous membranes. Quinine bisulphate, 2 per cent. has also been used in tonsil and throat operations.

Data on the *relative anesthetic efficiency* are given by Sollmann, 1917 and 1918. The anesthetic effect of cinchona alkaloids for the *cornea* was investigated, by Morgenroth and Ginsberg, 1912.

Double Quinine Salts.—The increased solubility of quinine hydrochloride (3 parts) by antipyrine (2 parts) was announced by Triulzi, 1892, and Santesson, 1897. Gaglio, 1898, and Gicmsa, 1908, advise the urethane compound as being less acid and less readily decomposed by boiling, than is the urea salt (Filippi, 1912). It is made with 1 Gm. of quinine hydrochloride, 0.5 Gm. urethane, and 2 c.c. of water.

Skeletal Muscle.—Quinine, quinidine, cinchonine and cinchonidine produce similar muscular depression with dilute solutions and toxic rigor with more concentrated solutions; see quinidine.

Circulation.—Quinine and the other cinchona alkaloids depress the excitability of the cardiac muscle. Further details are discussed under quinidine, which is used against auricular fibrillation. With normal individuals, moderate doses of quinine have little effect on the circulation. Toxic doses lower the blood pressure by cardiac depression and vasodilation through peripheral action.

Mammalian Circulation.—In mammals and man small doses cause first a *quickened pulse with rise of blood pressure* (Literature, de Arric, 1912; Biberfeld, 1916).

The cause of the former is still under dispute, but is perhaps central. The rise of pressure depends mainly upon a *vasoconstriction*, but the cause of this is also still undetermined. It may possibly be due to a direct stimulation of the unstriated muscles of the blood vessels.

Larger doses (in man, from 1 Gm. upward) cause a fall of blood pressure and slowing and weakening of the heart from the outset.

The fall is due in part to *vasodilation*. The slowing and weakening of the heart are analogous to those observed in the frog. It is seen in the *excised organ* (Langendorff method). In this it often causes irregularity, but may regulate the heart if it is already irregular.

The *cardio-inhibitory center* is stimulated when quinine is perfused through the medulla of turtles (Bush, 1920).

Perfused mammalian vessels are dilated by quinine, whilst those of the frog are constricted. Apocodeine and yohimbine act similarly (Gunn, 1909).

Quinine antagonizes the constrictor effect of veratrine, but not of barium (Kondo 1919).

The *brain-vessels* are dilated in rabbits and fish (Berezin, 1916)

Uterus.—Quinine stimulates the contractions and increases the tone. It is used clinically (0.5 to 1 Gm.) in labor, to intensify weak contractions. It may be employed at any stage, since it does not to progress uterine spasm, with this dosage.

Excised Uterus.—This is strongly stimulated (Kurdinowski; Kehrer, 1906), by concentrations as low as 1 : 100,000 (Lieb, 1914). On pregnant uterus, Acton, 1921, found 1 : 300,000 ineffective; the stimulation of the contractions of the longitudinal and circular muscles began with 1 : 150,000, under favorable conditions, and increased with the concentration. Tonic spasm occurred with 1 : 44,000, but this concentration would scarcely be attained clinically. Higher concentrations (1 : 5,000 to 10,000) may produce relaxation and paralysis (Biberfeld, 1916; Guggisberg, 1921).

Cinchonine and cinchonidine act similarly; quinidine produces only relaxation. All these effects are the stronger, the more active the uterine movements (Sanda, 1910 and 1912). The relative efficiency of the cinchona alkaloids has been studied by Hall, 1916.

Use in Obstetrics.—Therapeutic doses do not suffice to excite persisting activity in the quiescent gravid uterus, and are therefore not reliable for inducing premature labor; but if even weak contractions are present, they are intensified. The greater the activity and tone of the uterus, the more rapid the action of the quinine (Franz and Katz, 1921). It is usually perceptible within 40 minutes after oral administration, (Maurer, 1907) and is more persistent than with pituitary, and safer. The oral dosage is 0.25 to 0.5 Gm. every hour, to a total of 1 Gm. Combined intravenous and intramuscular administration has also been used: 0.5 Gm. of the hydrochloride in 10 per cent. solution intravenously, and the same dose as 5 per cent. solution intramuscularly, at the same time (von Werner, 1919; Seggelke, 1921; Muschallik, 1921); but has no serious advantage. Local necrosis may occur with hypodermic, though not with intramuscular injection.

Other Smooth Muscle.—The spleen and intestines may be contracted. High concentrations (1 : 5,000 to 10,000) may relax the intestines (Biberfeld, 1916). Excised tracheal muscle is relaxed (Trendelenburg).

Egg-production.—Quinine, when fed to doves, reduces the size of the yolk and albumen of the eggs. This continues for some time after the administration is stopped, and is then followed by a compensatory increase (Riddle and Anderson, 1918; Behre *et al.*, 1919).

Effect of Digestion.—Small doses of quinine (0.05 Gm., 1 gr.), taken before meals, act as a stomachic and tonic; but they are probably inferior to other bitters. Larger doses diminish gastric secretion (Klocman, 1912), and interfere with the ferments and with absorption; even small doses when long continued lessen the utilization of blood. Toxic doses stimulate the vomiting center (Eggleston and Hatcher, 1915). Tinct. Cinchonæ Comp. (5 c.c., 15) adds the stomachic effect of aromatics and alcohol,

and the astringent action of tannin. It may be useful in chronic gastric catarrh.

Metabolism and Temperature Regulation.—Therapeutic doses of quinine have little or no effect on normal temperature. The same doses lower febrile temperature (although not quite as effectively as the antipyrene group). The mechanism of action consists primarily in diminished heat production, through limitation of the nitrogenous metabolism. This is especially marked in fever. This action of quinine is peripheral, *i.e.*, directly on the heat-producing foci.

The diminished heat production tends to set up secondary changes, particularly a limitation of the heat loss. These are adequate to preserve the normal temperature; but in fever they respond imperfectly, thus accounting for the fall of temperature (Literature, S. Weber, 1904). In the presence of fever, quinine also produces hyperglycemia and lowers the excessive concentration of the blood, and thus promotes heat-dissipation (Barbour and Herrmann, 1920).

In malaria, and possibly in some other infections, the superior efficiency of quinine is due to its specific destructive effect on the infectious agent.

Large doses of quinine (not necessarily toxic) lower even the normal temperature, sometimes with a preliminary rise. Toxic doses lower the temperature proportional to the collapse which they induce.

The relation of heat production and heat loss with normal and febrile temperature is well shown in the following quantitative data from the calorimetric experiments of Gottlieb, 1891:

Quinine, 0.1 Gm.	Fall of temperature	Level of temperature	Diminution of heat production	Diminution of heat loss
Normal rabbit.....	0.2-0.5°	38.6°	8-15%	10%
Puncture fever.....	1-1.4°	39.7-40°	28.9-40%	0%

Heat Production.—This is diminished in normal animals and much more in fever. The decrease concerns practically exclusively the nitrogen metabolism.

Nitrogen Metabolism.—This is diminished quite materially by small doses, even in normal animals; with large doses the reduction may reach 39 per cent. The reduction is often preceded by a primary rise. The decrease is markedly greater in fever. The ratio of urea to total nitrogen is not altered by moderate doses (Prior, 1884). One would be tempted to ascribe this diminution of nitrogen to the diminished utilization of food. Although this undoubtedly plays a part, the diminished excretion is out of all proportion, so that the nitrogen content of the body increases. Large doses of cinchonidine have a similar action.

Oxidation.—This marked influence upon nitrogen metabolism is in conspicuous contrast to its want of influence upon *oxidation*. The quantity of oxygen absorbed and CO₂ given off is practically unaffected by medicinal doses (up to 1.5 Gm.). There is a slight increase, but not more than can be accounted for by the excitement, chilliness, etc. The abnormally high gaseous metabolism of fever is reduced to normal by quinine; but this is probably the result of the antipyretic effect (Strassburg, 1874).

Nitrogen Metabolism as a Source of Energy.—The fact that quinine lessens heat production without lessening oxidation is interesting. We are accustomed to look upon the excretion of CO₂ as an index of chemic changes resulting in the liberation of energy and consequently of heat; and the excretion of CO₂ is not affected by quinine. But since the calorimeter shows conclusively that the production of heat is diminished by it, especially in fever, it follows that oxidation is *not* the only source of heat; that heat may also be liberated by other changes—by the splitting or hydration of nitrogenous molecules, in the course of which the nitrogen is converted into urea; and that these changes are those which are hindered by quinine. The reduction by quinine would naturally be greater when this nitrogenous metabolism is excessively high, as is the case in fever.

Heat Loss.—In normal animals, this is variable, generally slightly increased by cutaneous vasodilation. In fever, the heat loss generally undergoes very little change.

The essential share of diminished heat production is also demonstrated in several other ways: The quinine fall occurs even when the factor of heat loss is practically eliminated by high external temperature (Lewitsky, 1869); it occurs when variations in the cutaneous circulation are excluded by high section of the spinal cord (Naunyn and Quincke, 1869); indeed, it is here even more marked, because it can not be compensated by diminished heat loss.

The Action of Quinine is Peripheral.—This is shown by the observation of Binz, 1870, that quinine prevents the postmortal rise of temperature which ordinarily occurs when the spinal cord is divided and heat loss is prevented. This conclusion is also in harmony with the fact that quinine is a general protoplasmic poison, reducing the metabolism (for instance the hippuric acid synthesis) in perfused organs, lessening the oxidation in excised muscle (Senta, 1908), and retarding the action of ferments generally—which of course play an important rôle in the chemic changes by which heat is liberated.

Effect on Compensatory Mechanism.—The fact that the normal temperature is not lowered by quinine shows that it does not impair the normal compensation. This is effected by two means: increased carbon metabolism and diminished heat loss.

Efficiency in Heat Puncture.—It is often affirmed that quinine is relatively ineffective in heat puncture; but the table shows that it is fairly effective. Not much weight can be attached to slight quantitative differences.

Use in Fever.—The antipyretic action of quinine may be utilized in any fever. It has several theoretical advantages over the aniline antipyretics: It conserves energy by lessening metabolism, there is less risk of collapse, and its effects are more prolonged. On the other hand, the annoying cinchonism and occasional idiosyncrasies, eruptions, etc., limit its usefulness. It is employed mainly where the depressant action of the aniline derivatives is especially contraindicated, as in influenza; or where only small doses are required, as in colds. The full antipyretic dosage is from 0.3 to 1 Gm., 5 to 15 gr. Like other antipyretics, it is most efficient when the temperature has a natural tendency to fall. It takes about two hours to act, and should therefore be given about that time before an expected fall of temperature.

It has been suggested that its efficiency in fever is due to an antiseptic action in the blood. This is not probable since bacteria are rather resistant to it, and would scarcely be affected by it in the concentration in which it could exist in the blood.

Use in Pneumonia.—This is claimed to be especially benefited by quinine, but the natural course of this disease makes judgment very difficult.

S. S. Cohen, 1911 and 1913, recommends massive doses, 1 to 1.6 Gm., 15 to 25 gr., of quinine-urea-chloride, dissolved in 2 parts of hot water, and injected into the muscles; followed by further injections of 1 Gm. doses every third hour until the temperature remains below 100°F.—rarely beyond seventy-two hours. He claims that this does not produce cinchonism, gives great symptomatic relief (respiration, cough, pulse), and lowers the temperature at the ordinary time, but by lysis instead of crisis. The anatomic lung changes are not affected, indicating that the action is probably not on the local process but rather antipyretic and analgesic.

Bactericidal Action.—Although it is very improbable that quinine kills the pneumococci in the patient, the possibility that it restrains or weakens them is not entirely excluded; for these bacteria are especially susceptible to quinine and its derivatives (especially optochine). O. H. Brown, 1912, states that pneumococci cultures are killed in one-third to five hours by 0.1 per cent. of quinine (especially basic), whilst other organisms (strepto- and staphylococci) require much longer. Cohen, Kolmer and Heist, 1917, confirm the bactericidal action for pneumococci *in vitro*. It is much weaker than that of optochine, but is not hindered as much by serum.

It is also noteworthy that the concentration of quinine, after hypodermic injection becomes higher in the pneumonic lung than in the blood (Cahn-Bronner, 1919).

Disinfection of Pneumococcus Carriers.—Kolmer and Steinfeld, 1918, recommend gargling with quinine bisulphate or optochine hydrochloride, 1:10,000 of saturated watery thymol solution.

Use in Asiatic Cholera.—Quinine has been especially recommended in this disease, in which conditions would be favorable for a direct bactericidal action (Fullerton, 1896 Ussher, 1906). The dry sulphate, 0.6 Gm., 10 gr., is administered every hour for four to eight doses until bile reappears in the feces. Further confirmation is required.

Rabies.—V. H. Moon, 1913, reported apparently successful results with quinine on dogs. In 1915, he reports them only very slightly positive and practically negligible. All subsequent observers report negative results (Krumwiede and Mann, 1915; Fielder, 1914, 1916).

Use of Quinine in Colds, Headaches and Neuralgias.—Like other anti-pyretics, quinine has an analgesic effect in these conditions. It is used in doses of 0.05 to 0.2 Gm., 1 to 3 gr.

Central Actions.—The effects are not important, except with toxic doses. They consist in a rather *slow general paralysis* probably preceded by stimulation; the latter is somewhat difficult to make out in mammals.

In *frogs* there is first an increased reflex irritability. This is followed by loss of spontaneous movement, then paralysis of respiration, and lastly of the cord.

The depressing effects upon the hemispheres are much less marked in *mammals*, but a *diminished appreciation of pain* can be distinctly made out, and upon it rests the employment of quinine against neuralgic and rheumatic pains. Its addition to morphine or urethane does not increase their narcotic effect.

Mental efficiency tests, in man, showed marked impairment after 1 Gm. of quinine (Muensterberg, 1892).

Small doses increase the acuity of *hearing* (Macht et al., 1919).

Respiration.—Therapeutic doses have no definite effect. Toxic doses stimulate the respiratory center. If the vagi are intact, the respiration becomes fast, but shallow and therefore inefficient. If the vagi are divided, the respiratory volume is increased to such an extent as rapidly to lower the alkali-reserve of the blood to a fatal level (Sagata and Tatum, 1923).

Toxic Actions of Quinine.—With very high doses of quinine, the symptoms of cinchonism (see below) are accompanied by *difficulty of speech, confusion of ideas, somnolence*. Then *loss of consciousness*, alternating with *delirium, coma*, and at times *convulsions*.

It has been doubted whether the latter are really due to quinine or to the accidental presence of some of the convulsant cinchona alkaloids.

General paresis may appear, preceded by general depression and muscular weakness. The final symptoms are those of *collapse*, due to general paralysis of the central nervous system, and in part also of the heart. The *respiratory center* shows a short primary stimulation with following more marked paralysis. This latter is the usual *cause of death*. But since the medullary centers are not markedly affected until very late, quite large doses are often survived.

The *fatal dose* is usually given as 8 Gm., but 30 Gm., have been recovered from. It is doubtful how much of this really entered the circulation, since the sulphate is rather insoluble, so that a large amount may not have been absorbed.

Visceral Degenerations.—Cornwall, 1920, administered quinine to rabbits, hypodermically or intravenously, over long periods. He found damage to the epithelium of the suprarenals and kidneys, and increased disintegration of red corpuscles in the spleen. These observations require confirmation.

Purpura hemorrhagica is a not infrequent phenomena of intolerance after large doses (Samaja, 1918; Van der Horst, 1918).

Quinine on Hemolysis.—Quinine is not directly hemolytic but Rusznvak, 1920, claimed that it modifies the response to other hemolytic agents, for instance acidity. Confirmation is required.

Ultraviolet Radiation on Toxicity of Quinine and Quinidine.—Macht and Teagarden, 1923, claim that these alkaloids are more toxic to rats exposed to the sunlight or to the quartz lamp, than to those kept in the dark. Quinine was more toxic than quinidine. The radiation, without quinine, had only a slightly stimulant effect on the muscular activity.

Actions of Minor Cinchona Alkaloids.—These are qualitatively similar to quinine, but show important practical differences that make them therapeutically less desirable.

Cinchonine and Cinchonidine.—These produce clonic and tonic convulsions, located below the optic thalami. They are more depressant to the heart than is quinine, are more emetic, and less efficient against malaria (Albertoni, 1882).

Cinchonamine.—This is more toxic than quinine, (F. D. 75 mg. per Kg. of dogs or cats). It produces salivation, hallucinations, and epileptoid cerebral convulsions. It has little effect on blood pressure (Ellrain).

Cupreine.—This is said to be about half as toxic as quinine (Kobert).

Cinchonism.—Early symptoms of larger doses of quinine are headache, ringing in the ears, and disturbed vision, a complex of symptoms grouped together under the name of *cinchonism*. These are probably due to a selective action on the vessels of the eye and ear, which can also be demonstrated experimentally on animals. Toxic doses produce *photophobia*, *deafness*, and *blindness*, at first partial, later complete. These are probably partly central. Similar phenomena occur with salicylates and related drugs. Cinchonism is very subject to idiosyncrasy, being much more easily produced in some individuals. It is said that the minor symptoms may be somewhat diminished by bromides.

Anatomic Changes in Eye and Ear.—The retina is said to be anemic, whilst the internal ear is found congested, postmortem (Kirchner¹). Harnack, 1912, also ascribed the eye change to spasm of the retinal vessels with subsequent optic atrophy. Wittmann (1903) claimed that the aural congestion is not due to quinine, but to death, and points out that changes of blood pressure produce deafness. On the other hand, he demonstrated changes in the cells of the spiral ganglion, by the Nissl stain. He is therefore inclined to attribute the auditory effect to a specific toxicity of quinine to these cells. A corresponding origin is assigned by Altland, 1904, to the visual changes, the retinal cells being altered. This might be secondary to the ischemia.

Skin Eruptions and Endermic Test of Idiosyncrasy.—Scarlatinal or urticarial rashes are not very rare after therapeutic doses of quinine. In such susceptible individuals, local reactions are also produced by the application of quinine solutions (1:1000 to 1:10) to the scarified skin. Normal individuals do not react, so that this may be used as a harmless test of quinine idiosyncrasy (Boerner, 1197).

Two clinically hypersusceptible subjects, studied by O'Malley and Richey, 1919, gave positive skin tests with quinine, but not with cinchonine, cinchonidine, iodide, salicylic acid, caffeine, atropine or epinephrine; nor were these subjects clinically hypersusceptible to other cinchona alkaloids. The quinine idiosyncrasies were not congenital, and did not exist in blood-relatives. Edlavitch, 1919, also describes the endermic reaction.

Densitization.—This was proposed by Heran and St. Girons and partly confirmed in the cases of O'Malley and Richey, with parallel changes in the skin reaction. Further confirmation is desirable. They start with the oral administration of 5 mg. of quinine bisulphate plus 0.5 Gm. of sodium bicarbonate; after 1½ hours, they give 0.5 Gm. of bicarbonate with 2.1 Gm. of quinine. The double dosage is repeated daily, leaving the desensitizing dose at 5 mg. and increasing the second dose by 0.1 Gm. every day.

Quinine in Malaria.—Adequate dose of quinine kill the asexual plasmodia in the blood-plasma: the endo-globular and the sexual forms are but little affected.

Immediate Results.—Since the resistant endoglobular forms exist in the blood just before the paroxysm, and their sporulation gives rise to the characteristic chill and fever, and since quinine does not act well upon them, it will not be effectual against the oncoming paroxysm. But if it is given at this time it will be present in the blood when the spores are liberated, and as these are most susceptible to its action, it will kill them and thus prevent the development of the new cycle (providing that the dose has been sufficiently large). It should therefore be given several hours before the expected paroxysm so as to allow time for its absorption.

Recurrence.—A single large dose of quinine arrests the malarial attack; but usually a few of the protozoa are not reached and survive, and these tend to multiply after a time and produce re-infection (Bass, 1910¹). It is therefore necessary to continue the administration for some time, even though no symptoms remain. Reproduction is so rapid that it is said

that the survival of 4 per cent. of the parasites would suffice to reproduce the original number by the time of the next cycle. If, however, the multiplication is checked, either by the large dosage of quinine, or by the resistance developed by the patient, a proportion of the surviving weakened plasmodia propagate into the sexual forms which cannot multiply until they have passed through the mosquito. These are therefore harmless to the patient, but render him an infective carrier. Such carriers have acquired sufficient resistance to prevent rapid asexual multiplication, but not enough to destroy the parasites completely. Relapses may occur if the conditions become more favorable to multiplication.

Differences in Susceptibility of Plasmodium Species.—The plasmodium vivax of the benign tertian fever responds promptly to relatively small doses of quinine, so that the immediate results are excellent; but it is difficult to eradicate completely. The plasmodium falciparum of the malignant tertian fever is much more resistant to the quinine, partly at least because only a fourth of the parasites are in the active blood-stream, and three-fourths are in the stagnant capillaries, where they are not easily reached by the quinine; but if the effective dosage is attained and maintained, the cure is much more likely to be permanent. The plasmodium malariae of the quartan fever stands between the others in its susceptibility to quinine.

Action on Plasmodia.—These are especially susceptible to quinine. On a slide a 1:10,000 solution immediately arrests the movements of the parasites, and similar phenomena occur in the body. About three hours after the administration of quinine by the mouth, the endoglobular forms of tertian and quartan fever become immobile, granular, lose their nucleoli and their affinity for certain stains. Several hours later they may be seen deformed and fragmented (Lo Monaco and Panichi, 1899).

Mechanism of the Antimalarial Action.—After the administration of 2 Gm. of quinine, the concentration in the blood does not exceed 1:100,000; and it is doubtful whether it would be directly fatal to the parasites. Morgenroth, 1918, believed that the quinine is concentrated almost entirely in the corpuscles, and either kills the trophozoites in the interior, or prevents the merozoites from entering; but direct determination of the quinine by chemical methods indicates that the concentration in the corpuscles is about the same as in the plasma (Acton and King, 1921) or even smaller ($\frac{1}{2}$ to $\frac{1}{3}$, Ramsden, Lipkin and Whitley, 1918). It is conceivable that the resistant film that is presumably formed by the condensation of the quinine at the surface of the corpuscles constitutes a difficult barrier to the penetration of the merozoites, which would thus be prevented from completing the cycle, and which would then be killed by the plasma.

Bass and Johns, 1912, who have cultivated the plasmodia, find that they are readily destroyed by normal serum. They suggest that quinine acts by rendering the red blood corpuscles more permeable to the toxic constituents of the serum; but there is no other evidence for this view.

Actions of Hematin.—W. H. Brown, 1912; and Brown and Loevenhart, 1913, find that the injection of small doses of hematin into rabbits produces paroxysms similar to those of human malaria: A "cold stage" of cutaneous vasoconstriction with falling surface temperature and rise of blood pressure; succeeded by cutaneous vasodilation with hot skin. Larger doses cause splanchnic dilation (central) and central vagus stimulation with falling blood pressure. The respiration is depressed, ending in death. Butterfield and Benedict, 1914, failed to confirm these effects, and claim that large doses kill by intravascular precipitation of hematin.

Administration.—The effective dosage consist of 1 or better 2 Gm. given (fasting, if possible) two to three hours before the expected attack (which will in all probability occur); or 0.3 Gm. four to five times a day in the interval; 0.65 Gm. per day should be continued for at least two months after the last chill. Doses above two grams per day may produce renal injury and albuminuria. There is no material difference in efficiency between the different quinine salts, or between oral and intravenous

administration; except in the rapidity of action. With oral administration, solutions act more promptly than do the difficultly soluble sulphate or tannate in powder or especially given in pills.

The sulphate requires 720 parts of water for solution. The hydrochloride is more soluble (1:18) and the bisulphate (1:8.5) and the dihydrochloride (1:0.6) are very soluble.

It is not customary to prescribe the bisulphate directly, but to bring the sulphate into solution by the addition of a sufficient quantity of dilute sulphuric acid. *The quantity of acid should be rather in excess.* If it is only just sufficient, some sulphate will be precipitated on the tongue by the alkaline saliva, and give rise to a very persistent aftertaste. There will be very little of this if an excess of acid is used and the mouth rinsed afterward.

Intramuscular injections have been used (quinine dihydrochloride, 1 Gm. in 10 c.c.; or quinine-urea hydrochloride, 2 Gm. in 5 to 10 c.c.); but they are generally not absorbed materially more rapidly than the oral doses, and they cause considerable local irritation, especially if they are made too near to the sciatic nerve (Sicard, Rimbaud and Roger, 1917).

Intravenous Injections.—These act immediately, and may be needed in urgent cases of malignant malaria; but they should be avoided if time is not a vital element. Concentrations of 1:150 are dangerous (MacGilchrist); and even lower concentrations should be used with caution, for fear of direct cardiac effects. Immediate death has been reported by Thayer, 1911, and James, 1911 (cited by Eggleston, 1917). Under proper precautions, however, very strong solution (to 5 or 10 per cent.) may be injected (A. D. McLean, 1917). The hydrochloride is usually employed for the weaker and the dihydrochloride for the stronger solutions; but the quinine-urea hydrochloride should be preferable.

Prevention of Relapse.—For adults, Bass, 1920 advises two 5 grain (0.3 Gm.) tablets (of the sulphate) at night continued for at least 8 weeks after the last paroxysm. For children the proportionate dose may be given in syrup of yerba santa. This dosage disinfects 90 per cent. of the patients; complete disinfection can be assured by giving three daily 10 grain doses for the first three or four days, then the single daily 10 grain dose for 8 weeks.

Quinine as Antimalarial Prophylactic.—Opinions differ as to its efficiency; but it is now generally believed to protect at least a fair proportion of the exposed if adequate doses are used; at least 0.5 Gm. and better 0.65 Gm. per day; and proportional doses for children.

Efficiency.—This is high, although it does not equal mosquito-control. It inhibits, rather than kills, the organisms; for malaria may develop after the quinine is stopped, although the patients have not been exposed to further extraneous infection (Carter). This explains why quinine prophylaxis does not eradicate the disease from a region; for those taking prophylaxis may become carriers. Accordingly Orenstein, 1912, after subjecting a malarial community to systematic quinization by the Koch-Ollwig method, found the incidence of malaria practically unchanged.

Side Effects.—The cinchonism from 0.5 Gm. per day is usually not serious, and those who object to it at first may become accustomed in a week or so. The sulphate seems to be better tolerated than the more soluble forms. No injurious effects have been reported from extensive use of 6 grains daily for 2½ years (Carter). It does not favor hematuria, and does not render the plasmodia resistant to active quinine treatment, should this become necessary (Carter).

Prophylactic Administration.—The Italian method of daily administration is now generally preferred to the Koch method, which used somewhat larger doses with longer intervals. The Koch method required less quinine, but is less efficient and more uncomfortable (H. R. Carter, 1914).

Italian Method.—Mariani proposed 0.5 Gm. daily, in divided doses. Bass found that this sometimes failed, and proposed 0.65 Gm. of the sulphate (in tablets) every night. The tannate may be used for children.

Koch Method.—This consists in 1 Gm. of quinine on each of 2 successive days, with intervals of 7 to 9 days; or 0.5 Gm. twice a week (Carter).

Antimalarial Efficiency of Cinchona Alkaloids.—Mac Gilchrist states this to be in the order of: Hydroquinine > cinchonine, quinine, quinidine > ethylhydroxycupreine > cinchonidine > quinoidine; the first being the most, the last the least active. The same order holds for the different forms of the parasites. Confirmation would be desirable.

The efficiency of the cinchona alkaloids has also been compared by Giemsa and Werner, 1914. Waters, 1916, again recommended *quinoidine* as a cheap and fairly efficient quinine substitute.

Quinine is practically ineffective (Stephens et al., 1918).

Acton, 1920, found levorotatory quinine more active against malignant tertiary parasites; and dextro-quinine more efficient against benign tertiary plasmodia.

Gilchrist also found arsphenamine as effective as quinine; Fowler's solution was ineffective, as also mercuric chloride. Ehrlich advised the administration of methylene blue with the quinine.

Amebic Dysentery.—Quinine is used for rectal irrigation. Its administration by mouth (2 Gm. per day) is sometimes effective, but less certain than emetine (Brooks, 1914).

Administration of Small Doses.—Small doses of quinine sulphate or hydrochloride may be easily administered in the forms of pills or capsules; or in solution, the taste disguised by glycyrrhiza. (No acid must be prescribed with the latter!) The free alkaloid is almost tasteless, and the tanate quite so, because of their slight solubility. Their absorption may not suffice for large, but is probably adequate for small doses. They can be placed dry on the tongue and swallowed with a draught of water.

Quinine Esters.—The esters of quinine with various acids are insoluble and therefore tasteless. They pass the stomach unchanged, but are slowly saponified in the intestines; in this way exhibiting a very gradual and presumably weak action. They are more easily administered, and produce less side actions, but are not always devoid of cinchonism (Seifert, *Nebenwirk.*, 1915, pp. 115-119).

They are used in the same doses as quinine, in powder or suspended in liquids. To this type belong:

Aristochine (diquinine carbonic ester); and **euquinine** (quinine ethyl carbonic ester).

Absorption.—Quinine is absorbed mainly from the small intestine (MacGilchrist). The absorption is materially hindered by gastrointestinal irritation, vomiting, diarrhea, etc. (Porak, 1918).

Fate.—The greater part of the administered quinine is destroyed in the body.

The destruction involves usually 60 to 70 per cent. and sometimes to 90 per cent. of the quinine (Merkel, 1902; Biberfeld, 1916; Schmitz, 1907; Porak, 1918; Hartmann and Zila, 1918). Perfused liver also destroys quinine (Grosser, 1908).

Persistence in Blood and Organs.—After intravenous injection, the concentration in the blood sinks rapidly at first, then more slowly. With oral administration, the blood concentration remains practically level for 24 hours (Hartmann and Zila, 1918). With doses of 1 to 2 Gm. per day, the quinine concentration of the blood is maintained at 3 to 10 mg. per liter. Concentrations above 10 mg. are highly toxic.

The brain, liver and spleen generally contain more than the blood (Baur et al., 1918).

Excretion.—Quinine is excreted mainly by the urine, and somewhat by the feces, even after parenteral administration. Traces are also found in other sections.

With 1 to 2 Gm. per day, the concentration in the urine is about 600 mg. per Liter: *i.e.*, more than 60 times as much as in the blood.

Quinine is always present in the gastric and intestinal content after hypodermic injection, in man and in animals. Its appearance in the bile and saliva is irregular (Hartmann and Zila, 1918; Baur et al., 1918; Lacage and Valdigruie, 1919; Koldewijn, 1910).

Course of Excretion.—The urinary excretion begins within half an hour, and is practically completed in 24 hours (Nishi, 1909; Baldoni). Traces may continue for 3 days or longer (Lacage and Valdigruie, 1919). The feces do not contain it after 24 hours (Lacage and Valdigruie).

The maximum in the urine is reached in 4 to 10 hours, independent of the dose or method of administration. This would indicate that doses should be repeated every 3 or 4 hours. The excretion is delayed in severe nephritis and diminished in cardiac decompensation (Porak, 1918).

PREPARATIONS

The ordinary salts of quinine are white, odorless, and intensely bitter. They are *incompatible* with alkalies and other alkaloidal precipitants, and with salicylates, benzoates, tartrates. Solutions containing free organic acids deteriorate slowly. *Average dose of all quinine salts:* tonic, 0.1 Gm., 1½ gr.; antimalarial, 1 Gm., 15 gr. daily, U.S.P.; *ordinary dose*, B.P., 0.06 to 0.6 Gm., 1 to 10 gr. The solubilities are shown in the following table.

	One part dis- solves in water	In alcohol	Reaction of solutions
Quinina (Quin.), U.S.P.; $C_{20}H_{24}N_2O_2 \cdot 3H_2O$	1,560	0.8	Alk.
*Quin. Bisulph., U.S.P.; $Qu. \cdot H_2SO_4 \cdot 7H_2O$	9	23.0	Acid
Quin. Hydrobr., U.S.P.; $Qu. \cdot HBr \cdot H_2O$	40	0.9	Neutr.
*Quin. Hydrochl., U.S.P., B.P.; $Qu. \cdot HCl \cdot 3H_2O$	18	0.8	Neutr.
Quin. Dihydrochl., U.S.P.; Quin. Hydrochl. Acid., B.P.; $Qu. \cdot 2HCl$	0.6	12.0	Acid
*Quin. Sulph., U.S.P., B.P.; $Qu. \cdot 2H_2SO_4 \cdot 7$ or $8H_2O$	725	107	Neutr.

1 "Qu" stands for $C_{20}H_{24}N_2O_2$.

Quinina Tannas (Quin. Tan.), U.S.P.—A compound of quinine and of tannic acid of somewhat varying composition and containing about 33 per cent. of anhydrous quinine. Pale yellow, amorphous powder; tasteless, or having not more than a slightly bitter and astringent taste. Slightly sol. in water; somewhat more sol. in alc. *Dose*, 0.2 Gm., 3 gr., U.S.P.

**Quinina et Urea Hydrochloridum* (Quin. et Urea. Hydrochl.), U.S.P.; $Qu. \cdot HCl \cdot CO(NH_2)_2 \cdot HCl \cdot 5H_2O$.—Colorless prisms or white granular powder, bitter taste. Very sol. in water (1:0.9), freely sol. in alc. (1:2.4). Solutions are strongly acid. *Dose*, 1 Gm., 15 gr., once daily, hypodermic, U.S.P.

(*Ferr. et Quin. Cit.*—See Index.)

(*El. Ferr. Quin. et Strych. Phosph.*—See Index.)

Pil. Quin. Sulph., B.P.—82 per cent. *Dose*, 0.12 to 0.5 Gm., 2 to 8 gr., B.P.

Tr. Quin., B.P.—2 per cent. in Tr. of Orange. *Dose*, 2 to 4 c.c., ½ to 1 drachm, B.P.

Tr. Quin. Ammon., B.P.—2 per cent., in ammoniated alcohol. *Dose*, 2 to 4 c.c., ½ to 1 drachm, B.P.

Qin. Quin., B.P.—0.23 per cent. *Dose*, 16 to 30 c.c., ½ to 1 ounce, B.P.

Tinctura Antiperiodica, N.F. (Warburg's Tincture).—This is used in India for administering quinine against malaria. It contains 2 per cent. of quinine sulphate, 0.3 Gm. per tablespoon, with rhubarb, aloes, camphor, and aromatic drugs.

Quinina Ethylcarbonas, (Quin. Ethylcarb.), U.S.P.; Quinine Ethylcarbonate (Euquinine), $C_{20}H_{23}N_2O_2 \cdot CO \cdot OC_2H_5$.—Nearly tasteless and insoluble. *Dose*, as for Quinine.

Cinchonidina Sulphas (Cinchonid. Sulph.), U.S.P.; $(C_{18}H_{22}N_2O)_2 \cdot H_2SO_4 \cdot 3H_2O$.—White, glistening, silky needles or prisms; odorless and having a very bitter taste. Sol. in water (1:65) or alc. (1:90). *Dose*, 0.15 Gm., 2½ gr., U.S.P.

Cinchonia Sulphas (Cinchonin. Sulph.); $(C_{19}H_{22}N_2O)_2 \cdot H_2SO_4 \cdot 2H_2O$.—White, lustrous, prismatic crystals; odorless; very bitter taste. Sol. in water (1:60) or alc. (1:12.5). *Dose*, 0.15 Gm., 2½ gr.

Cinchona (Cinch.), U.S.P.; *Cinchonae Rubrae Cortex*, B.P.; Cinchona (Peruvian Bark).—The dried bark of Cinchona succirubra and its hybrids, known as Red Cinchona. The U.S.P. also includes the bark of other species, known as Yellow Cinchona or Calisaya Bark. It should yield not less than 5 per cent. of alkaloids, U.S.P., 5 to 6 per cent., B.P. *Dose*, 1 Gm., 15 gr., U.S.P.

Inf. Cinch. Acid., B.P.—5 per cent. of Cinchona, with 1.25 per cent. of Acid Sulph. Arom. *Dose*, 15 to 30 c.c., ½ to 1 ounce, B.P.

Fldext. Cinchon., U.S.P.; *Ext. Cinch. Liq.*, B.P.—4 to 5 per cent. of alkaloids. *Dose*, 1 c.c., 15 minims, U.S.P.; 0.3 to 1 c.c., 5 to 15 minims, B.P.

Tinctura Cinchonae (Tr. Cinch.), U.S.P., B.P.—20 per cent. of Cinchona, with 2½ alcohol. *Incompatible* with water, iron and alkaloidal precipitants. *Dose*, 4 c.c., 1 drachm, U.S.P.; 2 to 4 c.c., ½ to 1 drachm, B.P.

**Tr. Cinch. Co.*, U.S.P., B.P.—10 per cent. of Cinchona, with 2.5 per cent. of Serpentaria, together with Bitter Orange. The B.P. is colored with Cochineal; strongly alcoholic. *Dose*, 4 c.c., 1 drachm, U.S.P.; 2 to 4 c.c., ½ to 1 drachm, B.P.

Alstonia, B.P.—The dried bark of *Alstonia scholaris* and constricta. Contains alkaloids and is employed in India against malaria; also a bitter tonic, anthelminthic and against diarrhea.

Inf. Alston., B.P.—5 per cent. *Dose*, 15 to 30 c.c., ½ to 1 ounce, B.P.

Tr. Alston., B.P.—12.5 per cent. *Dose* 2 to 4 c.c., ½ to 1 drachm, B.P.

HYDROCUPREINE DERIVATIVES

General Statement.—The alkyl derivatives of hydrocupreine were found by Morgenroth to possess a high bactericidal efficiency, even in the presence of protein; and at the same time a relatively low toxicity to the tissue cells. They were therefore proposed as tissue-antiseptics, both for local and systemic application. The germicidal power varies specifically for different bacteria. Ethylhydrocupreine ("optochine") is especially toxic to pneumococci; whilst higher homologues, such as "eukupine" and "vuzine" are more efficient against pus organisms.

The practical application of these derivatives is in an experimental stage. Optochine, whilst effective against experimental pneumonia in mice, is not very successful clinically; and on the other hand, is liable to produce blindness.

Eukupine and vuzine were introduced by Morgenroth, 1917, as wound antiseptics. Enthusiastic reports were published as to the results especially in the German army. They were also employed in pleural empyema; but their use has not spread. Their pharmacologic actions agree in most respects with those of quinine. The literature is reviewed by Bylsma, 1920, and Bruhn, 1919.

Composition: Optochine is ethylhydro-cupreine: $C_2H_5O \cdot C_9H_6N \cdot CHOH \cdot C_7H_{13}N \cdot C_2H_5$. *Eukupine* in iso-amyl hydrocupreine (the alkyl replacing the first C_2H_5 in the quinoline); and vuzine is iso-octyl hydrocupreine.

ETHYL-HYDROXYCUPREINE (OPTOCHINE)

Action of Pneumonia.—This drug has a specific toxicity for pneumococci (Morgenroth and Halberstaedter). It is highly successful against experimental pneumonia in mice; but much less successful in man. Its application is further limited by the fact that efficient doses are liable to produce blindness.

Bactericidal Action on Pneumococci.—*In vitro*, the drug inhibits the growth of pneumococci with a concentration of 1:800,000 in serum; it kills them with 1:400,000 (Wright, 1912). The action is very slow with low concentrations, and increases in speed with the concentration.

Serum reduces the activity to $\frac{1}{5}$ or $\frac{1}{10}$ (Cohen, Kolmer and Heist, 1917).

Solutions in blood are even less active than those in serum; but the entire blood is more active than the serum separated from it, since the corpuscles take up a higher percentage of the drug (Morgenroth, 1918).

Specificity.—All strains of pneumococci, as also streptococci, are inhibited *in vitro* by concentrations of 1:100,000; whereas other streptococci, meningococci and gonococci require 1:10,000–5,000. However, transition races are occasionally found. Quinine requires much higher concentrations. Optochine also increases greatly (potentiates) the efficiency of anti-pneumococcus serum (Nachmann, 1915; H. F. Moore, 1915).

Phagocytif.—Optochine (and quinine) accelerate the phagocytosis of pneumococci (Cohen, *et al.*).

Experimental Pneumonia.—Morgenroth, 1911, found optochine more effective than quinine against trypanosomes and pneumococcus infections of mice. With these, optochine is effectively prophylactic in 90 per cent., and curative in 50 per cent. of the experimental infections (Morgenroth and Levy; Engwer, 1912). The serum of rabbits is bactericidal after hypodermic doses of 0.1 Gm. per kilogram, which are well tolerated. Larger doses are usually toxic. Oral administration is not as effective (Moore, 1915).

Human Pneumonia (Lobar).—The clinical efficiency is difficult to judge, but it is at best much less successful than in animals. Some clinicians report improvement when it is used in the first two or three days of the disease (Lapinski, 1915, A. Fraenkel, 1915); but the trend of literature is not encouraging (Moore and Chesney, 1917, 1918, Leuck, 1918).

Reasons for Failure in Human Pneumonia.—Really effective doses are too dangerous. Although it is possible to render the blood serum toxic to the pneumococci in a few hours, by fairly safe dosage (see under administration), the germicidal action is so slow (requiring 20 hours *in vitro*), as to permit new generations of bacteria to come into the blood from the lungs, etc. (R. Cole). Insufficient dosage induces "fastness" in the body and *in vitro*. It is also very doubtful whether the drug penetrates through the alveolar exudate (Moore and McChesney, 1918).

Further reviews of the clinical results are given by Cohen, Kolmer and Heist, 1917; Moore and Chesney, 1917, 1918.

Blindness.—This occurs all too frequently even with the ordinary therapeutic doses, such as 1.5 Gm. per day. Fraenkel, 1915, obtained some degree of amblyopia in 10 per cent. of his series. One case has been reported after 0.5 Gm. Whilst this is usually temporary, the administration of the drug involves serious responsibility.

Course of the Amblyopia.—The disturbance of vision generally starts abruptly and is usually severe, often progressing to complete amaurosis. The pupils are maximally dilated. If the drug is stopped, the vision usually improves, after a few days, but sometimes only after months; and even in the more favorable cases there remains more or less restriction of the visual field, central scotoma, and impaired color vision (literature, A. Adler, 1916).

Pathology.—Optochine produces the same changes as quinine, but with much smaller doses and greater frequency. The eye ground is ischemic, sometimes preceded by venous stasis. The optic disc becomes swollen and the retina edematous. There may be effusion into the lymph-sheath of the optic nerve, resulting in compression of the vessels and nerve fibers. Improvement of vision may begin whilst the ischemia still persists; on the other hand, the condition may progress, to retinal and optic nerve changes (literature, Adler, 1916, experimental, Hirschfelder, 1915).

Other Side Actions.—The susceptibility to these varies greatly in different individuals. Temporary cinchonism and vomiting are of frequent occurrence (Seifert, Nebenwink, 1915).

Administration.—Moore and Chesney find oral administration most satisfactory, and use the hydrochloride, preferably in capsules. The daily dose should be 0.024 Gm. per Kg. (1.5 Gm. per 60 Kg.), and this should be divided so that a fraction (*i.e.*, 0.15 Gm., is taken every $2\frac{1}{2}$ hours, to maintain a constant concentration in the blood (on the first day this routine is modified, starting with an initial dose of 0.45 Gm., and following this every 3 hours by 0.15 Gm.). There is a slight accumulation, and the drug should not be continued beyond 3 or 4 days. The vision should be carefully tested throughout.

Pneumococcus Meningitis.—Rosenow, 1920, used lumbar subdural injection of 20 c.c. of 1:500 on a patient, with recovery. He claims that this dosage is harmless, and may be repeated after 1 or 2 days; but this statement would require confirmation.

Other Infections.—Izar and Nicosia, 1914, use it in malaria because the cinchonism is shorter than with quinine. Levy, 1912, also claims a curative effect against streptococcus mucosus.

Hayfever.—Hacke, 1919, reports good results from swabbing with 1 per cent. optochine hydrochloride. Confirmation is required.

Ophthalmic Use.—Optochine hydrochloride is used locally as antiseptic, irritant and anesthetic, in conjunctivitis, and on ulcers, especially ulcus corneae serpens. A fresh 1 per cent. solution is applied, at first every 2 hours (Bedell, 1920). The first instillation is painful but this is followed by *local anesthesia*, lasting $\frac{1}{2}$ hour or longer (Morgenroth and Ginsberg, 1912 and 1913).

Weaker concentrations are ineffective; 1 per cent. does not cause permanent damage, but stronger solutions injure the cornea. Subconjunctival injections of $\frac{1}{2}$ to 1 per cent. also produce local injury (R. Schneider, 1920).

Pharmacologic Actions.—These correspond qualitatively with quinine, but are more toxic. Intravenously, optochin is more depressant to the heart; the blood pressure however, falls less than with quinine, since there is also vasoconstriction. The antipyretic efficiency of optochine is smaller (Smith and Fantus, 1916). It has but little inhibitory action on the emigration of leucocytes (Ikeda, 1916).

Frog Heart Perfusion.—Smith and Fantus observed decrease of both diastole and systole by 1:50,000 in Ringer's.

Perfused Mammalian Heart.—Doeschate and Laeuwen, 1917, obtained diminished contractions with 1:40,000, and standstill with 1:20,000, in Tyrode's.

Perfused Vessels.—The peripheral vessels are constricted in frogs and mammals (S. and F.); but the coronary vessels are dilated (D. and L.).

Blood Pressure.—Intravenous injection produces marked fall (S. and F.; D and S.), due to cardiac depression. In *man*, intravenous administration produces cardiac arrest.

Fate.—The alkaloid disappears rapidly from the plasma after intravenous injection. It persists longer and in greater amount in the corpuscles (Boecker, 1915).

QUINIDINE

Quinidine, one of the cinchona alkaloids, is the dextroisomer of quinine; the latter being levorotatory. The actions of the alkaloids agree qualitatively, but quinidine is less toxic to protoplasm and less effective against malaria. Both alkaloids lower the contractility of skeletal and cardiac muscle, and lengthen the refractory period, but with quinidine the depression of contractility is less, and the prolongation of the refractory period relatively greater.

Quinidine against Auricular Fibrillation.—The lengthening of the refractory period is utilized clinically to combat auricular fibrillation (M. Frey, 1918, 1921; Th. Lewis, 1922; Clerc and Pezzi, 1922; H. M. Korns, 1923). Quinidine invariably slows progressively the extremely high rhythm of the auricles, and in about half the cases this terminates in a sudden cessation of the fibrillation and the return to the normal heart rhythm. Whilst the auricular oscillations are slowing the ventricular contractions increase in regularity, but also in rate, toward a 1:3 or 1:2 rhythm, until the normal rhythm is restored. This may be attained in one to three days, sometimes with only a total of 0.6 Gm. of quinidine. The normal rhythm may then persist indefinitely without medication. In other cases the quinidine medication must be maintained continuously day and night; and in others again the quinidine fails to break up the fibrillation.

Analysis of the Cardiac Actions. The intravenous injection of therapeutic doses (5 to 10 mg. per Kg. corresponding to 3 to 10 grains in man) into normal animals (especially dogs) produce the following effects (Th. Lewis, Drury, Ilescu and Wedd, 1922; H. M. Korns, 1923; D. F.

Jackson, Friedlander and Lawrence, 1922; Cohn and Levy, 1921; Hecht and Rothberger, 1918):

Prolongation of the refractory period, by 50 to 100 per cent. This explains the other phenomena in a large part, if not altogether.

Depression of excitability, *i.e.* higher threshold of stimulation, greater resistance to extrasystoles, disappearance of extrasystoles (the latter discovered for quinine by Starkenstein, 1907); relief of aconitine and barium irregularities. The decreased excitability is largely a manifestation of the increased refractoriness.

Slowing of the rhythm, sometimes after a temporary acceleration. The rate of the atropinized heart (135 to 190) may be slowed by 30 to 80 beats per minute. This also results from the refractoriness.

Increased amplitude of excursions, (16 to 100 per cent.) due to greater diastolic filling which results from the longer diastolic pause; *i.e.* also the result of the lengthened refractory state. The systolic volume is not altered by these doses.

Inconstant effects on the T wave; frequently reversed and changed in volume.

Slowed conduction, auriculo-ventricular and also within the auricular and within the ventricular muscle. Toxic doses may produce a 1:2 block auriculo-ventricular block.

Inconstant alterations in the response to vagus-stimulation. It might be expected that the reactions would be modified by the altered condition of the heart muscle. Jackson *et al.* found the response generally increased. Lewis *et al.* found little effect on the response of the sinus rate, but the decrease of A-V conduction that is normally produced by vagus stimulation was materially smaller under quinidine, and in some cases vagus stimulation produced even an increase of conduction. This "vagus reversal" has been studied by Dale, 1922, who considers it analogous to the effect of nicotine and curare, and distinct from that of atropine.

Brief fall of blood-pressure is a constant characteristic of the *intravenous injection* of quinidine, but is apparently quite independent of the cardiac effect and possibly an anaphylactoid phenomenon. The pressure in the pulmonary artery rises with small doses, but with large doses it falls more than the systemic blood pressure.

Toxic doses impair the heart; producing sino-auriculo or auriculo-ventricular block or ventricular fibrillation, of gradual inhibition of the whole heart; in this case the auricles usually cease after the ventricles.

Frog Heart.—This is depressed by quinine (Santesson): The heart is slowed by 1:50,000 solution and weakened in its contraction; its effectiveness is consequently diminished. The slowing occurs after atropine, and is therefore muscular. A 1:5,000 solution kills the heart in a few minutes.

Segments of the apex of the ventricle also respond by weakened contractions, increased refractoriness is shown by higher resistance to tetanization (Sasaki, 1921).

Turtle Heart.—All the cinchona alkaloids diminish the amplitude and frequency, ending in diastolic arrest. The levo-bases (quinine and cinchonidine) are more toxic than their dextro-isomers (Fredericq and Terroine).

De Arric, 1912, also found the turtle heart slowed by all doses, and the excursions diminished by the higher concentrations; but he describes them as increased by low concentrations.

The effects of quinidine have been studied especially by J. Waddell and M. Cohn, 1924, and Hirschfelder, 1925.

Perfused Mammalian Heart.—F. B. Hoffmann, 1920, investigated the effect of quinidine on the auricles of perfused heart. He found considerable increase of the resistance to electric extrasystoles and fibrillation. It also lowered the force of the contrac-

tions, without much change in rate. Larger doses abolish the contractions and render the muscle inexcitable. Further studies have been made by Boden and Neukirch, 1921.

Skeletal Muscle.—As has been pointed out, most if not all of the quinidine phenomena are consequences of the increased refractoriness; and this in turn would be a natural result of the antiferment-action of the quinine alkaloids, which would slow the metabolic processes that are necessary to restore the excitability of the muscle after a contraction. Analogous phenomena may be observed on skeletal muscle: Immersion in quinidine solution (1:25,000) lengthens the refractory period, so that the muscle does not respond to rapid stimulation by the usual tetanus, but by a relatively slow, independent rhythm of contractions followed by a complete relaxation, (Figure 20). Such a rhythm would be more favorable to the performance of external work, such as pumping, than the continued tetanus, which consumes a larger amount of energy but dissipates it as heat. The latter is essentially the condition of the fibrillating auricle.

FIG. 20.—*The effect of quinidine on skeletal muscle.* The upper tracing is of a frog's gastrocnemius muscle that has lain in unpoisoned Ringer solution for 20 hours; the second tracing is the muscle of the opposite leg in quinidine 1:25,000. The lowest tracing shows the rate of stimulation with a tetanizing current, which passed simultaneously through both muscles. The unpoisoned muscle responds with a smooth tetanus, the quinidine muscle with slow rhythmic contractions (J. G. Brody and Sollmann, 1923).

The force of the contractions of the muscle tends to be depressed by quinidine, although not as much as by the quinine; but this is largely compensated by the rest in the refractory pause, as may be seen in the figure.

Quinidine, quinine, cinchonine and cinchonidine act essentially alike upon striped muscle; but with quantitative differences of practical importance (Brody and Sollmann, 1923, Santesson, 1892; Secher, 1915).

Concentrations above 1:5,000 abolish the response to stimulation, but produce a permanent spontaneous tonus or rigor.

Concentrations between 1:50,000 and 1:10,000 depress the muscle; the depression is manifested by lowered contraction, more rapid fatigue, prolonged refractory period, and earlier death. These occur at the same concentrations, and go hand in hand; but quinine affects the contractibility more than quinidine. All these phenomena are exaggerated or hastened by fatiguing or loading the muscle.

Intact frogs may show an increased height of muscular contraction early after the injection of quinine (Santesson); but this does not occur in excised muscle; with these, dilute solutions are simply ineffective.

Mechanism of Quinidine in Auricular Fibrillation.—The prolonged refractory state tends to render the auricular muscle incapable of maintaining the rapid rate that is characteristic for fibrillation. It also tends

to break up the circuits of auricular excitation which Lewis and Garrey consider the mechanism of the rapid rate; for the wave of excitation would die out when it found the muscle inexcitable on completing the circuit; and with the cessation of these stimuli, the sinus rhythm would resume its pace-making function. The auriculo-ventricular block resulting from the excessively numerous stimuli would diminish; partly because fewer stimuli arise and partly because the refractoriness of the bundle would also be increased by the quinidine, so that it would not be affected by the majority of the stimuli. The stronger and more regular impulses would again set a pace that the ventricles can follow; at first, imperfectly, *i.e.* with a partial block. So long as fibrillation persists, even this blocked ventricular rhythm would be faster than the more completely blocked rate that was obtained before the quinidine; but the ventricular rhythm would be much more regular, and much more efficient for the propulsion of the blood. When the circuit of fibrillation or the unfavorable cycle of rapid rate-short refractory period, is broken and the normal length of the pendulum of strong refraction and strong contractions is re-established, the latter tends to perpetuate itself automatically. However, if the original cause of the fibrillation persists, it may reproduce the fibrillation when the quinidine has been excreted, and continuous administration may be necessary. In nearly half the cases quinidine is unsuccessful. It is conceivable that the conduction might sometimes be so much slowed that the excitability of the muscle is restored, before the circuit is completed, notwithstanding the prolonged refraction; but it is quite probable that the failure may sometimes be due to failure to reach and maintain an adequate dosage, because of fear of the dangers of the drug. Failure is most frequent in cases of long standing, with marked cardiac insufficiency. The most favorable cases are those of short duration or of paroxysmal type. Previous digitalization probably increases the chances of success and diminishes the danger of accidents. Quinidine is more depressant and toxic to skeletal muscle when this is overloaded and fatigued. This doubtless holds also for the heart, and would be counteracted by digitalis. On the other hand, digitalis would reinforce the beneficial lengthening of the refractory period. It is well to observe that the two drugs produce prolonged refraction and slowed conduction by absolutely different mechanisms; the digitalis by the increased force of the preceding contraction, the quinidine by the slowing of the restorative metabolism.

Accidents.—In susceptible individuals, quinidine may produce phenomena similar to those of quinine hypersusceptibility; *i.e.*, nausea, vomiting, convulsions, palpitation, headache, faintness and flushing. Occasionally, but rarely, quinidine may change the auricular fibrillation to more serious irregularities, intra-auricular block, ventricular tachycardia, and fatal ventricular fibrillation.

Cumulation need not be feared, since quinidine is rapidly excreted.

Use in Other Cardiac Irregularities.—R. W. Scott, 1922, found the continued administration of quinidine completely successful in arresting and preventing ventricular tachycardia. Pezzi and Clerc, 1920, report favorable clinical effects from quinine, against extrasystoles, paroxysmal tachycardia, and auricular fibrillation. They administer 0.5 Gm. by mouth, 2 or 3 times per day. J. H. Wyckoff and Otto, 1926, found quinine ineffective in patients who responded to quinidine.

Administration.—Quinidine sulphate may be administered in capsules or tablets. The susceptibility of the patient is tested by a dose of 0.2 Gm., which is repeated in 2 hours. If there are no bad effects, the regular

dosage is started on the following day, with 0.2 to 0.4 Gm. three to five times per day; and not exceeding 2 Gm. per day. If no benefit follows within three days, quinidine is generally considered unsuccessful. In case of complete success, the drug may be omitted, and re-administered on recurrence. The maintenance dose is about 0.25 Gm. per day. If any toxic manifestations occur, it should be discontinued.

PREPARATIONS

* *Quinidine Sulphas* (Quinidin. Sulph.), U.S.P.; $(C_{20}H_{24}O_2N_2)_2 \cdot H_2SO_4 \cdot 2H_2O$.—Fine needle-like, fleecy, white crystals, darkening on exposure to light. Very bitter taste, no odor. Soluble in water (1:90) and alcohol (1:10). *Dose*, 0.3 Gm., 5 grains, four times a day; *caution*; U.S.P.

PYRAZOLON DERIVATIVES: ANTIPYRINE (PHENAZONE), AMIDOPYRINE (PYRAMIDON) AND MELUBRINE

These compounds are used as analgetics and antipyretics. Their effects are essentially similar to those of the acetanilid group. They are feeble bases, readily soluble in water. This is an important difference from the acetanilid group. Amidopyrine is effective in about a third of the dose that is required with antipyrine. It is used mainly as analgetic, and antipyrine as antipyretic. The discrimination is perhaps merely fanciful. Melubrine has not become popular in America.

Structure.—Antipyrine (phenazone) is phenyl dimethyl pyrazolon:

Amidopyrine (pyramido) is dimethylamino antipyrine, the H at (a) being replaced by $\text{N}(\text{CH}_3)_2$. Melubrine is amidmethane-sulphonate of antipyrine, the H at (a) being replaced by $\text{NH} \cdot \text{CH}_2 \cdot \text{SO}_2 \text{Na}$.

Antipyretic Action.—This is essentially the same for the pyrazolon derivatives, and the acetanilid and salicylate groups. They have little or no effect on normal temperature, but reduce febrile temperature toward, or to, or below normal, according to the dose. The fall is due to increased heat loss, partly by cutaneous vasodilation, partly by the restoration of the water-contact of the blood. The therapeutic use and dosage are discussed under the acetanilid group.

The relation of heat production and heat loss may be illustrated by the calorimetric data of Gottlieb, 1891. A comparison of this table with that for quinine (see index) shows striking differences.

Antipyrine, 0.5 Gm.	Fall of temperature	Level of temperature	Heat production	Heat dissipation
Normal rabbit.....	0.2-0.4°	38.63-38.9	+5.9%	+10-20%
Puncture fever.....	0.8-1.1°	39.3-41.6	+2-10%	+21-55%

Heat Loss.—This is considerably increased in normal animals, and the increase is several times greater in fever (see the preceding table).

Heat Production.—The calorimetric data show a moderate compensatory increase, more marked at normal temperature than in fever. The metabolism data are contradictory (Review, S. Weber, 1904). Excessive doses (0.75 Gm. in rabbits) diminish heat production, presumably by incipient collapse.

Nitrogen Metabolism.—With therapeutic doses, and normal temperature, the results are variable, generally negative or some fall. Large doses often increase the nitrogen excretion, especially in man. In fever, therapeutic doses decrease the excessive nitrogen metabolism.

Carbon Dioxide Metabolism.—Therapeutic doses with normal temperature produce no change or some decrease. Larger doses (2 to 3 Gm. of antipyrine for man) produce a small but unmistakable decrease in both gaseous exchange and nitrogen excretion (incipient collapse?). The effect on carbon dioxide metabolism is also inconstant in fever: Therapeutic doses may somewhat increase or diminish the CO_2 excretion, or leave it practically unchanged.

After the fall of temperature has set in, the carbon and nitrogen metabolism are commonly lowered. This may be ascribed to the removal of the hyperpyrexia, for metabolism is naturally less active at the lower temperature.

Antipyrine, and especially phenacetin and acetanilid, decrease the arterial oxygen; the CO_2 is less changed (Piccini, 1912).

The respiration of excised muscle is not affected by antipyrine (in contrast to quinine and salicylate) unless very high concentrations are used (Senta, 1908).

Mechanism of the Fall of Temperature.—The constant feature in the action of the antipyrine group is the increased heat loss; and this must therefore be considered the specific element in their antipyretic action. The inconstancy of the variations of the heat production indicates that these are secondary results.

Mechanism of the Increased Heat Loss.—This might occur through an increased production of sweat, or by exposing a larger amount of blood to the cooling influence of the surroundings by *dilation of the cutaneous vessels*. In the case of this group it is accomplished by the latter means.

The dilatation may be deduced from the hot and reddened skin; it can be plainly shown by the plethysmograph (Maragliano, 1880). And since the reduction occurs even after atropine, which suppresses the secretion of sweat, the latter is not essential. The *vasodilatation is confined to the cutaneous vessels*, and this is important, since, if the blood vessels in the remainder of the body were also dilated, the circulation through the skin would be diminished rather than increased. This limitation of the vasodilatation to the region concerned with the regulation of temperature also indicates that the action is central.

Localization of Action.—Antipyrine does not lower the temperature after high section of the spinal cord (Sawadowski, 1888), even if the temperature is artificially raised by external heat. This constitutes a conspicuous difference from quinine, which latter is effective under these conditions. The result shows that the vasodilator action of antipyrine is located above the spinal cord.

Antipyrine also does not increase the natural rate of fall which occurs when the brain is divided at the posterior margin of the corpora striata. Nor does antipyrine interfere with the normal compensation against increase of external temperature; in fact, it renders the compensation rather more efficient. This goes to show that its action does not consist in a depression or narcosis of heat regulation as such. (Toxic doses, however, render the compensation less perfect—a natural result of extensive toxic action.)

Large doses cause considerable fall, even of the normal temperature, with evidences of collapse. The fall is proportionate to the metabolic rate (Githens, 1925).

Side Actions.—Large doses of antipyrine and its derivatives produce collapse effects essentially identical with those of the acetanilid group (which see). They have less action on the blood, but are much more likely to produce skin eruptions.

Antipyrine Eruptions.—With susceptible individuals, these occur promptly even after small doses; in the form of round or oval erythematous somewhat pigmented patches, which may become bullous. When the drug is discontinued, these are replaced by pigmented areas, which become rapidly congested if another dose is taken (H. MacCormac). It has been claimed that the hypersusceptibility may be desensitized by small doses (Widal and Vallery-Radot, 1920).

Other side-actions are described in Seifert, *Nebenwirkungen*, 1915, page 4.

Intravenous Injection of Melubrine.—The fad for intravenous therapy has led to the injection of this substance in rheumatic fever (5 c.c. of 50 per cent., three times daily; Hahn, 1913). This is often harmless; but even 0.5 Gm. has been followed by extreme anaphylactoid collapse and dyspnea (Martz, 1918). Melubrine naturally has the same side-actions as antipyrine.

Fate.—Antipyrine is eliminated largely unchanged by the urine (Jonescu, 1906), traces also by the sweat (Tachau, 1911), and sputum (Hofbauer, 1915). The urine volume is generally decreased. Occasionally the urine is blood red, and green in reflected light (Penzoldt).

PREPARATIONS

* *Amidopyrina* (Amidopyrin.), U.S.P., Pyramidon.—White, crystalline, odorless powder. Soluble in water (1:18), alc. (1:15). Dose, 0.3 Gm., 5 grains, U.S.P., to 0.4 Gm., generally in tablets. Usually only a single dose is administered per day.

* *Antipyrina* (Antipyr.), U.S.P.; *Phenazonum*, B.P.—White crystalline powder; almost odorless; slightly bitter taste. Very sol. in water (1:1), freely sol. in alc. (1:1.3). *Incompatible* with nitrites (Sp. Aether. Nitros), with tannin, and with mixtures of calomel and sodium bicarbonate (immediate blackening formation of soluble and toxic mercury compound; Paderi, 1919). Liquefies with sodium salicylate, etc. Dose, 0.3 Gm., 5 gr., U.S.P.; 0.3 to 1 Gm., 5 to 15 gr., B.P., in solution, powders or capsules. *Maximum dose*, 1 Gm., 15 gr.

Melubrine.—Properties similar to the preceding. Dose, 1 to 2 Gm., 15 to 30 grains. As much as 10 Gm. have been given daily.

ACETANILID, ACETPHENETIDIN AND PARAMIDOPHENOL DERIVATIVES

These drugs, the so-called "*coal tar antipyretics*," lower febrile temperature by dilating the cutaneous vessels through a central action. They are highly effective; but the antipyretic doses are apt to produce undesirable side actions, and are clinically supposed to be depressant to the circulation. Smaller doses are efficient analgetics in headache, neuralgic conditions, etc. Their use is not without danger from acute collapse. Chronic poisoning, with methemoglobin formation, has also been reported. Acetphenetidin (phenacetin) is somewhat less dangerous than acetanilid but the difference is merely one of degree. These drugs are relatively insoluble, and are therefore used as powders or tablets. Their taste is not objectionable.

The former high price of quinine caused chemists and pharmacologists to look about for cheaper efficient substitutes. It was attempted to make quinine or similar substances synthetically, departing from quinoline, one of the decomposition products of quinine. Whilst this search did not result in an artificial quinine, nor even of any substance analogous to it in action, it brought to light a very large number of substances, in some respects even more valuable than the alkaloid itself, and served to direct attention to the pharmacologic significance of the derivatives of the aromatic series.

It was found that all the simpler compounds built up from the benzol nucleus (with a very few exceptions) possess certain physiologic actions in common, as follows:

Common Actions on Benzol Derivatives.—*Central Actions*: Stimulation, followed by more pronounced *depression* of the entire central nervous system, but particularly: An *antipyretic* action on the heat-centers, and an *analgesic* action in neuralgias.

Local Actions: A *coagulant*, irritant, toxic and *antiseptic* effect on all forms of protein and protoplasm—on tissue cells, bacteria, and ferments. A quinine action on all forms of muscle. Local anesthesia. The formation of methemoglobin.

The actions are exerted in a different manner and to a different degree by the several members of the series, mainly in two directions, so that these may be classified somewhat arbitrarily as "*Antipyretics*" and "*Antiseptics*."

The antipyretic group is distinguished by the predominance of the action of the heat-regulating center.

The antiseptic group is characterized by a much more marked local action on protoplasm, which determines the usefulness of the members as antiseptics. The effect upon the thermic centers passes much more readily into general collapse than with the former group.

The distinction is by no means sharp, and many of the substances—*f.i.*, the salicylates—could be classed under either group.

Structure and Antipyretic Action.—The large number of antipyretic benzol derivatives differ only quantitatively in their actions, these differences having definite relations to their chemic structure. Practical experience has shown that acetphenetidin and acetanilid are the most useful representatives of the group, and that all the others may well be spared.

The enterprise of manufacturers of synthetic products has overwhelmed the profession with almost numberless antipyretics; but it must be confessed at once that the number of really new and valuable product is comparatively small. The great mass of this material consists simply of insignificant variations in the established products, introduced for the purpose of evading patents; and amounts to little more than do the various flavorings in the elixirs of the older *materiamedica*. This multiplication can only do harm by creating confusion, and should be abolished as speedily as possible. The selection of the worthy products from this collection would be an almost hopeless task, were it not that certain definite laws have been deduced from the experimental evidence, according to which we may foretell the action of a coal-tar derivative from its composition, with considerable probability. In this way many new compounds can be adjudged as unworthy of extended trial. A presentation of some of these laws will therefore be of practical value, aside from their scientific interest.

The antipyretic action really resides in the benzol ring. Yet benzol (C_6H_6) itself is not antipyretic, because it can not readily enter into reaction with the body cells; this capacity of reacting may be given to it by substituting for one of its [H] atoms an [OH] group, as in phenol, C_6H_5OH ; or still more strongly by an NH_2 group, as in aniline, $C_6H_5.NH_2$ (phenylhydrazine, $C_6H.NH.NH_2$ being yet stronger); or by both as in paramidophenol, $C_6H_4OH.NH_2$.

In a few modifications of the benzol ring, the antipyretic action is quite wanting; thus in Pyridine, C_5H_5N ; in Naphthalene, $C_{10}H_8$; in Phenanthrene $C_{14}H_{10}$. But it reappears in Quinoline C_9H_7N , and is also present in the pyrazol ring (see Antipyrine),

These aromatic alcohols and amides are called the "mother-substances" of the antipyretic drugs. They are strongly antipyretic, but they also produce collapse. Before they can be used in practice, this collapse

action must be diminished. This may be done by replacing the [H], either of the [OH] or of the [NH₂], by other radicals; the reduction of toxicity being greatest if the substitution is made in the NH₂.

These substituted compounds act only after the mother-substance is liberated from them in the body. Their action is therefore more gradual, less violent, and more easy of control.

The influence of the substituted radical is as follows:

The reduction of toxicity is greatest if the substituted radical is an alkyl (C_nH_{2n+1} or CO₂.C_nH_{2n+1}); less if it is an acetyl (CO.C_nH_{2n+1}). If several H atoms are substituted, the toxicity will be less if both an acetyl and an alkyl radical are introduced, than if both radicals be of the same kind.

The toxicity and the therapeutic qualities *both* diminish with the size of the introduced radical. The most useful is the ethyl (C₂H₅) or acetyl (C₂H₃O) radical; with the methyl or formyl group, the toxic action is too great; with larger groups, and particularly with aromatic groups, the compound becomes so resistant that the therapeutic action is reduced almost to nothing. This is true of the citrate and salicylate radicals. Such compounds are of course correspondingly harmless.

The above laws must be modified if the compound is decomposed in the stomach with liberation of the mother-substance. It must also be remembered that the radicals must be introduced into the ring by substitution; the mere addition of acid radicals, forming salts, does not modify the properties of the original substance. Therefore Aniline acetate (C₆H₅.NH₂.HC₂H₃O₂) preserves the original toxic action of aniline; whereas this is greatly weakened in acetanilid (C₆H₅.NH.C₂H₃O).

The substitution of an H by I, Br, or Cl, does not modify the antipyretic or toxic action of the original substance.

Analgesic Action.—Like quinine and the salicylates, all the antipyretics have an analgesic effect against neuralgic and muscular pains, headaches, migraine, colds, rheumatic conditions, etc.; but are ineffective against other forms of pain, such as trauma. The mechanism of the analgesic action is obscure. It has been suggested that it consists in changes of the meningeal vessels. There is little if any evidence of true narcosis; nor do the antipyretics reinforce the action of the ordinary narcotics to a marked degree (Lomonosoff, 1911).

The analgesic action is extensively used. Small doses (acetanilid, 0.2 Gm., 3 gr.; acetphenetidin 0.3 Gm., 5 gr.) may be repeated a few times with three-hour intervals, if necessary. If these small doses fail to give relief, larger doses are usually also ineffective.

Psychologic Experiments on Man.—Quinine, antipyrine and acetphenetidin in doses of 1 Gm. produce marked impairment in mental efficiency tests (Hugo Muensterberg, 1892). Analgesic doses (0.025 to 0.5 Gm.) do not impair neuro-muscular coordination, as judged by the "tapping test," but they retard the reaction-time (Macht et al, 1918) and raise the threshold of cutaneous sensibility (Martin et al., 1915; Hale and Grabfield, 1923).

The *acuity of hearing* was decreased by the salicylates, but rather increased by small doses of other antipyretics, including quinine (Macht et al, 1920). The discrimination of musical pitch appears to be diminished by all.

Intracranial Vessels.—The effect of antipyretics and hypnotics on the cerebral and meningeal vessels should be investigated by plethysmograph on trepanned patients. Cavazzani, 1918, showed that the cerebral vessels undergo large oscillations with the emotions.

Proprietary Headache Powders.—These usually contain from 50 to 70 per cent. of acetanilid or acetphenetidin (Report C.P.C., J.A.M.A., 1905, 44: 1701), generally mixed with caffeine, salicylates, bromides, ammonium carbonate or sodium bicarbonate. The caffeine, salicylate and bromide would reinforce the analgesic action. The alkalis

were supposed to increase the solubility, but do not do so (Puckner, 1906). It was also claimed that all these drugs diminish the toxicity, but even caffeine lacks this effect (E. D. Brown and Moorehead, 1925). This indiscriminate use of the powders by the laity has repeatedly produced acute and chronic poisoning. Authoritative statistics of this are presented in the report of Kebler, Morgan and Ruppe, 1909.

Chronic Poisoning.—The continued use of acetanilid ("headache powders") has occasionally caused the development of a drug habit, with craving, and withdrawal symptoms. An individual predisposition appears to be necessary, for the condition is relatively rare; but it should be guarded against in the administration of the drug. The symptoms of chronic acetanilid poisoning consist in methemoglobinemia (chocolate-colored blood) with the histologic blood changes of pernicious anemia; marked leucocytosis; cyanosis; cardiac weakness; progressive mental and physical debility. Methemoglobin may also appear in the urine. (D. D. Stewart, 1905.)

Diabetes Insipidus.—Beneficial results have been claimed for the antipyretics, *f.i.*, by Hirschfeld, 1904. They require confirmation.

Antipyretic Action and Effects on Metabolism.—These were described under Antipyrine and Temperature Regulation.

Antipyretic Dosage.—On account of the possibility of a direct collapse action if the dose is relatively large, the antipyretics must be administered with care.

In general, it may be said that, from the smallest effective dose (0.2 Gm. for acetanilid, 0.5 to 0.7 Gm. for antipyrine or phenacetin), the extent of the antipyretic action increases with the dose of the drug, until the normal temperature has been reached. Up to this point there is little danger of a direct collapse action. But if the dose necessary to secure this result is exceeded, the toxic effects set in.

The full antipyretic dose may be stated as 0.5 Gm. (7 gr.) of acetanilid; 0.8 Gm. (10 gr.) of phenacetin; 1 Gm. (15 gr.) of antipyrine. In beginning the treatment, this dose has to be repeated once or twice, with an hour's interval, until the desired fall is secured. After this, the single dose is repeated whenever the temperature begins to rise. Four or five doses are required per day to keep the patient practically fever-free. The action does not persist after the drug is excreted. With single doses the antipyretic effect reaches its maximum in about two hours, and then declines gradually, so that the febrile level is practically restored in eight hours (Gottlieb, 1890). Consequently the administration must be continuous, in the manner indicated. Those antipyretics which are rapidly excreted (as is phenocoll) are therefore less useful.

In regard to details, and in determining the *choice of the particular substance* to be used, experience is the best guide. The same holds here as in other cases: Very much more can be accomplished by any one drug that is thoroughly understood by the user, than can be done with a number of drugs with which he has had only limited experience.

Side Actions.—Undesirable effects are rather common, especially when antipyretic doses are used. Some of these are the indirect results of the heat regulation—sweating and chills, indirect collapse; some are due to irritation—gastric disturbances, skin eruptions, renal irritation; others to the direct systemic actions of the drugs—cinchonism, cyanosis, true collapse. The susceptibility to them varies greatly in different individuals.

The literature of the side actions is given by Siefert, *Nebenwirk*, 1915; Acetanilid, page 2; Antipyrine, page 4; Acetphenetidin, page 26.

The *sweating* is due to the increased circulation through the skin, and is produced in the same manner, and has the same significance, as the critical sweat of fever. It must be looked upon as beneficial rather than otherwise, since it aids the reduction of

temperature. But should it become too troublesome, it can be suppressed by small doses of atropine.

The cutaneous hyperemia is perhaps also responsible for the *skin eruptions*. They are particularly frequent after antipyrine.

The tendency to this eruption as also to a *stomatitis* which is often seen, increases with the repeated use of the drug.

The *chills* occur when the temperature begins to rise again, and are due to a diminished circulation through the skin, just as the chills of malaria. They are therefore not to be attributed to the drugs, but are rather a sign that the action of the antipyretic has worn off.

Gastric symptoms are due to local irritation, but are not frequent. Most of these drugs have a sharp, warm or bitter taste.

Renal irritation, varying from slight diuresis without histologic change, to violent, desquamative, hemorrhagic, parenchymatous nephritis, may be produced by all coal-tar derivatives. There is not, however, any danger of nephritic lesions from ordinary doses of the antipyretics. Thalline produces a peculiar papillary nephritis.

Cinchonism symptoms are rare, but have been reported. The *cyanosis* is due to the methemoglobinemia.

Lactophenine produces *icterus* in over half of the patients, usually on the ninth to twelfth day of its use. There is no relation to dose. It appears to be harmless, and is probably of the retention type rather than hemolytic (Hanssen, 1916).

Methemoglobin Cyanosis.—All drugs of the coal-tar series act more or less upon the blood, inside of the body, producing methemoglobin, and in larger doses causing a disintegration of the corpuscles. This action is much more pronounced in the mother-substances—*aniline*, *phenylhydrazine*, etc.—and in the antiseptic group it is stronger with acetanilid than with the other antipyretics. It leads to a peculiar cyanosis, and contributes to the collapse.

The methemoglobin formation proceeds much more weakly in shed blood than it does in the body. The relation of the methemoglobin formation to the chemic constitution of benzol derivatives has been investigated by W. Heubner, 1913.

Collapse Action.—Excessive, and sometimes therapeutic doses, produce serious collapse, with weak and irregular pulse, dyspneic or shallow respiration, pale or cyanotic skin, cold sweat, disturbed consciousness, subnormal temperature, and death by circulatory failure. This collapse is sometimes a direct effect of the drugs (cardiac and vasomotor depression); in other cases it is due to the reduction of the febrile temperature, “unmasking” a preëxisting febrile collapse: Circulatory failure is a frequent feature of fevers. It may be partly masked by the stimulant effects of high temperature, and will then reveal itself when normal temperature is restored, whether by antipyretic drugs or by baths. Caution is therefore necessary in the use of all antipyretic measures in asthenic fevers. Menstruation also favors the development of collapse.

Of the more usual antipyretics, acetanilid produces probably the strongest direct collapse effects; then come antipyrine and then phenacetin.

The collapse action is strongest in the mother substances—*aniline*, *quinoline*, *phenetidin*, *phenylhydrazine*, and *carbolic acid*, and generally in the members of the antiseptic group; so strong, indeed, that the action of these can not be controlled, and they are hence unfit for internal administration.

The **treatment of poisoning** by overdoses of the antipyretics is the same as for collapse from other causes—stimulants, heat, etc. (see *Aconite*).

Circulation.—The general circulation is but little affected by ordinary doses. They will slow the heart indirectly by reducing the temperature; this has probably sometimes been misinterpreted as cardiac depression.

The *cutaneous vessels* are dilated; the *intracranial vessels*, after a short dilation, show a more persistent constriction, similar to caffeine or alcohol (E. Weber, 1909). Berezin, 1916, reports dilation in rabbits and fish. Hirschfelder, 1915, describes dilation of the pia and retinal vessels, from acetanilid, antipyrine, amyl nitrite, caffeine and alcohol. This tends to raise intraocular pressure, enjoining caution in glaucoma (Wessley, 1915).

With *toxic doses*, the heart is first accelerated, and later slowed. This is due to direct action upon the heart muscle. Strips of terrapin's ventricle are slowed and arrested by acetanilid (Carr, 1910).

The *vasomotor center* is not affected by moderate doses (with the exception of the part controlling the cutaneous vessels). In consequence, the *blood pressure* depends solely upon the cardiac action, being at first increased and later diminished. In doses producing collapse there is paralysis of the vasomotor system, and consequent fall of blood pressure.

Striped Muscle.—Immersion in acetanilid solution (1:5,000) diminished the direct and especially the indirect excitability of muscle (Macht, 1919). Muscle immersed in dilute antipyrine solution preserves its excitability much longer than when immersed in Ringer's fluid (J. G. Brody, unpublished).

The *antiseptic action* of the antipyretics is not very strong. They are, however, sometimes used as antiseptic, astringent, and *hemostatic dusting powders* (acetanilid; or antipyrine in 5 per cent. sterilized solution). They are less poisonous and less irritating than iodoform; although toxic effects have been reported from the application of acetanilid to wounds.

Leucocytosis.—It has been believed that this is produced by antipyretics; but Gehrig, 1915, found no effect. The migration of leucocytes from the inflamed mesentery of frogs is inhibited by antipyrine (Ikeda, 1916). Phagocytosis *in vitro* is also unaffected (Arkin, 1913).

Absorption, Fate and Excretion.—The antipyretics are rapidly absorbed and excreted. Acetanilid, acetphenetidin and their derivatives are mainly oxidized to paramidophenol, which is probably the form in which they produce their actions. This is excreted in the urine, chiefly as paired compounds with sulphuric and glycuronic acids. It gives the "indophenol reaction" in the urine.

PREPARATIONS

**Acetanilidum* (Acetanil.), U.S.P., B.P. (*Antifebrin*, Phenylacetamide, etc.), $C_6H_5NH_2 \cdot CH_3CO$.—White crystalline powder; odorless; warm taste. Slightly sol. in water (1:90), freely sol. in alc. (1:3.4) or glycerinn (1:5). Liquefies with chloral or antipyrine. *Dose*, 0.2 Gm., 3 gr., U.S.P.; 0.12 to 0.3 Gm., 2 to 5 gr., B.P.; in powders or capsules. *Maximum dose*, 0.5 Gm., 8 gr.

**Acetphenetidinum* (Acetphen.), U.S.P.; *Phenacetinum* (Phenacet.), B.P. (Para-acet-phenetidin), $C_6H_4(OC_2H_5) \cdot NH \cdot CH_3CO$.—White crystalline powder or scales odorless and nearly tasteless. Very slightly sol. in water (1:1,310); sol. in alc. (1:15). Liquefies with chloral or antipyrine. *Dose*, 0.3 Gm., 5 gr., U.S.P.; 0.3 to 1 Gm., 5 to 15 gr., B.P.; in powders or capsules. *Maximum dose*, 1 Gm. 15 gr.

SALICYLIC COMPOUNDS

Salicylic acid (ortho-oxybenzoic acid, $C_6H_4OH \cdot CO_2H$, 1:2) and its compounds produce marked antipyretic and analgesic effects and striking relief of the phenomena of acute articular rheumatism. The systemic toxicity is relatively low, but large therapeutic doses produce the so-called "toxic" symptoms resembling cinchonism. The different compounds act qualitatively similar but present quantitative differences. The salicylates are excreted by the urine, partly free and partly combined.

Free salicylic acid is an antiseptic and an active irritant and slow corrosive.

Historical.—An excellent review of the introduction of salicylic acid is furnished by W. O. Moore, 1879. The entire literature to date is presented by Hanzlik, 1914. Salicylic acid was first prepared in 1838 by Piria from salicin, which had been discovered in 1872 by Leroux. Cahours, in 1844, and Procter, prepared the acid from gaultheria oil. Kolbe and Lautemann produced salicylic acid synthetically from phenol in 1860; and Kolbe devised a commercially practical synthetic process in 1874. He also investigated its antifermentative action. It soon became thoroughly established as a surgical antiseptic (Thiersch, 1875); antipyretic (Buess, 1875); and antirheumatic (Strickler, 1876).

Salicyl Esters.—The desire to avoid the disagreeable taste and the gastric symptoms of the ordinary salicylates led to the introduction of esters and similar compounds which are more or less insoluble, and in which the salicyl radical is bound so as to be liberated only in the intestine or after absorption. These compounds have little or no direct action on the stomach, but they do not avoid the nausea and vomiting (Hanzlik, 1913; MacLachlan, 1913), since these are probably central. In this respect they are therefore not superior to sodium salicylate, which also does not produce direct gastric irritation, if properly guarded by bicarbonate. The taste is materially improved, but this advantage scarcely balances their high cost. The alkyl esters (methyl salicylate) are more efficiently absorbed from the skin and are therefore better for external use. The acyl derivatives (acetyl salicylic acid) possess a higher analgesic and antipyretic action and have therefore a special field. The salols contain active phenols which adapt them to intestinal antiseptics. These compounds may be arranged under three types:

1. **Replacement of the H of the Hydroxyl by Acyl Radicals.**—To this type belong: Acetyl salicylic acid (aspirine), $C_6H_4.O(COCH_3).COOH$, and the corresponding compounds of salicylic acid with methylene-citric acid (*Novaspirin*); with salicylic acid (*Diplosal*); and with succinic and (*Diaspirin*).

2. **Replacement of the H of the Carboxyl by Alkyl Radicals.**—Methyl salicylate, $C_6H_4.OH.CO_2(CH_3)$, and the corresponding salicyl esters of ethyl (*Sal Ethyl*); of methoxymethyl (*mesolan*); and of monoglycol (*spirosal*).

3. **Replacement of the H of the Carboxyl by Phenyl Radicals.**—Phenyl salicylate (*salol*), $C_6H_4.OH.CO_2(C_6H_5)$, and the corresponding salicyl esters of naphthol (*betol*); of guaiacol; and of acetparamidophenol (*salophen*).

To these may be added *salicin*, from which salicylic acid is formed in the organism. Only a few of these derivatives need be considered in any detail; the others which are acceptable are described in N.N.R.

Percentage of Salicyl in Various Derivatives.

100 parts of:	= Parts of salicylic acid:	= Parts of sod. salicylate:
Sod. salicylate.....	85.6	100
Methyl salicylate.....	90.7	106
Acetyl salicylic acid.....	77.0	89
Salicyl salicylic acid.....	106.2	124

Analgesic Action.—The salicylates act essentially similar to acetanilid, which see: Acetyl-salicylic acid (aspirin) is widely used to relieve headache.

Antipyretic Action.—Salicylates lower febrile temperature energetically and promptly. The mechanism is probably similar to that of acetanilid, *i.e.*, increased heat dissipation by cutaneous dilatation, aided by perspiration. In healthy individuals this is compensated by increased heat production so that the normal temperature is not easily affected. Salicylates may take the place of other antipyretics, and are probably safer; but the side actions of large doses are more disagreeable. Small doses of acetyl-salicylic acid are often used in mild fevers.

Yamatoto, 1919, finds acetyl-salicylic acid more efficient than simple salicylate.

Differences in Health and Fever.—The heat-regulation apparently is affected quite differently. With normal men, at absolute muscular rest, 1 gram does not lower the temperature, but increases the heat production (CO_2 excretion about 6 per cent.), with the heat dissipation practically unaffected (Barbour and Devenis, 1919).

With febrile patients, even with very mild fever or when the temperature is merely unstable, the same dosage lowers the temperature to 0.8°C . below normal; and produces a great increase (38 per cent.) of heat dissipation, and a slight decrease of heat-production. When the effect passes off, there is a compensatory decrease of heat dissipation to half the normal level (Barbour, 1919).

The nitrogen excretion is primarily increased (Weber); although there is often a later decrease. The oxidation of excised muscle is retarded by small concentrations.

Therapeutic Effects in Rheumatic Fever and Rheumatic Tonsillitis.—

The proper administration of salicylates controls the manifestations of this disease in a most remarkable manner in nearly all typical cases—so uniformly that failure throws suspicion on the diagnosis: the pain and fever disappear; the local inflammation, the immobility, swelling and redness subside; the general condition of the patient is vastly improved; and the disease is under complete control in one to at most five days. These benefits last only so long as the patient is kept salicylated and relapses occur when this is discontinued. According to statistics, the total duration of the disease, as judged by the stay in the hospital, is not affected (J. L. Miller, 1914).

The rheumatic cardiac lesions are not relieved directly (Vulpian, 1880). Indirectly the salicylate treatment doubtless has an important tendency in this direction by favoring rest and avoiding the extra tax of fever, pain and insomnia.

Efficiency in Related Conditions.—Salicylates are much less certain in atypical, subacute, chronic, and muscular rheumatism, lumbago, etc., although they usually have some analgesic effect. In acute gout they are often quite effective (Vulpian, 1880). They are notably inefficient in scarlatinal and gonorrheal arthritis (G. Sée, 1877; Stockman, 1906). They are also used in headache, neuralgias, sciatica, tabes and other similar pains, but with inconstant results. In chorea it is difficult to prove any benefits.

Response in Different Affections.—In the routine statistics of Hanzlik, 1913, in 132 cases of rheumatic fever, salicylates gave complete relief in 82 per cent., partial relief in 16.5 per cent., and failed in only 1.5 per cent. In subacute rheumatism, thirty cases, it gave complete relief in 53 per cent.; partial in 30 per cent.; failures in 17 per cent. In sciatica, eleven cases, it did not give complete relief in any, failed completely in 27 per cent., and afforded partial relief in 73 per cent.

Ophthalmitis.—Large doses (10 gm. of sodium salicylate per day) have been administered over long periods in all types of intraocular inflammation, with the claim that they check or relieve the congestion (H. Gifford, 1922).

Mechanism of Antirheumatic Action.—This is probably connected with the analgesic and antipyretic action. It is improbable that the salicylates have a germicidal effect in the tissues; nor do they improve chemical irritations and edemas (Hanzlik and Tainter, 1923; Laqueur and Magnus, 1921).

The analgesic explanation is based on the efficiency of salicylates in other painful conditions (Laborde, 1877; Vulpian, 1880); and on the effect of other analgesics in rheumatic fever.

Hanzlik et al., 1918, found that combination of other analgesics (for instance, morphine) and antipyretics (for instance, quinine) also relieve the symptoms of acute rheumatic fever promptly and effectively, and sometimes permanently. Quantitatively, however, salicylates are superior.

Tissue Antisepsis.—This was suggested by the large doses which are required; the small efficiency of other antipyretics and analgesics; the relative inefficiency of the salicylates in other forms of arthritis.

Against this view speak the prompt recurrence of the symptoms if the salicylate is discontinued and the failure to prevent the cardiac infection. In rabbits, the prophylactic use of salicyl does not prevent or even influence arthritis from intravenous injection of rheumatic hemolytic streptococci (Miller, 1914; Davis, 1915); but this is not conclusive since the etiology has not been established, and the administration is very different.

Administration.—For *internal use*, the free salicylic acid is too irritant. The sodium salicylate is the most commonly used, notwithstanding its mawkish, nauseant taste. This may be partly disguised by giving the salt in carbonated water, or flavoring with peppermint or wintergreen water. The direct gastric irritation is avoided by adding an equal or double quantity of sodium bicarbonate.

To be effective in acute rheumatism, large doses must be administered: 1 to 1.3 Gm. (15 to 20 gr.) should be given every hour until "toxic" symptoms (tinnitus, nausea, etc.) set in. The administration should then be stopped for twelve hours. After this, 1 Gm. (15 gr.) should be given every four hours for several weeks, keeping the patient in bed as long as possible. If the sodium salicylate is not tolerated, oil of gaultheria or acetyl salicylic acid may be substituted. Methyl salicylate also gives some relief when applied externally to the affected joints.

Sodium salicylate may be administered by rectum, if it is not retained by the stomach. The drug is absorbed so promptly that there is no necessity for hypodermic or intravenous injections; although these have been used (hypodermic, Seibert, 1911; intravenous, Mendel, 1905, 1908; Conner, 1914).

Rectal Administration.—This is preferred by Heyn, 1914, as being more prompt and less disagreeable. He gives a cleansing soap-sud enema. When it has taken effect, it is followed by sodium salicylate through a rectal tube, inserted 6 to 8 inches. The first dose is of 8 to 11 Gm. for men, 6 Gm. for women, in 150 c.c. of water or thin starch, with 1 c.c. of Tr. Opii. It may be repeated in twelve hours, but usually one enema per day suffices. Salicyl appears in the urine within fifteen to thirty minutes.

Therapeutic "Toxic" Actions.—When the dosage of salicylate is raised to the full therapeutic effect, there occur usually a series of side actions resembling cinchonism. They consist in nausea and vomiting, ringing in the ears and deafness, vertigo and headache, mental dulness and confusion, diaphoresis, quickened pulse and deepened respiration; rarely skin eruptions, albuminuria, impaired vision (de Schweinitz, 1895; Claiborne, 1906), and delirium, the latter especially in alcoholic patients. All these effects are usually without danger, disappearing promptly when the drug is discontinued. Abortion has sometimes occurred, but it is doubtful whether this was due to the drug or to the disease. Mattos, 1905, claims an emmenagogue action.

The nausea and vomiting are not due to local irritation, except if free salicylic acid is given. The salicylates and esters are not especially irritant; and if fractional doses are given, the gastric phenomena set in only after some hours, about the same time as the ear and other systemic effects. They are therefore probably central. This has been confirmed by the direct method of Eggleston and Hatcher, 1915.

The ear symptoms are perhaps connected with congestion of the auditory apparatus (Kirchner, 1881; but Haike, 1904, believes these lesions to be asphyxial, artefacts). The brain vessels are dilated (Berezin, 1916).

Therapeutic Toxic Dose.—This has been investigated by Hanzlik 1913, in over 500 administrations. If the salicylates are administered in repeated doses of about 1 Gm., one or two hours apart, the "toxic" effects appear usually when the total dose of sodium salicylate attains between 7 and 13 Gm., 100 to 200 gr.; the mean being about 12 Gm., 180 gr. Women require about four-fifths of this dose. There are no differences between sixteen and seventy-five years of age. Children have a relatively high tolerance, *i.e.*, the toxic dose is much higher than would be calculated from their age (Archambault, 1878). The dose is the same for the white and the colored race. It is not affected by the presence or nature of disease. Occasionally there are unexplained idiosyncrasies or tolerance (toxic doses as low as 20 and as high as 1,300 gr.). These are usually only temporary. The toxic dose of acetylsalicylic acid and methyl salicylate is about two-thirds, that of salicyl-salicylic acid (MacLachlan, 1913) about one-half that of sodium salicylate. The toxic dose and effects of strontium salicylate are the same as for the sodium salt (Blankenhorn, 1916).

Dangerous poisoning by sodium salicylate is rare, and it is often difficult to judge whether the effects attributed to the salicylate were not really due to the disease.

The symptoms are described as vomiting, unconsciousness, delirium, dyspnea and deepened respiration (Quincke, 1888), fall of temperature, arrhythmia, albuminuria, paresis, collapse, asphyxial convulsions (Peterson, 1877; Weckerling, 1877; Allaire, 1879; Vinci, 1905). Sicard and Meara, 1915, attribute a case of sino-auricular block, with standstill of the entire heart, to salicylate. The *fatal dose* is stated as 5 to 12 Gm.; but must be very variable, even severe cases ending generally in recovery. The *autopsy* in Quincke's case showed hyperemia of the brain and its membranes, of the kidneys and lungs, and pericardial ecchymoses.

Acidosis.—Vuipcke called attention to the resemblance of serious salicylate poisoning to diabetic coma. Langmead, 1906, and Lees, 1908, emphasize this resemblance in children, and describe the occurrence of acetone even after relatively small doses of salicylates. The acetonuria is probably often due to the associated conditions of the disease rather than to the salicylate; but it is advisable to follow their suggestion to administer sodium bicarbonate for prophylaxis and treatment of any acidosis.

Toxic Effects in Animals.—These are similar to those in man. The respiration is deepened and labored, first quickened, then slowed to final asphyxia with convulsions. The blood pressure rises at first, then falls severely; the pulse is inconstant. The intracranial vessels are constricted (Wiechowski, 1902). There is general collapse and sometimes paralyses. The heart stops with the respiration. The autopsy shows the same congestions as in man (Koehler, 1876; Deseille, 1879; Blanchier, 1879; Quincke, 1882). The toxicity is low, the fatal dose per vein for dogs being about 1 Gm. per kilogram. Methyl and ethyl salicylates intravenously produce pulmonary edema by injuring the capillary walls.

Excised Heart.—The Straub frog-heart and the excised rabbit heart are depressed by perfusion with sodium salicylate 0.1 to 0.2 per cent. in blood; but the concentrations that could be attained in life have no effect (Fridericksen, 1917).

Skeletal Muscle and Nerve.—These are practically unaffected by moderate concentrations of salicylate.

Kidneys.—Salicylates may have a slight and inconstant diuretic effect (Blanchier, 1879). Full doses, however, decrease the output of urine, partly by diaphoresis, partly by water retention. This is accompanied by evidences of renal irritation (slight albumin and casts) and diminished renal permeability (phthalein test and non-protein nitrogen of blood). With the ordinary doses, these changes disappear rapidly, and apparently without permanent damage, on discontinuing the administration (Scott, Thoburn and Hanzlik, 1916; Leuthje, 1902; Knecht, 1904; Quenstedt 1905; Ehrmann, 1907).

The albuminuria, etc. occurs in normal individuals, and is therefore due to the drug, not to the rheumatic fever (Hanzlik, *et al.*). It is also produced in animals, by doses corresponding to the therapeutic. Their kidneys show histologically various grades of nephritis, especially cloudy swelling (Hanzlik and Karsner, 1917).

Highly toxic doses produce anatomic parenchymatous lesions (Vinci, 1905).

The albuminuria, edema, etc. are not modified by the administration of bicarbonate (Hanzlik, *et al.*, Ehrmann, 1907) contrary to the earlier claims (E. Frey, 1905; Glaesgens, 1911).

Salicyl Edema.—Full therapeutic doses of salicyl diminish markedly the quantity of urine, with an almost corresponding increase of body weight. This is demonstrable about 20 to 80 hours after the start of the salicyl administration. There is no dilution of the blood hemoglobin, so that the fluid must be mainly in the tissues; *i.e.*, this is essentially an edemic condition, although the edema is not visible (Hanzlik, Scott and Reycraft, 1917).

Continued Administration.—The effects of continued moderate doses are important because of the use of salicylate as food preservative. They have been investigated by Wiley, 1906, on healthy individuals. The drugs were administered in capsules or tablets of 0.2 to 2 Gm. per day. The appetite, digestion and utilization of food was at first increased. This effect became less apparent after a time, but the food consumption generally remained above normal. Notwithstanding this increased intake, there was a slight loss of body-weight and nitrogen. The excretion of phosphates was diminished. The quantity of urine was not affected; there was some tendency to albuminuria.

Metabolism.—Salicylates increase the elimination of nitrogen (Laqueur, Bruenecke and Crampe, 1912), especially in the form of *uric acid*; the latter is followed by a compensatory decrease (Kumagawa, 1898; Ulrici, 1901; Schreiber and Zandy, 1899). The increase of uric acid is probably due partly to lessened destruction, but the uric acid concentration in the blood is also decreased, in the same way as with atophan (Denis, 1915).

The normal non-protein nitrogen of the blood is not lowered; but when abnormally high it may be decreased. The creatine of the blood is not affected (Denis, 1915). Gaulier 1913, claims that the chloride excretion is diminished. Phosphate excretion is slightly increased (Denis and Means, 1916). There are few definite data on the respiratory metabolism (review, S. Weber, 1904). Denis and Means found uncertain changes in the basal metabolism in man.

The gastric secretion is somewhat decreased (Klocman, 1912); but the absorption of food is not materially affected. The secretion and flow of *bile* are somewhat increased.

Uric Acid.—The increased elimination is due (as with atophan) to increased permeability of the kidneys to uric acid; for the uric acid content of the blood falls during salicyl administration, to resume its original level when the salicyl is discontinued. In man, 6 Gm. of sodium salicylate may reduce the blood uric acid to one-half or one-third. The efficiency may be greater even than with atophan (Fine and Chace, 1915; Frank and Pietrulla, 1914; Denis, 1915). The increase of urate excretion may reach 30 per cent. (Denis and Means).

By less direct methods, Hall, 1904, and Rockwood, 1909, also reached the conclusion that the increased excretion of uric acid is not due to increased production; but they could not exclude diminished destruction of uric acid as a factor. Excised organs indeed destroy uric acid more rapidly in the presence of salicylic acid (Stookey and Morris, 1907). Waucomont, 1911, concluded that salicylates decrease the urate and purine excretion in experimental gout.

The para- and meta-isomers do not affect the uric acid excretion (Denis, 1915).

Postmortem Autolysis of the Liver is increased by small, and decreased by large concentrations (Lacqueur, 1912).

Cholagogue Action.—Salicylates are among the few drugs which cause a genuine increase of the secretion of bile (D'Aff and Balch, 1897; Okeda, 1915; Pitini & Fernandez, 1914). Other aromatic products which conjugate with sulphuric acid act similarly

(Petrova, 1912). Salicylates have been used in obstructive jaundice and biliary colic, but it is doubtful whether they are of value.

Diabetes Mellitus.—Salicylates have been credited with decreasing the output of sugar and the consumption of water (Ebstein and Mueller, 1876; von Noorden, 1912); but their efficiency is at best inconstant (Kaufmann, 1903).

Absorption, Fate and Excretion.—The salicylates are rapidly absorbed from mucous membranes, and circulate as such. Salicylic acid may be liberated in the stomach, but not in the blood or tissues. The esters are also readily absorbed from the intestines, partly after saponification, partly without decomposition. Some absorption of the esters occurs from the intact skin. Salicylate is excreted in all the secretions (sweat, Tachau; none in the feces, Hanzlik); but by far the larger part appears in the urine, mainly free, but partly conjugated. A part is oxidized to dioxybenzoic acid and hydroquinone. The excretion begins within fifteen minutes, and is practically completed in six to forty-eight hours. The rapid excretion explains the need of large and frequent doses. Larger doses may color the urine green.

Fate of Salicylic Acid.—The greater part of the salicylic acid is excreted as such, or conjugated with sulphuric and glycuronic acid. U. Mosso estimated that more than half is conjugated; but his methods are perhaps open to doubt. A part is oxidized to $C_6H_3COOH(OH)_2$, 1-2-5 (oxysalicylic, dioxybenzoic or gensitinic acid) and thence to hydroquinone, $C_6H_4(OH)_2$ (C. Neuberg, 1911; F. Angelico, 1921). It was formerly believed that the salicylic acid combined with glycocholic acid to form a compound analogous with hippuric acid, and named "salicyluric acid" (Bertagnini, 1856 and others); but this was probably merely impure salicylic acid, for modern workers have been unable to recover any salicyluric acid from either dog's or human urine (Baldoni; Neuberg; Hanzlik, 1916; Angelico, 1921). Baldoni announced two other derivatives but these are probably impure gensitinic acid.

Absorption of Salicylates.—This starts promptly, but a part of sodium salicylate may remain a considerable time in the stomach, especially if it has been precipitated as salicylic acid. Sodium salicylate is also absorbed from the rectum (Ziemsen; Massol and Minet, 1908); although not quite as readily as by mouth (Fiedler, 1905).

Absorption of the Esters from the Alimentary Canal.—The insoluble esters pass rapidly through the stomach, without material change, and are gradually absorbed from the intestines, (Burow, 1911, dogs with duodenal fistula). They are partly hydrolyzed and saponified, but a part is absorbed without decomposition, as indicated by the differences in the actions of acetyl-salicylic acid, *i.e.*, its greater activity, and the tendency to urticaria. This has been definitely established by the study of the urine. With full therapeutic ("toxic") doses the median percentage of unchanged esters in the urine of patients averaged about 25 per cent. of the total salicylate in the urine, when acetyl-salicylic acid was given; 6 per cent. with salicyl-salicylic acid; and only 0.2 per cent. with methyl salicylate. Acetyl-salicylic acid was found to be hydrolyzed in acid as well as in alkaline buffer mixtures within the physiological range (*i.e.* in the stomach as well as in the intestines), but was fairly stable at neutral reaction. Salicyl-salicylic acid and methyl-salicylate underwent but little hydrolysis; they must therefore be decomposed in the tissues rather than in the alimentary tract (Hanzlik and Presho, 1923, 1925).

Absorption from the Skin.—Free salicylic acid, sodium salicylate, methyl salicylate and some of the other esters, in ointments or alcoholic solutions, are absorbed by the skin but less rapidly than by mouth (Franceschini, 1906; Schumacher, 1908; Sauerland, 1912).

Sodium salicylate is absorbed from the skin much less than free salicylic acid (Lener-towicz, 1914).

The absorption by various channels has been studied by Lewin, 1912.

Diffusion through Colloid Membranes.—This is hastened by salicylic acid or sodium salicylate (Oswald, 1910; Hanzlik, 1912). Salicylic acid also enters living cells which are generally impermeable to other acids (Harvey, 1914).

Distribution in Organs.—Blanchier, 1870, investigated this in dogs and found the salicyl in the saliva, bile, cerebro spinal fluid, articulations, etc. Nencki, 1895, found it in the bile but not in the gastric juice. Filippi, 1900, demonstrated it in the synoviae, in the brain and in the spinal cord. Vinci, 1905, again confirmed its presence in all organs and secretions, but found more in the secreting organs (kidney, liver, gastric

mucosa) and in blood than in other organs (spleen and muscles). The nervous system showed the salicyl reaction only after large doses. Olmer and Totiau, 1910, confirmed its presence in cerebro-spinal fluid and found its quantity there independent of the dose. Stockman, 1906, found none in the saliva, traces in sweat, and considerable in the joint-fluid, blisters, bronchial mucus and pleural effusions. Scott, Thoburn and Hanzlik 1916, found the percentage in joint fluids of rheumatic patients a trifle smaller than in the blood. Hofbauer, 1915, concludes that it appears in the sputum only under certain conditions. The concentration in the aqueous humor was reported as higher than that of the blood (S. R. Gifford, 1922).

The concentration in the serum is perhaps a little higher than in the corpuscles (Fridericksen, 1917).

Distribution in Normal and Infected Animals.—Bondi and Jacoby, 1906, found the concentration of the salicyl highest in the serum, and relatively high in the joints, especially in rabbits infected with staphylococcus; so that infected joints would appear to have a higher elective affinity for salicylates. However, the evidence is not altogether convincing, as the data were obtained with very rough methods and the authors point out that the apparently larger quantity might be due simply to the serous effusion.

Free Salicylic Acid Does Not Exist in the Tissues.—Although salicylic acid may be liberated from sodium salicylate by high concentrations of carbon dioxide (Binz, 1876 and 1879), the buffer action of the tissues prevents the acidity from rising to the necessary level, even in asphyxia (Hanzlik, 1921). Scott, Thoburn and Hanzlik, 1916, also failed to find any free salicylic acid in the joint fluids of rheumatic patients.

Bondi and Jacoby, 1905, found that the salicyl is precipitated from the serum with the albumin by ammonium sulphate, and they believe that it forms labile compounds with serum albumin and polypeptids. More likely, however, the precipitation is simply an adsorption phenomenon.

Time of Excretion in Different Conditions.—This varies with the preparation, the dose, and also in different patients. It is possible that these differences may partly explain the variations in the efficiency and toxicity (Fraser, 1885).

Normal Time of Excretion.—Blanchier, 1879, investigated this on sodium salicylate, administered by mouth. It appeared in the urine in fifteen to eighteen minutes; with doses of 1 to 2 Gm. the excretion was completed in twenty-two hours; with 4 to 5 Gm. in forty-four hours. After continued administration, the excretion persisted from three to eight days. In dogs, the excretion was relatively slow; in herbivora, somewhat quicker than in man. Ehrmann, 1907, found the excretion in man completed in three to twelve hours. He believes that the excretion is hastened by alkalies. Gaulier, 1913, reports the excretion as completed in eighteen to twenty-six hours. The excretion was not influenced by giving sodium bicarbonate. It was not parallel to the excretion of methylene blue. After application of a salicyl ointment to the skin, the excretion lasted two days (Schumacher, 1909).

The elimination after intravenous injection has been studied by F. Mandel, 1908.

Excretion and Fate in Rheumatic Fever.—This averages about 10 per cent. less than in normal individuals; the deficit being greatest in the first ten to twenty hours of administration. It is not due to retention, or to differences of diuresis, but partly to excretion in the sweat, and chiefly to increased destruction. The percentage of salicyl in the blood and urine at this time is little more than half of that in normal subjects (Scott, Thoburn and Hanzlik, 1916). Ehrmann, 1907, claimed no difference between the normal and rheumatic.

Excretion in Other Pathological Conditions.—The excretion is also diminished in chronic alcoholism and morphinism; tuberculosis; and diminished renal efficiency (H. A. Scott, and Thoburn, 1917).

Purpus and Chebchowski report delayed excretion in *renal and circulatory diseases*.

Time of Excretion of Salicyl Esters.—Full therapeutic doses of acetyl-salicylic acid required a median of nearly 5 days; salicyl-salicylic acid and methyl salicylate, 2 to 3 days (Hanzlik and Presho, 1923, and 1925). Phenyl salicylate is said to be excreted more slowly than the other esters (Block, 1909; Pinczower, 1910).

Quantity of Total Salicyl Recovered from Urine.—With therapeutically toxic doses of sodium salicylate, Hanzlik recovered about 80 per cent.; with acetyl-salicylic acid, a median of 9.37 per cent.; with salicyl-salicylic acid, 63 per cent.; methyl-salicylate, 51 per cent.

Quantity of Salicyl Recovered.—This was investigated for sodium salicylate by U. Mosso, 1890, and for ethyl salicylate by Bondzynski, 1897. In each case 90 per cent. of the salicyl was recovered from the urine. However the methods give high

results. More recent investigations indicate that about 20 per cent. is not excreted, but destroyed (Hanzlik).

In rheumatic fever, and in some other pathologic conditions, the destruction is more extensive (36 to 55 per cent. for sodium salicylates; R. W. Scott, Thoburn and Hanzlik, 1917).

Antiseptic Action.—Free salicylic acid is about equivalent to phenol and benzoic acid; its salts, however, are scarcely antiseptic (Kolbe, 1874). The irritant effects disqualify salicylic acid as a surgical antiseptic. It has been used as a food preservative, but it is doubtful whether this should be permitted. Salicylates have a moderate antiseptic effect on the urine (Sollmann, 1908; Jordan, 1911), and may be used for this purpose. The saturated solution of salicylic acid has been recommended as a harmless fly-poison.

Action on Leucocytes.—Binz, 1875, found that these are paralyzed and killed, similar to quinine and many other aromatic derivatives. Ikeda, 1916, observed no effect on the emigration of white cells from inflamed mesentery. In mammals, the leucocytes of the blood are said to be doubled an hour after the administration, and return to normal in two hours but Gehrig, 1915, finds that salicylate and other antipyretics do not produce leucocytosis, as was commonly believed.

Local Actions on Skin.—The application of salicylic acid in substance or strong solution, produces a slow and painless destruction of the epithelium. It is used as ointment, 2 to 10 per cent., in itching skin diseases (urticaria) and against pityriasis versicolor; as lotion, 1 to 2 per cent., in alopecia; as powder, 3 per cent. in talc, against sweating feet; and in collodion, 10 to 20 per cent. and plasters to soften corns and warts.

Berkenbusch, 1915, recommends a 10 per cent. ointment (spread thickly) against skin inflammation, boils and eczema.

Hypersensitiveness of Skin to Salicylates.—Sauerland, 1912, found that external applications (not the systemic administration) of salicyl preparations cause a gradual development of persistent sensitiveness, leading to eruptions after an incubation period. This involved all parts of the skin, not only that to which the salicylate had been applied. The skin was not hypersensitive to other irritants.

Local Actions on Mucous Membranes.—Strong solutions of salicylic acid cause considerable irritation and superficial corrosion. The salts are free from this objection, and the free acid is therefore little employed internally. It also softens the enamel of the *teeth* and should not be used in mouth washes.

"Natural" and Synthetic Salicylates.—It is often stated that the synthetic sodium salicylate, owing to the presence of supposed impurities, is more toxic and less efficient than that prepared from oil of wintergreen or birch. The evidence for this view, which has been fostered mainly by interested manufacturers, can not stand critical examination. There need be no hesitation in employing the much more economical synthetic product (Rep. Counc. Pharm. Chem., 1913; J.A.M.A., (61:979).

The literature of the subject and its uncritical status have been fully discussed by Eggleston, 1912. Various impurities have been announced in synthetic salicylates, especially cresotic acids, phenol, para-hydroxybenzoic acid, and hydroxy-isophthalic acid; but the evidence for their presence is not convincing. However this may be, Hilpert, 1913, showed that at the present time even the cheapest commercial samples are quite as pure as the most expensive. Waddell, 1911, proved that the effects of natural and synthetic salicylates on animals are quantitatively alike; and the coöperative clinical tests, instituted by the Counc. Pharm. and Chem., arranged so as to exclude all bias, showed that their effects on patients are indistinguishable (Hewlett, 1913). In practice, it is almost impossible to be certain of their source, since the oils of wintergreen or birch are very often adulterated, beginning at the still.

Relation to Constitution to Specific Anti-rheumatic Action.—Phenol, $C_6H_5.OH$, is quite inactive. Bnezoic acid, $C_6H_5.CO_2H$, has a limited efficiency. The OH and CO_2H groups are both necessary, and must be in the ortho position to obtain the full efficiency. Derivatives, which can be converted into salicylic acid in the organism are effective, in proportion to the ease of their conversion; but if the H of either group is firmly combined (as in methyl salicylic acid, $C_6H_4.CO_2H.OCH_3$, and in salicyluric acid), they are inactive. The introduction of additional groups into the benzol nucleus, as in the cresotinic acids, does not disturb the action (May, 1909; Stockman, 1913).

Cresotinic Acids.—These were at one time blamed for the reputed higher toxicity of synthetic salicylates. In fact, however, they act very similarly and have about the same toxicity as salicylic acid (R. May, 1909; Stockman, 1890, 1909 and 1912; Waddell, 1911). They have a similar specific effect in rheumatic fever, although they are somewhat inferior. They have even been used therapeutically in doses up to 8 Gm. (Buss, 1876; Gatti, 1879; Demme, 1888). The resemblance is explained by their chemical structure, $C_6H_3.OH, CO_2H.CH_3$; with the OH and CO_2H in ortho position.

Isomers of Salicylic Acid.—Meta- and para-hydroxybenzoic acids, which differ from salicylic acid only in the position of the side-chains, are practically inactive and non-toxic. The efficiency therefore depends on the adjacent position of the OH and CO_2H groups. The cause of this has not been explained. Another difference is, that these isomers are excreted in combination with sulphuric acid instead of glycooll.

P-hydroxybenzoic acid, when given to monkeys, does not pair with glycooll (Sherwin, 1918).

PREPARATIONS

* *Acidum Salicylicum* (Acid. Salicyl.), U.S.P., B.P.; Salicylic Acid (Ortho-hydroxybenzoic acid), $C_6H_4.OH.COOH$. Prepared synthetically from phenol; or by saponification of methyl salicylate (oil of birch). White, light crystalline powder or needles, odorless or with faint odor of wintergreen, of sweetish, then acid taste. Slightly sol. in water (1:460); freely sol. in alc. (1:2.7) or eth. Dose, 0.75 Gm., 12 gr., U.S.P., 0.3 to 1.2 Gm., 5 to 20 gr., B.P.

Ung. Acid. Salicyl., B.P.—2 per cent. in Paraffin Ointment.

Ammon. Salicyl., U.S.P., $NH_4.C_7H_5O_3$. Resembles Sod. Salicyl. Freely sol. in water (1:1) or alc. (1:3). Dose, 1 Gm., 15 gr., U.S.P.

* *Sodii Salicylas* (Sod. Salicyl.), U.S.P., B.P.; Sodium Salicylate, $NaC_7H_5O_3$.—White amorphous or crystalline powder or scales, or not more than faint pink tinge, odorless, or disagreeably sweet saline taste. Very sol. in water (1:0.9), freely sol. in alc. (1:9.2). Incompatible with acids, iron salts, spirit of nitrous there and quinine. Dose, 1 Gm., 15 gr., U.S.P., 0.6 to 2 Gm., 10 to 30 gr., B.P.

Stront. Salicyl., U.S.P., $Sr(C_7H_5O_3)_2 + 2H_2O$.—Resembles Sod. Salicyl. Sol. in water (1:19) or alc. (1:61). Dose, 1 Gm., 15 gr., U.S.P.

Salicinum (Salicin.), U.S.P., B. P., $C_{13}H_{18}O_7$.—Colorless, silky, shining, crystalline needles or a white, crystalline powder; odorless, and having a very bitter taste. Sol. in water (1:23.5) or alc. (1:88.5). Dose, 1 Gm., 15 gr., U.S.P.; 0.3 to 1.2 Gm., 5 to 20 gr., B.P., in solution or wafers.

Salicin occurs in willow bark, which was used as antipyretic in antiquity. It also occurs in poplar bark. It was introduced against rheumatic fever by MacLagan, 1876, on the basis of the fancied resemblance to malaria. It is inferior to the salicylates, because its conversion is often incomplete. Salicin is a glucoside, yielding on hydrolysis *saligenin*, $C_6H_4(OH)CH_2OH$; this in turn is oxidized to salicylic acid (Nencki, 1870), but a part is excreted unchanged. Salicin yields 45 per cent. of salicylic acid, and is therefore at most half as effective.

ACETYSALICYLIC ACID (ASPIRIN)

This was introduced by Dreser, 1899. It was supposed that it would pass unchanged through the stomach, thus avoiding gastric irritation; and that the salicylic acid would be liberated in the intestine. In fact, however, it produces some gastric irritation (Roch) and the intestinal decomposition is slow and incomplete, a part being absorbed unchanged. Acetyl salicylic acid is about one and one-half times as toxic as sodium salicylate in man (Hanzlik, 1913); about twice as toxic in animals (Chistoni and Lapresa). In man even small doses (0.3 to 0.65 Gm., 5 to 10 gr.)

occasionally produce *alarming symptoms*, especially acute local or general edema of the skin and mucous membranes, urticaria, erythema, pruritus, etc. (Graham, Morgan, Gilbert, 1911; Krause, 1914; literature of side actions, Seifert, Nebenwirk, 1915, p. 12.) The effects of poisonous doses in animals are similar to other salicylates (Block, 1909). These side effects make this drug inferior to sodium salicylate in rheumatic fever. It has, however, stronger analgesic and antipyretic actions, even in non-rheumatic affections, perhaps because the undecomposed acetyl compound enters the nerve cells more readily. It is used extensively in colds, influenza and other fevers; and in neuralgias, headaches, tabes, and other pains, in tablets or capsules of 0.3 Gm., 5 gr.

Desensitization.—Widal and Vallery-Radot, 1920, claimed to have desensitized a hypersusceptible patient by graduated dosage.

Chronic Poisoning.—Symptoms of conjunctival catarrh and urticaria have occurred after six years of the continued use of 20 grains daily (Stiell, 1917).

PREPARATIONS

* *Acidum Acetylsalicylicum* (Acid. Acetylsal.), U.S.P., B.P.; Aspirin; $C_6H_4O(CH_3CO)COOH$.—White, crystalline, odorless powder of sour taste. Slightly sol. in water (1:300), freely sol. in alc. (1:5). *Dose* 0.3 Gm., 5 gr., U.S.P., 0.3 to 1 Gm., 5 to 15 gr., B.P., in powder, tablets or capsules. *Maximum dose*, 1 Gm., 15 gr. It forms soluble salts with calcium (Bercke, 1912; Lewin, 1912) and with methylenamine (Puckner, 1913); but these are unstable.

Practically all American brands are of the pharmacopeial standard (Leech, 1918).

Incompatibilities of Acetyl-salicylic Acid.—These are so numerous that it should always be prescribed in pure, solid form. It is decomposed by water, by the weakest alkalies, even by acetates or lime water, by the weakest acids; and it is incompatible with acetanilid, antipyrine, quinine, methenamine, ammonium chloride, potassium iodide, iron salts and tannates, (Bulletin of the American Drug Manufacturers Association, 1923 page 177).

Novaspirin.—The methylene-citryl ester of salicylic acid is said to be but slowly absorbed, and therefore, to be less powerful than aspirin, and less liable to produce unpleasant side effects (Koerner, 1910; Dreser, 1907). The literature of its side actions is given by Seifert, Nebenwirk, 1915, page 25.

Salicyl-salicylic Acid (Salsal, Diplosal).—Tasteless and yields one-half more salicylic acid than aspirin and one-fourth more than sodium salicylate—a matter which is easily compensated by the dose. Its toxicity in man is twice that of sodium salicylate (MacLachlan, 1913). It is very resistant to gastric juice, but is rapidly saponified by the duodenal secretion (Tocco, 1912).

METHYL SALICYLATE

This acts somewhat more slowly, but otherwise as efficiently as sodium salicylate; the "toxic" dose being about two-thirds of that of the sodium salt. The effects may be considerably delayed, suggesting slow and irregular absorption (Hanzlik and Prescho, 1925). It is given internally in extemporaneous capsules; or externally as counter irritant, generally diluted with 1 to 2 parts of olive oil and painted over the affected region.

Fatal poisoning by methyl salicylate is rare but has been reported (Nerthney, 1903), especially from its use as abortifacient. An ounce is usually fatal, with convulsions, coma, gastritis and congestion of the kidneys (Pinkham, 1887).

Rosenbloom and Johnston, 1919, report severe poisoning, after one ounce, but with ultimate recovery. There was immediate emesis; later, severe salicylism and albuminuria, both persisting about a week. They cite the bibliography.

Ethyl salicylate is less irritant and half as toxic (Houghton, 1903). Spirosal is used externally being non-irritant and easily absorbed (Impens, 1907; literature, Seifert, Nebenwirk., 1915, p. 32).

Mesotan was introduced by Floret, 1902. It is decomposed by water into salicylic acid, formaldehyde and methyl alcohol. It is used externally, but has caused dermatitis.

PREPARATIONS

**Methyl Salicylas* (Methyl. Salicyl.), U.S.P., B.P.; *Oleum Betulae* (Ol. Betul.), U.S.P.; *Oleum Gaultheriae* (Ol. Gauth.), U.S.P., B.P.; Methyl Salicylate; Oil of Sweet Birch; Oil of Gaultheria (Wintergreen), $C_6H_4OHCO_2CH_3$.—Produced synthetically or obtained by distillation from Gaultheria procumbens or from Betula lenta. A colorless, yellowish or reddish liquid; characteristic odor and taste of gaultheria. It is sparingly sol. in water; sol. in all proportions in alc. *Dose*, 0.75 c.c., 12 minims, U.S.P.; 0.3 to 1 c.c., 5 to 15 minims, B.P. *Maximum dose*, 2 c.c., 30 minims.

PHENYL SALICYLATE

Salol was introduced by Nencki, 1886. Being insoluble, it passes the stomach practically unchanged; but is gradually decomposed into its components, 40 per cent. of phenol and 60 per cent. of salicylic acid, in the intestine, by the saponifying action of the alkali, pancreatic lipase and putrefactive bacteria. This avoids the taste of the components and the local gastric action; and since the decomposition is gradual, the local intestinal action is less violent but more prolonged, and the toxicity is materially lessened. This "Nencki's salol principle" has been extensively applied in the form of other phenolic esters, *f.i.*, guaiacol carbonate, to mitigate the taste, local actions and toxicity of other active phenols or acids.

Therapeutic Uses.—Salol proper has not fulfilled the original expectations. The toxicity of the phenol limits the dosage, and its absorption is so slow that it is practically inferior to the other salicyl compounds in rheumatism or as urinary antiseptic (Sollmann, 1908). The phenol component was thought to be valuable as intestinal antiseptic, especially in infantile diarrhea; but the decomposition is so slow and the absorption of the phenol so rapid that effective quantities could scarcely come into action. The clinical and experimental evidence is not conclusive (Harris, 1912). As a wound antiseptic it would be valueless because it is not decomposed by wound secretions and only very slowly by bacteria. Its use in tooth powders has caused eczema of the lips (Hugenschmidt, 1907). Perhaps its main value is as a coating for "enteric pills," *i.e.*, pill masses which are intended to pass the stomach unchanged (*f.i.*, ipecac in dysentery). It must be remembered that a coating sufficiently heavy to be effective introduces large doses of salol.

Decomposition and Antiseptic Action.—Salol is also decomposed to a slight extent in the mouth and stomach by bacteria (Lesnik, 1887). It is split by human milk, so that its administration to nursing infants may cause gastric irritation (Usener, 1912). Its saponification by pancreatic ferments and alkalies is very slow and incomplete, insufficient to prevent putrefaction even in test-tube experiments; it is inferior to sodium salicylate or bismuth subnitrate (Sollmann, 1908). Its antiseptic action on the blood is also slight. A part escapes decomposition in the intestines and passes unchanged into the feces—5 to 8 per cent. in the experiments of Bondzynski and Humnicki, 1909; but doubtless often much more. If given in capsules, it may be found in the feces as crystals, "*salol calculi*" (Brossard, 1897), formed by the partial fusion and recrystallization of the salol (C. R. Marshall, 1897). It should therefore be administered subdivided as emulsion or with indifferent powders.

PREPARATIONS

**Phenylis Salicylas* (Phenyl. Sal.), U.S.P.; *Salol*, B.P., $C_6H_5(OH)COOC_6H_5$.—White crystalline powder, of faint aromatic odor and taste. Very slightly sol. in water

(1:6,670); freely sol. in alc. (1:6); very sol. in fixed or volatile oils. *Dose*, 0.3 Gm., 5 U.S.P.; 0.3 to 1.2 Gm., 5 to 20 gr., B.P., in powders, generally with bismuth. Externally, as 5 per cent. ointment. *Maximum dose*, 2 Gm., 30 gr.

BENZOIC ACID AND BENZOATES

Benzoic acid, $C_6H_5.CO_2H$, occurs in the balsams (Benzoin, Tolu, etc.), in cranberries and in other vegetables; and in the decomposed urine of herbivora. It is now prepared synthetically. It is a fairly strong antiseptic of about the same rank as phenol; the salts are somewhat less efficient. The free acid in concentrations above 0.1 per cent. produces moderate local irritation; the salts are not irritant. The systemic toxicity is very low, even large doses producing mainly digestive derangement, sometimes with further effects, resembling those of salicylates. There is also a similar, but weaker therapeutic action in rheumatic fever. Fatalities are unknown. Benzoic acid combines in the kidneys with glycocoll to form the inactive hippuric acid.

Use as Food Preservative.—The low toxicity and the absence of odor or marked taste has led to the use of benzoates for the preservation of foods, especially fruits and vegetable products. Sodium benzoate is generally employed for this purpose in the concentration of 0.1 per cent.; in acid foods, especially fruits, most of the benzoic acid would be liberated. This concentration suffices to restrain bacterial growth considerably, but may not prevent it completely.

Antiseptic Efficiency.—Buchholz, 1875, found the free acid to be germicidal in 0.4 per cent., and antiseptic in 0.1 per cent. Salkowski, 1899, found that 0.25 per cent. kept meat sterile for five months; with 0.1 per cent. there were only a few colonies. Sodium benzoate in neutral media inhibits growth in 0.3 to 0.5 per cent. (Th. Smith).

Action on Digestive Ferments.—In test tubes, benzoic acid up to 0.1 per cent. does not interfere markedly; but higher concentrations are detrimental, especially to pepsin (Leffmann, 1899). However, peptic digestion proceeds fairly rapidly, even in a saturated solution (Dakin). These actions have no practical importance (Long, 1912).

Actions of Moderate Doses.—These are especially important in view of the use of benzoates for the preservation of food. In a very careful investigation, Chittenden, Long and Herter, 1911 (Report 88, U. S. Dept. Agr.), could not demonstrate any effects on healthy individuals, if larger quantities than are likely to be used in foods, 0.5 Gm. per day, were continued for weeks. Even still larger doses, to 4 Gm., were not generally injurious. They were sometimes followed by indications of slight digestive disturbance (Herter); but it is doubtful whether these had any significance. Excessive concentrations (above 0.1 per cent.) of the free acid, consumed too freely (as in cider or fruit juices) probably cause more pronounced gastro-intestinal irritation (Lucas, 1910) but not albuminuria (Herter, 1910; Gerlach, 1909). These concentrations have a noticeable taste which might serve as a warning. There is no reason to assume that the benzoate has a cumulative action, since it is promptly excreted as hippuric acid; nor is there any evidence that the formation of this acid is in any way detrimental.

Investigations of the Referee Board.—Chittenden, Long and Herter each experimented on four to six healthy young men, administering sodium benzoate, dissolved in food or drink, 0.3 Gm. per day for two months, then 0.6 to 1 Gm. for one to two weeks, and 4 to 6 Gm. for shorter periods. Clinical observations and extensive analyses of food and excreta were made. Chittenden and Long observed no effects whatever on the general

feeling of the subjects; on pulse or blood pressure; red or white blood corpuscles or hemoglobin; no loss of appetite, nausea, headache, intestinal disturbance and no change in the intestinal flora. The body-weight did not diminish; the digestion, assimilation and utilization of fat or protein food; the composition of the feces; the N-balance; the quantitative composition of the urine; and the distribution of nitrogen, remained absolutely normal. There was no indication of damage to the kidneys.

Herter agreed with these negative results; but with doses above 1 Gm., he observed a slight increase of indican, of coecal bacteria and of free gastric hydrochloric acid. These effects could mean a slight irritant action from the use of these doses, which, however, are larger than would ordinarily be introduced with foods.

The Prussian Scientific Deputation of Medical Affairs, 1911, accepted the conclusion that 0.5 Gm. distributed in small doses during the day, are innocuous; but they do not consider the experiments with doses of several grams as affording proof of absolute harmlessness.

The conclusions of Wiley and his collaborators (Bull. 84, 1908), were less favorable. Their experiments were also made on healthy young men with doses of 1 to 2.5 Gm.; but these were given dry in capsules, offering opportunity for more violent local actions than when the benzoate is dissolved, as in food. This may in part explain the claimed deleterious results (gastric pain, vomiting, digestive and metabolic disturbances, reduction of body-weight, etc.). However, these results were not very striking, nor their causal connection with the benzoate administration at all conclusive (K. B. Lehmann, 1911).

Effects of Large Doses.—Sodium benzoate is tolerated without serious symptoms even in much larger doses, at least up to 60 Gm. per day (*f.i.*, Jaksch, 1897). Such doses were formerly used in therapeutics. There are generally symptoms resembling those of salicylates (Lewinski, 1908; Rost, Franz and Heitzel, 1913); as with the latter, the dose required to elicit these symptoms varies greatly: Nausea and vomiting were obtained in some cases with 6 to 8 Gm. (Meissner and Shepard, 1866); whilst in others, 25 Gm. had no effect. The urine sometimes contains reducing substances, presumably glycuronic acid, especially if very large doses (25 Gm.) are taken (Lewinski).

Toxic Effects on Animals.—These are analogous to phenol: gastric irritation, vomiting, dyspnea, decrease of reflexes, narcosis, sometimes convulsions (Kobert and Schulte, 1880). Dogs tolerate 1.7 Gm. per kilogram by vein without danger. This produces short vagus stimulation and prolonged rise of blood pressure (Naumann, 1879).

Permissibility of Benzoated Foods.—These investigations justify the conclusion that healthy individuals may safely consume reasonable quantities of benzoated foods (0.5 Gm. of benzoate per day, in concentration of 0.1 per cent.), if these foods are not otherwise spoiled or unhealthy; but the patients with gastro-intestinal or renal diseases would do better to avoid them. Benzoate is probably the least harmful of food preservatives, and where these are needed, its use appears permissible; provided that its presence is stated so that it may be avoided by patients to whom it could be harmful. However, it is very difficult to pass a final judgment on such questions.

Possible Objections.—The evidence in favor of benzoates is really negative, viz., that no deleterious effects have been proven. Such negative evidence is always open to the objection that our methods of investigation are not sufficiently delicate or comprehensive, or otherwise are not adapted to reveal the possible deleterious effects. More serious probably is the objection that the investigations have so far been confined almost exclusively to healthy individuals. It is quite conceivable that irritant actions which would be too feeble to influence normal organs, might become deleterious to these organs, especially the gastro-intestinal tract or kidneys, if these are already diseased, or when the

general resistance is lowered. Herter, 1910, advises against the free use of benzoates in dyspepsias. There is also evidence that the formation of hippuric acid, which is probably in part responsible for the harmlessness of benzoic acid, is interfered with in at least some types of kidney diseases.

Hippuric Acid Synthesis.—Benzoic acid and its homologs (cinnamic acid, quinic acid, etc.) combine in the body with glycocholic acid to form hippuric acid, which is excreted in the urine. The normal hippuric acid (averaging 0.7 Gm. per day in man) arises in this manner from the benzoic acid occurring naturally in vegetable foods; and from its homologs which are formed in protein putrefaction in the intestines (Salkowski, 1885; Baumann, 1886). The synthesis of hippuric acid was discovered by Woehler. Meissner and Shepard, 1866, showed that this occurs in the kidneys. Bunge and Schmeideberg, 1877, demonstrated the process in excised kidneys, and believed that this is the only organ concerned in dogs. However, considerable hippuric acid is formed in nephrectomized dogs (Kingsbury and Bell, 1915). In herbivorous animals, the synthesis also takes place partly in other organs (Salomon, 1877), in the small intestines and liver (Jaarsveld and Stokvis, 1879).

The liver also participates in dogs; for the hippuric acid is diminished by the injection of hydrazone, which induces fatty degeneration of the liver, but is supposed to leave the kidneys untouched (Lackner, Levinson and Morse, 1918). Chickens do not form hippuric acid (Yoshikawa, 1911). In man, benzoic acid up to 10 Gm. per day is excreted almost quantitatively as hippuric acid (Dakin, 1910) (85 to 90 per cent. within five or six hours; H. B. Lewis, 1914). With very large doses (25 Gm., Lewinski) a part escapes synthesis. After the administration of benzoic acid, a fifth of the total nitrogen of the urine may be in the form of hippuric acid. Injected hippuric acid is excreted rapidly, *i.e.*, within nine hours (Raiziss, Raiziss and Ringer, 1914).

In parenchymatous nephritis, even smaller quantities are excreted in part as benzoic acid (Jaarsveld and Stokvis, 1879; Kronecker, 1883).

Uric Acid.—Large doses of benzoates (8 Gm. per day, in man) increase the elimination of urates in the urine, and decrease the urate content of the blood. The effect is therefore similar to salicyl. The creatinine of the blood is not lowered (Denis, 1915).

H. B. Lewis and Karr, 1916, observed a marked decrease in uric acid excretion during the period of maximal hippurate excretion, after 7 to 8 Gm. of benzoate. This effect is not produced by administering hippuric acid directly. Creatinine excretion was not affected by the benzoate.

Therapeutic Uses.—The slightly irritant and stimulant action of free benzoic acid is sometimes used to promote expectoration in bronchitis with abundant thin secretion; and in the form of benzoin, to promote the healing of small wounds, chapped hands, etc.

Benzoate was formerly employed in uric acid diseases (Ure, 1841); in arthritis, where it acts similarly to salicylates, but weaker; in tuberculosis; and as diuretic and antiseptic in cystitis. It is not diuretic, and its antiseptic action on the urine is even weaker than that of the salicylates (Sollmann, 1908).

PREPARATIONS

Acidum Benzoicum (Acid. Benz.), U.S.P., B.P., $C_6H_5.COOH$.—Obtained from benzoin by sublimation, or prepared synthetically. Colorless, lustrous scales or needles; odor resembling benzoin, acid pungent taste. Slightly sol. in water (1:275), freely sol. in alc. (1:2.3). *Dose*, 1 Gm. 15 gr., U.S.P.; 0.3 to 1 Gm., 5 to 15 gr., B.P.

Troch. Acid Benz., B.P.—0.03 Gm., $\frac{1}{2}$ gr.

Ammon. Benz., U.S.P., B.P., $NH_4.C_6H_5O_2$.—White, laminar crystalline powder; odorless, or a slight odor of benzoic acid, saline, bitter, afterwards lightly acid taste; gradually losing ammonia on exposure to air. Sol. in water (1:10) or alc. (1:35.5); freely sol. in glyc. (1:8). *Dose*, 1 Gm., 15 gr., U.S.P.; 0.3 to 1 Gm., 5 to 15 gr., B.P.

Sodii Benzoas (Sod. Benz.), U.S.P., B.P., $NaH_7C_6O_2$.—White powder; odorless; sweetish taste. Freely sol. in water (1:18.); sol. in alc. (1:61). Incompatible with acids and iron. *Dose*, 1 Gm., 15 gr., U.S.P.; 0.3 to 2 Gm., 5 to 30 gr., B.P.

* *Liquor Antisepticus Alkalinus*, N.F.—A mildly antiseptic, alkaline and demulcent mouth wash, containing about 25 per cent. of glycerin; 3 per cent. each of sodium benzoate and potas. bicarbonate; 0.8 per cent. of sodium borate; flavored with thymol and aromatic oils, and colored purplish red with persicins. Applied with 4 to 5 volumes of warm water.

CINNAMIC ACID

Cinnamic acid, $C_6H_5.CH:CH.COOH$; its soluble sodium salt and Balsam of Peru (which contains large quantities of cinnamic-benzyl ester and free cinnamic acid) produce leucocytosis. They were administered intravenously by Landerer against tuberculosis, with the idea of setting up a localized inflammatory reaction about the tubercular foci, leading to cicatrization. The results have been disappointing and the treatment has gone out of fashion. Sodium Cinnamate (Hetol) and its administration are described in Rep. Counc. Pharm. Chem., 1911, p. 60.

Not much is known about the pharmacologic actions of cinnamic acid. Erdmann and Marschand, 1842, showed that it is largely converted into benzoic and hippuric acid. It has no effect on urate metabolism (Denjs, 1915). Cinnamic acid has been proposed as a food preservative; but the German commission decided that whilst its toxicity is low, its harmlessness has not yet been sufficiently demonstrated to make its use permissible (Heffter and Rubner, 1914).

QUINIC ACID

This is hexahydro-tetraoxy-benzoic acid $C_6H_7(OH)_4.COOH.H_2O$. It occurs in cinchona bark, coffee and many other plants. In man (also in rabbits, not in dogs; Stadelmann, 1879) it is largely transformed into benzoic acid and excreted as hippuric acid (Lautemann, 1863). Weiss, 1899, claimed that it lessened the formation of uric acid and that it had a beneficial effect upon gout. Decreased urate elimination was also claimed by Forester, 1900. Several observers reported clinical benefits, and various compounds were placed on the market (*urosine, sidonal, chinotropin*, etc.). Further observations, however, showed the effects to be inconstant (Delacamp, 1901) or rather negative (Hupfer, 1903; Fatavall and Gies, 1903; Waucumont, 1911). Denis, 1915, found neither increase of urate elimination nor decrease of the urate content of the blood.

CINCHOPHEN

This substance, which was introduced under the name of atophan, is phenyl-quinoline-carboxylic acid:

Its actions closely resemble those of the salicylates. It is about equally effective as analgetic and antipyretic, and provokes an even greater excretion of uric acid, by a direct action on the kidneys. The side-actions are usually smaller, and the toxicity is lower even than with the salicylates. It was introduced by Nicolaier and Dohrn, 1908, to eliminate uric acid in gout; but the relief seems to be due almost entirely to its general analgetic effect. Large doses are administered in rheumatic fever, in place of the salicylates; and smaller doses are used in tonsillitis, colds, influenza, headache.

Cinchophen is but slightly soluble in water; but its acidity produces some irritation in the throat and stomach. Neocinchophen (tolysin), in which the carboxyl hydrogen is replaced by an ethyl group, and an hydrogen in the quinoline by a methyl group, lacks this acid action, and is therefore non-irritant. Its limited solubility appears to preclude the absorption of toxic doses; but is sufficient for the therapeutic effects. Other related compounds have been investigated by Impens, 1912.

Administration as Analgetic and Antipyretic.—The usual dosage of cinchophen is 0.5 to 1 Gm. suspended in water, four times per day. With larger doses, it is advisable to render the urine alkaline for one or two days by the administration of 15 Gm. of sodium bicarbonate, acetate, or citrate,

to prevent the precipitation of urates. Neocinchophen may be given as tablets in the same dosage. The cinchophens are fairly efficient against neuralgic and rheumatic pain, and sometimes even against sciatica (McLester, 1913); but as most analgetics, they tend to become less effective with continued use. Gifford, 1922, believed that the continued use of 2 Gm. per day diminishes the congestion in irido-cyclitis.

The antipyretic action has been studied on animals by Barbour and Lozinsky, 1923.

Acute Rheumatic Fever.—Neocinchophen is generally as efficient as the salicylates; 2 Gm. may be repeated every 2 hours for 3 doses, then every four hours. Partial relief has occurred with 7 to 8 Gm.; complete relief of fever, pain and swelling generally requires 10 to 16 Gm. The patients do not show the nausea and other symptoms of salicylism, nor does there appear to be any renal irritation with therapeutic doses, (Hanzlik et al., 1921; Barbour, Lozinsky and Clements, 1923).

Antiphlogistic Action.—It has been claimed that the administration of cinchophen diminishes experimental inflammatory edema in croton-oil dermatitis and mustard-oil chemosis (Wiechowski and Starkenstein, 1913; Starkenstein, 1919); but this holds true only of doses that produce collapse (Fuerst, 1925). Doses corresponding to the therapeutic toxicity do not improve chemosis, or phosgene pulmonary edema (Laqueur and Magnus, 1921), nor paraphenylene-diamine anasarca (Hanzlik and Tainter, 1923).

Cinchophen inhibits completely the emigration of *leucocytes* in the inflamed frog's mesentery, and exhibits in this respect a potentiated synergism with quinine (Ikeda, 1916).

Use in Gout.—The mobilization of uric acid was supposed to be useful in gout by removing it from the blood and by dissolving the tophi. The uric acid and the non-protein nitrogen of the blood are in fact lowered by it (Folin and Lyman, 1913). Zuelzer, 1911, states that the increase of urate excretion in gout is more marked and prolonged than in health. Feulgen, 1912, claimed that the tophi are actually decreased in some cases. Clinically, however, cinchophen is much less efficient in chronic gout than in the acute attacks and in non-uratic joint affections. This throws some doubt on the uric acid explanation, and makes it probable that cinchophen acts similarly to salicyl, perhaps as a specific analgesic. In agreement with this, Klemperer, 1913, found derivatives which lack the uratic action equally efficient clinically.

Effect on Uric Acid Elimination.—The excretion of uric acid is greatly increased, sometimes more than doubled by therapeutic doses, even on a purin-free diet. The increased excretion begins within an hour (maximum in three hours) and lasts only so long as the drug is continued; and is followed by a compensatory decrease (Haskins, 1913). With continued administration, the uric acid returns to normal after one or two days, unless the diet contains purins. In that case, the decrease may be postponed till the fifth day (Grabfield and Pratt, 1922). The uric acid of the blood is diminished by the increased excretion (Folin and Lyman, 1913; McLester, 1913), but soon reaches an irreducible minimum; there being no further lowering even if the administration is continued forty-five days. When the administration is stopped, the initial concentration is restored within two to four days (Fine and Chace, 1914; Frank and Pietrulla, 1914). The effects on the blood were also studied by Base, 1914.

The effect is attributed to increased permeability of the kidneys for urates. The concentration of urates in the urine may become so great

that they are precipitated before the urine is voided; cinchophen apparently also decreases the solubility of urates in urine (Haskins, 1916). The urine is of a dark color, due to urochrom (Skorczewski, 1912). In other respects, its composition and quantity are not notably changed. The leucocytes of the blood are also unaltered.

Mechanism of Action.—This has been attributed to increased destruction of nucleoproteins (Starkenstein, 1911; Schittenhelm and Ullmann; Retzlaff, 1913); to increased eliminative activity of the kidneys for uric acid (Weintraud; Bauch, 1911; Folin and Lyman, 1913; Fine and Chace, 1914); to conversion of adsorbed into filtrable uric acid (Frank and Pietrulla, 1914); to an intestinal action (Abl); and to increased formation of uric acid by lessened oxidation of its purin and nuclein precursors; perhaps as the result of its more rapid elimination (Dohrn; Frank and Prozedborski; Skorczewski, 1912). The curve of excretion—temporary increase followed by compensatory decrease—and the lowering of the uric acid concentration of the blood indicate increased elimination of uric acid already present in the body. Weintraud, and Frank and Pietrulla, 1914, find that uric acid injected into the blood is excreted more rapidly. The urate excretion is not increased by cinchophen in kidney disease (Fine and Chace, 1915). The absence of increased phosphate elimination speaks against destruction of nucleoproteins. The decrease of allantoin indicates diminished destruction of uric acid in animals, but this might be different in man. In surviving organs, cinchophen does not lessen the destruction of uric acid (Starkenstein).

Other Changes in the Urine.—Skorczewski and Sohn, 1912, found an increase of purin bases and of neutral sulphur (parallel to the urochrom; Skorczewski, 1913); retention of chlorides and the diazo-reaction. Fromherz, 1912, did not find the uric acid increased in dogs; but Starkenstein, 1911, reports increase in rabbits and dogs, with diminished allantoin. Schittenhelm and Ullmann, 1913, found no increase of allantoin, but higher total N excretion in dogs. Biberfeld, 1913, found no increase in purin bases, but increase of phosphate in dogs. McLester, 1913, finds an increase in the quantity of urine and of total nitrogen. Eisner, 1915, reports the excretion of chloride and total nitrogen as often diminished. Renal-function tests gave inconstant results.

The creatine content of the blood is not decreased (Denis, 1915). In birds, the uric acid is decreased. The cinchophen itself is oxidized in the benzol nucleus (Dohrn, 1912).

Side Actions.—The precipitation of uric acid contraindicates its use in urate calculi. It is generally free from other unpleasant effects, even in large doses; but occasionally it produces vertigo, digestive disturbances, complete anorexia, cardiac distress (Loening, 1913) and purpural, urticarial and scarlatiniform skin eruptions and fevers (Mueller; Phillips; Herrick, 1913; Maranon, 1914).

Toxic Actions on Animals.—Large doses produce convulsions, paralysis and coma. Intravenous injection, in rabbits, is followed by stimulation of the vagus and vasomotor centers; these, as also the respiratory center, are finally depressed. The pupils are constricted, even after atropine. Cinchophen is said to prevent asphyxial and puncture glycosuria (Starkenstein and Wiechowski, 1914). The fatal dose of cinchophen with oral administration to dogs is about 1.25 gm. per Kg., about twice as high as that of acetyl-salicylic acid. Neocinchophen is not toxic in any dose, as only a limited quantity is absorbed (Barbour and Lozinsky, 1923).

PREPARATIONS

**Cinchophenum* (Cinchophen.), U.S.P.; Cinchophen (Phenylcinchoninic acid; Atophan; Phenylquinoline carboxylic acid), $C_6H_5.C_9H_6N.(COOH)$.—Small colorless needles or white powder; odorless; bitter taste. Almost insol. in water; slightly sol. in alc. (1:120); sol. in alkalis. *Dose*, 0.5 Gm., 8 gr., U.S.P.

**Neocinchophen* (Novatophan, Tolysin).—The ethyl ester of methyl-cinchophen. Pale yellow crystalline powder; odorless and tasteless; nearly insol. in water and dilute alkalis; sol. in hot alc. *Dose*, 0.5 Gm., 8 gr.

ANTISEPTIC BENZOL DERIVATIVES

These differ from the antipyretic derivatives mainly by greater toxicity. On local contact they coagulate proteins, thus determining the death of cells, resulting in irritation and inflammatory changes, and in antiseptic effects. After absorption they produce some excitement and more pronounced depression of the central nervous system. Many alter the blood pigment to methemoglobin. Their effects are similar in principle, but differ in important details. The high toxicity is due to various side-chains, such as the hydroxyl and carboxyl groups, by which they can react with protoplasm.

Historical.—In the form of the natural mixtures, the antiseptic properties of this group have been long known empirically, as in the smoking of meat. One of the methods of embalming practised by the Egyptians utilized largely balsams and products rich in essential oils—the latter being very closely related to the aromatic series. The isolated substances, however, belong to the achievements of the nineteenth century. Creosote was first made in 1832, phenol in 1834; but almost thirty years elapsed before they were used in surgery.

Influence of Structure on Action.—Benzol, C_6H_6 , the mother substance of the coal-tar series, has a low toxicity, because it does not readily react with protoplasm. This capacity is given to it by replacing part of the H atoms by other groups, especially by OH (forming phenols) or by CO_2H (forming acids); or by both. The *OH radical* is the most active, the antiseptic and toxic actions increasing with the *number of OH groups* (*i.e.*, progressively from phenol, C_6H_5OH , to resorcin, $C_6H_4(OH)_2$, and pyrogallol, $C_6H_3(OH)_3$) but it is also influenced by the position; thus, phloroglucin, the isomer of pyrogallol, is not active. The introduction of the *CO₂H group* alone (*i.e.*, benzoic acid, $C_6H_5.CO_2H$), does not render the substance very active. The introduction of both OH and CO_2H in the

ortho-position¹ (*i.e.*, salicylic acid, $C_6H_4 \begin{smallmatrix} \text{OH} \\ \text{CO}_2\text{H} \end{smallmatrix}$) results in a compound

which is less toxic and less antiseptic than phenol, but which has peculiar antirheumatic properties. The antiseptic quality may also be brought out by *other acidyl groups* ($COCH_3$, etc.), the activity being proportional to the size of the introduced molecule. NO_2 also develops the antiseptic action, but adds its own toxicity to that of the phenols. The substitution

of an H of the C_6H_5 in phenol by *alkyls* (*cresols*, $C_6H_4 \begin{smallmatrix} \text{OH} \\ \text{CH}_3 \end{smallmatrix}$) leads to an

increase of the antiseptic power, and diminishes at the same time the toxicity to tissues. *Higher homologues* introduce no important modifications. The union of two phenols directly or by CH_2 , etc., increases the antiseptic action, but if united by CO or SO_2 , it is diminished. The *substitution of halogens* increases the antiseptic action, according to the number of atoms. The toxicity is diminished by the lower, increased by the higher numbers (Bechhold and Ehrlich, 1906).

¹ When the substitution occurs in the position 1,2, the ortho-compound results; 1:3 gives the meta compound; and 1:4 the para-compound.

The violence of the action may be moderated by replacing the H of the OH by other radicals (the "Nencki's salol principle"). These *esters* (e.g., salol $C_6H_4.OH.CO_2.C_6H_5$) develop their action when decomposed into their phenol. Combinations which are so firm as to prevent this liberation (e.g., the phenolsulphonates) are neither antiseptic nor toxic: in fact, it is by the formation of such compounds that the organism protects itself against these poisons.

The antiseptic and local actions of the salicylates or other *salts* are also much less than those of the corresponding acids.

Fate of the Benzol Derivatives in the Body.—The six-carbon ring is relatively resistant to decomposition, and for the most part passes through the body unbroken, although up to one-half may be burned. The hydrogen atoms and side-chains undergo more or less oxidation, resulting in new hydroxyl and carboxyl groups (phenols and acids) in considerable variety. These again enter combinations before being excreted by the urine; the phenols forming esters, chiefly with sulphuric acid (Baumann and Herter, 1876; O. Neubauer, 1901); and to a lesser extent with glycuronic acid. The aromatic acids combine with glycoll to form hippuric acid, etc.

Extent of Destruction.—Of the phenol that is normally absorbed from the intestine about half is oxidized and half conjugated. Paracresol is oxidized more rapidly than phenol (Pelkan and Whipple, 1922). The exclusion of the bile from the intestines, by increasing intestinal putrefaction, increases phenol elimination (Dublin, 1917). The normal phenol excretion (largely paracresol) tends to vary directly with the protein intake (Folin and Denis, 1915).

Distribution.—When phenol is administered orally the level of the free and especially of the paired phenols of the blood rises, reaching a maximum in half an hour, and returning slowly to the normal, which is reached in 6 to 12 hours. The conjugation is completed in an hour. The tissues take up a higher percentage of phenol than the blood. The urinary excretion parallels the concentration in the blood. If phenol is injected intravenously (500 mg. dog), a sixth disappears from the blood during the injection, and the normal level is restored in an hour (Pelkan and Whipple, 1922).

Protective Function of Conjugation.—The formation of the esters is generally proportional to the toxicity of the phenols (S. Fraenkel). Since the esters are much less toxic than the phenols they constitute an important protection of the organism against poisoning, especially against the phenols arising in intestinal putrefaction.

Origin of Sulphonate.—This is not derived from sulphates or other inorganic sulphur compounds, for the administration of these do not increase the conjugation. The phenol-sulphonates may be formed with a purely carbohydrate diet, so that the sulphur must come from the oxidation of tissue protein, presumably from the cystin; and the quantity can be considerably increased by feeding this amino-acid (Shiple and Sherwin, 1923).

Role of the Liver in Conjugation.—The liver takes an important part in the oxidation and conjugation of the phenols (Pelkan and Whipple), although other tissues are probably also concerned. The phenol destruction and conjugation are therefore greater with oral than with intravenous administration, and they are diminished by liver injury, for instance by chloroform poisoning (Pelkan and Whipple).

Therefore the sulpho-conjugation has been proposed as a test of hepatic function. Thymol, 0.5 Gm., is normally followed by considerable increase of the ethereal sulphates of the urine. This increase is sometimes absent in hepatic disease; but not always (M. Kahn, 1918).

Glycuronic Acid.—This corresponds to dextrose, with the end-chain (CH_2OH) oxidized to ($COOH$). It is probably an intermediate stage in the oxidation of glucose, for very little can be formed in glycogen-poor animals (Dakin). Glycuronic acid is probably not a normal stage of carbohydrate metabolism; for if it is administered parenterally, it appears almost quantitatively unchanged in the urine (Biberfeld, 1914). It is never excreted free, but always in combination with aromatic alcohols, phenols, ketones and acids. Haemaclaeinen, 1913, supposes that the alcohols first combine with glucose, and that this glucoside is then oxidized to the glycuronate. The glycuronic compounds may be mistaken for sugar, since they reduce copper, although more slowly.

The principal drugs which cause the appearance of *Glycuronic acid in the urine* are: Turpentine, chloroform, chloral, camphor, phenacetin, saccharin, salicylic acid, balsams, morphine; others are enumerated by S. Fraenkel, 3rd ed, p. 194.

The Hippuric Acid Formation.—This occurs in some animals exclusively in the kidneys; in some it may also be formed in other organs. Dogs, for instance, synthesize hippuric acid even after excision of their kidneys (Kingsbury, 1915).

The liver probably has a share, for the hippuric synthesis is diminished in hydrazine poisoning, which produces extensive degeneration of the liver, but is supposed to leave the kidneys unaffected (Lackner et al, 1918).

PHENOL

Phenol (carbolic acid, $C_6H_5.OH$) illustrates the characteristic properties of the series, and is the most widely known and used of these antiseptics. It owes this popularity to its being the pioneer of the group, through its introduction by Lister, 1867. Some of its derivatives are superior, at least for special purposes.

Antiseptic Action.—Phenol is a general protoplasmic poison and a fairly active disinfectant, although not nearly as powerful as mercuric chloride, or even as the cresols. It precipitates proteins, but the combination is so loose that it readily diffuses further, and therefore penetrates more deeply into the tissues than the metallic antiseptics; and its action is not so much hindered by the presence of organic matter. The *disinfectant power* varies greatly for different microorganisms; spores are especially resistant. Tubercle bacilli are killed by exposure to 5 per cent. for twenty-four hours. It is much more effective as an *antiseptic*, i.e., for checking bacterial growth; $\frac{1}{2}$ to 1 per cent. suffices for this purpose. These are the concentrations used on the body, for here it is not necessary to kill the bacteria if only their development is effectively prevented: These solutions do not ordinarily injure the tissues.

Antiseptic Uses.—Five per cent. solutions are used for the disinfection of the utensils, instruments, the hands, etc. The penetration and therefore the antiseptic efficiency are increased by the addition of salt. "Crude Carbolic Acid," which contains the more active cresols and is cheaper, is preferred for the disinfection of excreta. As antiseptic for wounds and mucous membranes, gargles, lotions or injections $\frac{1}{2}$ to 1 per cent. of phenol are used. A drop of undiluted phenol is useful for disinfecting and cauterizing small wounds, bites, etc. Injections of phenol have been tried against local inflammations, tubercular bones and lymph glands, boils, erysipelas (5 per cent. to scarified surface), etc. Lotions are used as parasiticide in scabies, sycosis, pityriasis, and against pediculosis capitis. Inhalations have been advocated in fetid bronchitis and pulmonary gangrene.

Solutions in Fatty Oils.—In these phenol is not antiseptic (Koch, 1886), because its solubility in fats is so much greater than its solubility in protoplasm that it prevents its transference to the bacteria or tissues. "Carbolated Oil" is merely a mild local anesthetic and dermal irritant, useful for promoting the healing of small wounds. Alcohol and glycerin have a similar restraining action. The solubility in petrolatum is very small, so that ointments made with this base should be very actively antiseptic and irritant.

As intestinal antiseptic, phenol has little value because of its prompt absorption and marked toxicity.

Solubility of Phenol in Mineral Oils.—Pilcher, 1914, found that 1 part of crystallized phenol dissolves in 8 to 9 parts of petroleum; 20 to 21 of gasoline; 23 to 24 of solid petrolatum; 45 to 50 of liquid petrolatum.

Phenol Injections in Tetanus.—These have been introduced by Baccelli. Rather large doses are used, a 2 to 3 per cent. solution being injected intravenously or hypodermically along the spine every two or three hours, the *daily* dose starting with 0.2 to 0.5 Gm., and increasing rapidly to 0.8 to 1.5 Gm. of absolute phenol in divided doses, according to severity (J.A.M.A., 53:2140, 1909). No bad effects have been reported, and it is said to cause prompt improvement and to lessen the mortality, even in severe cases (Baccelli, 1911; Ascoli, 1913) perhaps by its analgesic and antipyretic actions. The treatment has not been tried adequately by independent observers, and final judgment can not be passed on it (Dreyfus, 1914). McClintock and Hutchings, 1913, state that it has only a limited value, as a simple sedative. Joffe, 1914, commends it.

Fielder, 1914, obtained negative results in *rabies*.

Pediculosis Capitis.—Whitfield, 1912, advises soaking the scalp in a 2.5 per cent. phenol solution for ten minutes and leaving the solution on the hair for an hour.

Chancroid.—The early stages may sometimes be aborted by painting with pure phenol, followed by alcohol (H. N. Cole).

Actions on Ferments.—Phenol, salicylic acid, and other coal-tar antiseptics have a retarding effect upon *ferment action*—especially carbolic and salicylic acid. A 5 per cent. solution of phenol suffices to weaken materially the action of most ferments.

Local Actions.—Concentrated phenol applied to the skin or mucous membranes produces prickling, burning and pain, then numbness and anesthesia, wrinkling and softening of the epidermis, the color of the skin becoming first white, then red, and finally brown. There is no direct corrosion, but a local necrosis. A dry scab forms, which separates without pus. Short applications of weaker solutions determine merely some wrinkling and blanching of the epidermis and the sensory phenomena, but even a 5 per cent. solution of the acid may cause necrosis, especially when applied continuously to the extremities. This enjoins caution in the use of carbolic dressings.

The analgesic effect of dilute phenol solution and ointments is used against itching.

Pirrie advocated compresses saturated with phenolated oil (1:6) for *burns*. It relieves the pain promptly; but when applied to large surfaces, it is probably capable of producing systemic poisoning.

Schleich found that 5 per cent. watery solution applied to an exposed nerve causes *anesthesia*.

Undiluted phenol may be used for quick local anesthesia of the skin. A scalpel wet with phenol is drawn over the proposed incision, which may be made after a few seconds (Soresi, 1919).

Absorption.—Phenol is absorbed from all mucous membranes and wounds, and even from the intact skin. In the intestinal canal its absorption is at first very rapid, but soon becomes almost arrested, apparently by interference with the local circulation (Sollmann, Hanzlik and Pilcher, 1910). It is distributed through all the tissues.

Fate and Excretion.—A part of the phenol ($\frac{1}{4}$ to $\frac{2}{3}$) is completely burned in the body (Tauber, 1878; Schaffer, 1878; Jonge, 1897). The remainder is excreted in the urine, largely as ethereal sulphates and glycuronates of phenol, hydroquinone and pyrocatechin. However, Folin and Denis, 1915, find that 30 to 90 per cent. of the urinary phenol is not conjugated. With a rise of total phenol, a greater proportion is conjugated; except when bile is excluded from the intestines (Dubin, 1916). The oxidized products impart the smoky color to the urine. A trace of phenols is found in the sweat (Tachau).

Central Actions.—Very small doses of phenol, as of all the coal-tar antiseptics, produce at first an *analgesic and antipyretic action*. This is so fleeting, and passes so readily into the graver effects, that it can not be used in therapeutics. This preliminary stage is followed by more pro-

nounced symptoms resembling the "toxic" effects of salicylates. Dangerous doses produce prompt collapse and coma. Frogs and mammals exhibit characteristic muscular tremors, twitchings and convulsions, persisting until the blood pressure falls very low. These are absent, or at most very faint in man (Husemann, 1871).

Phenol Convulsions.—Salkowski, 1872, showed that these are located in the spinal cord (division of sciatic; decapitation). Morita, 1915, also found that the convulsions occur in rabbits after ablation of the hemispheres. Baglioni, 1900 and 1909, by the methods explained under strychnine, concluded that the convulsions depend on increased excitability of the spinal motor cells. Direct application of dilute phenol solutions to the exposed spinal cord produces anesthesia. The excitability of the *motor cortex* is lowered by its local application (Baglioni and Magnini, 1910), without convulsions (Amantea, 1913). *Muscle and nerve fibers* are also paralyzed by local contact with strong solutions, but do not seem to suffer if the drug acts systemically.

Phenol does not awaken animals from chloral sleep (Airila, 1913).

Symptoms in Frogs.—Phenol produces successively local reflex irritation, short stupor, a medullary cry, then gradually the twitchings and irregular and incoordinated contractions. The reflexes are preserved, but naturally ineffective because of the interference and interruptions of the convulsions (Baglioni); Arloing and Thevenot, 1920).

Circulation.—Intravenous injections of phenol, even with small doses, cause marked fall of blood pressure, usually with rapid recovery until a certain dosage is exceeded. The fall appears to be both cardiac and vasomotor. When phenol is given by stomach, the blood pressure remains low because of the continuous absorption (Sollmann and Brown, 1906).

Vasomotor Center.—This is usually depressed, probably directly. This may, however, be modified by indirect stimulation through the convulsions or ischemia. The center may therefore be stimulated; or a period of stimulation may precede or follow the depression period (Pilcher and Sollmann, 1915).

Respiration, Temperature and Collapse.—The *respiration* becomes slow and shallow, and finally stops. The *temperature* falls. Since the collapse affects all the medullary centers, and the cardiac muscle as well, it can not, of course, be removed by artificial respiration.

This constitutes an important difference from the collapse produced by the drugs of the alcohol series. Another difference consists in the fact that with the antiseptic group the *sensibility to pain* is often *preserved* far into the collapse. The local effects of the phenol play no important part in the production of the collapse (Sollmann and Brown, 1906).

Phenol causes an increase of *secretions*, especially of saliva, sweat, and tears, not yet accounted for.

Toxicology.—Suicidal poisoning by carbolic acid is very common, particularly in the United States. Accidental poisoning is also common; it may result even when the phenol is applied to the intact skin; its liberal application to open surfaces has frequently led to toxic symptoms. The *fatal dose* by mouth varies between 8.5 and 60 Gm. (Lewin); 0.8 Gm. has been given therapeutically without bad effects. The toxicity is about the same by mouth and hypodermically (Hale, 1913).

The course of carbolic acid poisoning is *very rapid*. In almost all fatal cases death ensues inside of twenty-four hours.

Symptoms.—The *local symptoms* consist in burning of the mouth and throat, nausea and vomiting, abdominal pain. The carbolic burns generally heal promptly, with small tendency to scar formation.

The *systemic symptoms* are those of a very speedy *collapse*, starting in a few minutes, even when the drug is taken by mouth. It is manifested by faintness and muscular weakness; rarely twitching and convulsions;

pulse small, weak, and slow; face livid; cold sweat; respiration slow and shallow; unconsciousness; coma; death by stoppage of respiration.

The *urine* is scanty and often contains albumin and casts, sometimes hemoglobin or the bile pigments. It has a dark smoky color, especially on standing, from the oxidation of the hydroquinone, pyrocatechin etc., that are formed from phenol. It gives little or no sulphate-precipitate with barium chloride. These points are of diagnostic importance. The urine rarely contains traces of uncombined phenol.

Chronic Phenol-poisoning.—In the days of the Lister spray, chronic phenol poisoning was not at all uncommon amongst surgeons. It presented the general symptoms of marasmus. The quantity of the acid entering the system under these circumstances is quite phenomenal: 2 Gm. of phenol were recovered from the urine of a surgeon who had assisted for two and a half hours at an operation under a 2 per cent. spray. Minor grades may occur from carbolic applications. They often show skin eruptions (Lewin) and renal irritation (kidney changes, Uyeno, 1909).

Treatment of the Local Effects.—These are removed by *promptly* washing with alcohol (or whiskey) and applying an oil dressing. Alcohol, fats, glycerin, turpentine and ether act simply by their solvent-affinity for phenol, preventing its penetration into the tissues or dissolving it from them (Sollmann, 1906).

Treatment of Internal Poisoning.—The best success is obtained by *lavage* of the stomach with warm water, or first with 10 per cent. alcohol; taking care that the fluid does not enter the trachea. The washing must be continued till the phenol odor disappears. It should be attempted even if an hour or more has elapsed since the poison was swallowed (D'Hotel, 1907), because a large part of the phenol remains for a long time unabsorbed in the stomach (Sollmann, Hanzlik, and Pilcher, 1910). Chemic antidotes are of less service. Syrup of lime or potassium permanganate are the most promising. Alcohol and sulphates are practically useless. Intravenous saline infusions have some value against the circulatory depression; and heat against the collapse.

Lime forms an insoluble compound and is fairly effective (Husemann and Ummethun, 1870). Syrup of lime may be given freely; lime-water is too weak. *Permanganate* destroys phenol, but it has not been ascertained whether the ordinary doses are efficient. Tincture of *iodine* was suggested by Maberly, 1909. Scoville, 1913, claims that charcoal is useful. *Alcohol* was formerly considered a chemic antidote, supposedly effective even when left in the stomach. Both the clinical and the experimental evidence disprove this view (Clarke and Brown, 1906). Its solvent action is useless if it is left in the stomach to be absorbed. Macht, 1915, asserts that alcohol given after phenol increases its toxicity; but that it is protective when taken before the phenol.

Sulphates have been given with the object of forming the non-toxic phenolsulphonates. This combination does not occur in the alimentary canal, and the sulphates are very slowly absorbed, so that the oral administration is useless except in chronic poisoning. The combination is so slow, that it is practically not available in acute poisoning, even if the sulphate is injected intravenously (Brown and Sollmann, 1906).

The antidote-fallacies are reviewed by Wilbert, 1916.

PREPARATIONS—PHENOL

**Phenol*, U.S.P.; *Acidum Carbolicum* (Acid, Carbol.), B.P., C_6H_5OH .—Should contain not less than 96 per cent. of hydroxybenzene, C_6H_5OH , obtained either from coal-tar by fractional distillation and subsequent purification, or prepared synthetically. Occurs as needle-shaped crystals, colorless but acquiring a reddish tinge by oxidation of traces of the phenol to quinone and other derivatives (Gibbs, 1909). Characteristic odor and sweetish caustic taste. Melts about $38^{\circ}C$.; sol. in water (1:15); miscible in all proportions with alcohol, glycerin and fats; dissolved by alkalis. The solubility in water diminishes with the temperature, and can be increased by the addition of

alcohol or glycerin. Phenol is sometimes very faintly acid to litmus, but this is due to impurities (E. Schmidt, 1911). It is not a true acid, either chemically or physiologically. It is *incompatible* with iron and collodion. *Dose*, 0.06 Gm., 1 gr., U.S.P.; 0.06 to 0.2 Gm., 1 to 3 gr., B.P.; diluted. *Maximum dose*, 0.2 Gm., 3 gr.

**Phenol Liquefactum* (Pheno. Liq.), U.S.P.; *Acid Carbol. Liq.*, B.P.—This is obtained by liquefying phenol with 10 per cent. U.S.P., 15 per cent. B.P., of water. It is more convenient for dispensing. When it is diluted with an equal volume of glycerin, the mixture is miscible with water. *Dose*, 0.06 occ., 1 minim, U.S.P.; 0.06 to 0.18 c.c., 1 to 3 minims, B.P.; diluted.

Glycer. Phenol., U.S.P.; *Glycer. Acid. Carbol.*, B.P.—20 per cent. Useful for making strong solutions. *Dose*, 0.3 c.c., 5 minims, U.S.P.

Supp. Acid. Carbol., B.P.—0.03 Gm., $\frac{1}{2}$ gr.

**Unguentum Phenolis* (Ung. Phenol), U.S.P.—2 per cent., in wax and petrolatum.

Ung. Acid., Carbol., B.P.—3 per cent. in White Paraffin ointment.

Carbolized oil is usually made of 5 per cent. strength.

Troch. Acid Carbol., B.P.—0.03 Gm., $\frac{1}{2}$ gr.

Liq. Sod. Bor. Camph., N.F. (Dobell's Solution).—This is often used on mucous membranes (nose, etc.). It contains 0.3 per cent. phenol, 1.5 per cent. each of sodium bicarbonate and borate, with glycerin and water.

PHENOL-CAMPHOR

When camphor and phenol are rubbed together they liquefy. Mixtures of this kind (phenol 30, camphor 60, alcohol 10) have been employed on suppurating wounds and abscesses, with the claim that the caustic action is diminished and the antiseptic efficiency increased. The latter is doubtful; but the decrease of irritation agrees with the effects of all good phenol solvents. There is no chemic combination (Yvon, 1876; Lemberger, 1906).

Chlumsky, 1905, and 1913, recommended phenol-camphor in superficial inflammatory conditions, especially erysipelas; painting it on and around the affected area.

F. Pohl, 1913; and Schiele, 1914, inject 2 to 5 c.c. into diseased joints, without bad effects.

PHENOLSULPHONATES OR SULPHOCARBOLATES

These are less toxic and irritant, but also much less antiseptic than phenol. They have little value.

Sodii Phenolsulphonas, (Sulphocarbolate), $C_6H_4(OH)SO_3Na.H_2O$.—Colorless, transparent prisms or crystalline granules, odorless, cooling, saline, bitter taste. Sol. in water (4:2). *Dose*, 0.25 Gm., 4 gr., as intestinal antiseptic, but inefficient. (*Zinc Phenolsulph.*, see Index.)

CRESOLS

The introduction of alkyl groups into phenol greatly increases the germicidal efficiency. The most important of these derivatives are the cresols, $C_6H_4OH.CH_3$, obtained from "crude carbolic acid." Attention was directed to their valuable properties by Fraenkel, 1889. The three isomers, ortho-, para-, and metacresol, differ somewhat quantitatively, the meta being the most antiseptic and least toxic, and para being the most toxic; but they are all contained in variable proportions in the commercial products usually employed.

The **germicidal power** averages three or more times that of phenol; preparations containing higher homologues (N.N.R.) may be 15 times more active than phenol.

The **toxicity** of the cresols averages somewhat less than phenol (Tollens, 1905; Hale, 1913; toxicity and fate, Jonescu and Bukarest, 1906), but they produce identical effects and lesions (Wandel, 1906; Hale, 1913). They are excreted for the most part "combined," but otherwise unchanged. The *treatment* would be similar. In practice, they are less

toxic than phenol, because they are used more diluted; but they are far from being "non-poisonous." Another advantage over phenol is their lower cost. Their *disadvantages* are the disagreeable odor, which depends mainly on impurities; their limited solubility in water; and their variable composition and activity. Organic matter slows their action rather more than with phenol. Acid and hard and salty water hinder them by precipitating the soap by which they are usually dissolved (Hamilton, 1914).

Solutions and Application.—The cresols may be rendered soluble by the addition of soap, as in the official Compound Cresol Solution; and in several other ways. The soap-mixtures partake of the slippery nature of soap and are therefore less useful in operating; but they are well adapted to cleansing the hands (brushing for two or three minutes with $\frac{1}{2}$ to 1 per cent. solution) and for other purposes. A dusting powder containing 3 per cent. of tricresol was been recommended for pediculosis (Herxheimer and Nathan, 1915).

Serum Preservatives.—Tricresol, 0.25 per cent., is often added to secure the preservation of serums. This is harmless with the usual hypodermic injections but may be a factor in the collapse that sometimes follows *intraspinal injection*, especially of the antimeningitis serum: Voegtlin, 1914; Livingston, 1920; but the experiments of Auer, 1914, on monkeys, render it improbable that the ordinary concentrations do any harm. Clinically, it has marked advantages, being more bactericidal than chloroform, and markedly analgesic. Without it, the pain of the injections is often so great as to interfere with efficient use (J. B. Neal and Abramson, 1917).

With *antipneumococcic serum*, a further danger might arise from the intravenous injection of relatively large doses. However, Voegtlin, 1918, finds that there is no danger of toxicity if the concentration does not exceed 0.5 per cent. and if the injections are made very slowly. With higher concentrations, the collapse is serious. Phenol acts similarly. Chloroform, even in saturated solution, is harmless. Auer, 1914, found monkeys much more resistant to cresol than the dogs used by Voegtlin. He considers the ordinary concentration quite harmless, and that other antiseptics have no advantage.

Arterial Changes.—Paracresol, in common with many other substances, is said to produce atheromatous lesions in rabbits (Denny and Frothingham, 1914).

Phenol Coefficient.—The variability of the cresols is best discounted by the determination of the "phenol coefficient," *f.e.*, the ratio of the germicidal power of the disinfectant to the germicidal power of phenol, both being tested under identical conditions. A disinfectant three times as active as phenol would have the coefficient 3, etc.

The phenol-coefficient is valuable only for the disinfectants related to phenol; not for metals, iodine, chlorine, etc.

Most disinfectants are now sold with the statement of their coefficient, generally determined either by the "Rideal-Walker" (1904) or preferably by the "Hygienic Laboratory" method (Anderson and McClintic, Hyg. Lab. Bul., 72, 1912) with or without the presence of organic matter (2 per cent. peptone and 1 per cent. gelatin). The degree of dilution for disinfection is obtained simply by multiplying by 50 the phenol coefficient (with or without organic matter, according to the material to be disinfected); *f.i.*, a disinfectant having the coefficient 3 would be diluted $3 \times 50 = 150$ times.

Benzene Derivatives on Insects.—W. Moore, 1917, tested the vapors of a series on house-flies. He found that all the benzol derivatives tested had a higher molecular toxicity than carbon disulphide; the physical characters being more important than the chemical composition.

PREPARATIONS

**Cresol*, U.S.P.; B.P., Cresol (Tricresol, Cresylic Acid), $C_6H_4CH_3OH$.—A mixture of the three isomeric cresols obtained from coal-tar, and freed from phenol, hydrocarbons and water. Colorless, yellowish or pinkish refractive liquid, of phenol-like odor, darkening on exposure to air. Sol. in water (1:50), usually forming a cloudy solution; miscible

in all proportions with alcohol, ether or glycerin and dissolving in alkalis. *Dose*, 0.05 c.c., 1 minim, U.S.P.; 0.06 to 0.18 c.c., 1 to 3 minims, B.P.; diluted.

For local use, the following concentrations are employed.

In surgery, $\frac{1}{4}$ to 1 per cent.; gargles or cystitis, $\frac{1}{4}$ per cent.; cuspidors (tubercle bacilli) or stools, 1 to $1\frac{1}{2}$ per cent.; for sponging rooms or soaking clothes, $\frac{1}{2}$ to 1 per cent. To make a 1 per cent. solution, add 2 teaspoonfuls to a quart of water.

Cresol is generally used in the form of:

**Liquor Cresolis Compositus*, U.S.P.—50 per cent. of cresol, brought into clear solution by a potash-line-seed soap. It has a phenol coefficient of about 3, and is in every respect equal to most of the proprietary solutions, with the advantage that it is not advertised under exaggerated and dangerous claims, such as being “non-poisonous.”

Liq. Cresol. Sap., B.P.—50 per cent., in castor oil-potash soap.

Proprietary preparations may be found in N.N.R.

Metacresyl acetate is very little soluble in water, and therefore less toxic (Greenwald, 1911). It was tried as a mild antiseptic for mucous membranes.

Commercial Cresol Preparations.—These contain usually 25 to 30 per cent. of cresol. They may be grouped according to the dissolving agent;

I. Emulsions: turbid, brownish liquids, yielding turbid suspensions with water.

Prepared with:

1. Resin-soap: *Creolin-Pearson*; *Izal*; *Cresolin*.

2. Petroleum Oils (the mixture lowering the specific gravity to that of water); *Saprol*.

3. Coal-tar Products (Carbolic Acid, Naphthalene, Pyridine).

II. Solutions: brownish liquids, yielding clear solutions, with sufficient water;

Prepared with:

1. Potash Soaps and Alcohol: *Lysol*, *Sapokresol*; (hard water will precipitate the soap, and cause a turbid solution).

2. Sulfo-acids (Made by heating crude carbolic with equal parts of concentrated H_2SO_4): *Sanatol*; *Creolin-Arimann* (sulfo-acids of resin and mineral oils may be employed).

Phenoloid Disinfectants.—Cresol mixtures containing the higher homologues are described in N.N.R.

POLYATOMIC PHENOLS

The introduction of further OH groups tends to raise the antiseptic, but also the irritant and toxic effects; however, the modifications depend largely on the position of the groups: Of the three isomers with two OH groups, *Resorcin*, 1:3 is perhaps somewhat more antiseptic than phenol, and rather less toxic and irritant. *Hydroquinone*, 1:4, is more toxic; and *Pyrocatechin*, 1:2, is much more so. They act as reducing agents, especially in alkaline solutions. Pyrocatechin is not used in medicine. Hydroquinone is not used directly, but is formed from arbutin, contained in *Uva ursi*. *Pyrogallol*, containing three OH groups, is highly toxic, whilst its isomer, *phloroglucin*, is practically inactive.

RESORCINOL

Resorcin coagulates albumin. Strong solutions soften and slowly cauterize the skin; weak solutions are merely antiseptic. It is employed externally in skin diseases, and internally in gastric fermentation and in diarrhea. After absorption, it produces the same effects as phenol, but with more prominent convulsion, occurring even in man; 8 Gm. have caused severe poisoning but with recovery (Murrel, 1881). Smaller doses are antipyretic, but the action is too short to be useful. They produce “toxic” effects resembling those of salicylates. The fate and excretion are similar to phenol.

PREPARATIONS

**Resorcinol* (Resorcin.), U.S.P.; *Resorcinum*, B.P.; (meta-dihydroxy-benzene), $C_6H_4(OH)_2$, 1:3.—Colorless needle-shaped crystals, of peculiar faint odor, and sweetish, then bitter taste. Acquires pinkish tint on exposure to light and air. Very sol. in water (1:0.9) or alc. (1:0.9), freely sol. in glyc. or eth. *Dose*, 0.125 Gm., 2 gr., U.S.P.; 0.06 to 0.3 Gm., 1 to 5 gr., B.P. *Maximum dose*, 1 Gm., 15 gr. On the skin, 5 to 50 per cent. ointment or 10 to 20 per cent. solution in glycerin. For urethral or vesical

irrigation, $\frac{1}{2}$ to 2 per cent. In alopecia, 1 to 2 per cent; however, resorcin discolors light or red hair to a greenish tinge; it does not appreciably alter the color of black hair (H. N. Cole).

Resorcin stains may be removed from the skin by citric acid (Mankiewicz, 1916).

HEXYL-RESORCINOL

The introduction of an alkyl radical into resorcinol, (analogous to the

very markedly increases the germicidal activity and at

the same time decreases the toxicity. V. Leonard, 1924, found hexyl resorcinol, $C_6H_3(OH)_2.C_6H_{13}$ (*Caprokol*, N.N.R.), a very promising internal antiseptic for the urinary tract. It is for the most part excreted in the conjugated and therefore ineffective form; but its activity is sufficiently high (the phenol-coefficient = 45), so that even the small fraction that is excreted uncombined renders the urine not only antiseptic, but germicidal. However, the results are somewhat variable, doubtless according to the amount of conjugation, which cannot be controlled. The germicidal activity is not modified by the natural range of the reaction of the urine, but is destroyed during the administration of large doses of sodium bicarbonate, for unknown reasons (see Leonard & Wood, 1925). Locally it is somewhat irritant and astringent, and therapeutic doses at first produce some diarrhea. As the conjugated form lacks this action, its excretion does not irritate the kidneys or urinary tract, even in large doses. Its systemic toxicity is low. Therapeutic doses have been taken daily for six weeks, without other side effect than an initial diarrhea. Rabbits have been fed 0.5 Gm. daily for three weeks without showing any toxic symptoms.

Clinical Use.—Hexyl-resorcinol appears to be clinically effective in urinary cystitis and pyelitis caused by streptococcus anhemolyticus, the staphylococci, and b. pyocyaneus. With these it often produces complete disinfection, without recurrence. It is less effective against b. coli; this may be diminished, but tends to recur and requires prolonged administration, best combined with local treatment. To avoid gastric irritation, the substance is administered in oily solution, supplied in gelatin capsules containing 0.15 gm. of the drug. One to four of these capsules are taken daily. There is often a decided cathartic action for the first two days, but this need not interfere with the administration. It generally disappears even if the administration is continued, and therefore need not interfere with the medication. Hexyl-resorcinol is not suited to hypodermic administration, since it would produce local necrosis.

UVA URSI

This plant has been used for its diuretic and antiseptic effects in vesical catarrh. It contains arbutin, tannin and other constituents.

Arbutin is a crystalline glucoside, yielding glucose and hydroquinone on decomposition. It is decomposed completely in the body (Lewin, 1883; Grisson, 1888); with large doses the hydroquinone appears in the urine (Bass, 1912) and is supposed to be the active agent. Lewin and others found it beneficial in cystitis, etc.; Paschkis and Feibes, 1884, doubted its efficiency; Bass found no action on healthy men, even with 20 Gm. The usual dose is 1 Gm., three to six times daily.

PREPARATIONS

Uva Ursi, U.S.P.; *Uv. Urs. Fol.*, B.P. (Bearberry).—The dried leaves of *Arctostaphylos Uva-ursi*. *Dose*, 2 Gm., 30 gr., U.S.P.

Fldext. Uvæ Ursi, U.S.P. *Dose*, 2 c.c., 30 minims, U.S.P.

Inf. Uv. Urs., B.P.—5 per cent. *Dose*, 15 to 30 c.c., $\frac{1}{2}$ to 1 ounce, B.P.

PYROGALLOL

The powerful reducing action overshadows the phenol effects. Locally, it is a mild caustic for wounds and mucous membranes; it produces but slight irritation of the intact skin, passing into erythemas on continued use. Absorbed into the blood it forms methemoglobin, disrupts the corpuscles and leads to intense acute nephritis. Concentrated solutions acting on blood *in vitro* (not in the body) produce a peculiar insoluble substance, hemogallol. Fatal poisoning may occur even when the drug is applied to the intact skin; and may set in suddenly after it has been used for some time without effects. The *symptoms* consist in diarrhea, and vomiting, chills, prostration, feeble pulse; nephritis with scant dark urine containing blood or hemoglobin derivatives (Neisser, 1881); sometimes icterus and glycosuria. The rapid cases show cyanosis, dyspnea, convulsions and collapse. The *treatment* would be symptomatic.

Uses.—The danger of poisoning and the black staining limit its employment. It is used similarly to chrysarobin in psoriasis, lupus, ringworm and other parasitic skin diseases; and in hair dyes.

PREPARATIONS

Pyrogallol (Pyrogall.), U.S.P.; (Pyrogallic Acid; Tri-hydroxy-benzene), $C_6H_3(OH)_3$. Freely sol. in water (1:1.7), alc. (1:1.3), or eth. Solutions turn brown, especially in the light; very rapidly if alkaline. Used externally (but dangerous) as 1 to 10 per cent. ointment in skin diseases; and as 1 to 3 per cent. solution to deodorize ozena and discharging wounds.

CREOSOTE AND GUAIACOL

Composition.—The empyreumatic products of the distillation of wood—the smoke, and the creosote and tar which may be condensed from it—possess very considerable antiseptic power. They consist indeed of a mixture of coal-tar derivatives. The most important of these products from a therapeutic standpoint is creosote, the variety which is obtained from beech-wood (first by Reichenbach, 1830) being particularly valued. Its principal constituents are

guaiaacol, $C_6H_4 \begin{smallmatrix} \diagup OCH_3 \\ \diagdown OH \end{smallmatrix}$; and creosol, $C_6H_3 \begin{smallmatrix} \diagup OCH_3 \\ \diagdown CH_3 \\ \diagdown OH \end{smallmatrix}$. The action of these

compounds could be largely deduced from their composition, which is similar to the cresols. They are more strongly antiseptic and antipyretic, and rather less irritant and toxic, than is phenol. Creosol should be superior theoretically, but practically does not differ sufficiently from guaiaacol, to offset its higher cost. Guaiaacol constitutes from 60 to 90 per cent. of the creosote, and shares all its properties, with the advantage of constant composition.

Uses.—Creosote and guaiaacol were extensively employed in *tuberculosis*, having been introduced especially by Sommerbrodt, 1887; but they have gone out of fashion since the clinical benefits did not prove sufficiently definite, and the laboratory results were quite negative.

Long continued administration of creosote or guaiaacol to early cases, was said to increase the appetite, nutrition and weight, and to lessen the cough, the fever and the night sweats, but such patients are likely to improve spontaneously; or through suggestions, at least for a time, and the results are therefore not convincing.

It would be still more difficult to explain the effects. The tubercle bacilli are certainly not killed in their foci; it is doubtful whether their growth is restrained. Even in vitro, it requires 0.1 to 1 per cent. of guaiacol and of its related compounds, to inhibit the growth of tubercle bacilli. Therapeutic tests on infected guinea pigs show absolutely no improvement (L. M. DeWitt et al., 1920).

On the other hand, it is conceivable that the anti-pyretic action may be symptomatically helpful.

Other Pulmonary Diseases.—These (bronchitis, pneumonia) were said to be benefited, especially by inhalation, where the local antiseptic and stimulant action can come into play. Absolutely none is excreted by the lungs (Bufalini, 1904). When guaiacol is injected hypodermically, the major part is contained in the blood, liver and spleen, much less in the lungs and kidneys (Hofbauer, 1915). It is therefore difficult to conceive of an antiseptic action in the lungs. However, it has been proven that creosote increases the secretion of mucus even when taken by the mouth. In *pleuritic effusions*, it hastens the absorption of the exudate when it is rubbed into the chest.

As an **antipyretic** guaiacol (10 to 30 drops, dissolved in an equal volume of oil or alcohol) may be rubbed into the clean and dry skin of the abdomen for ten to fifteen minutes, thus avoiding intestinal irritation. It causes considerable diaphoresis, and has no advantage over other antipyretics.

Digestive Tract.—Guaiacol has been classed as an *intestinal antiseptic*, although its action is difficult to demonstrate (Harris, 1912). Creosote-water is sometimes given to check *gastric fermentation*.

The local **anesthetic** action is utilized especially in dentistry.

Administration.—In tuberculosis, creosote or guaiacol are given in the largest doses which can be tolerated without too much gastro-intestinal irritation; beginning with 1 drop and increasing to 5 or 10 drops, in extemporaneous capsules, three times daily after meals. If they are not tolerated, guaiacol carbonate should be substituted.

Poisoning by Creosote.—This resembles that by phenol, but the effects are less convulsive. The local actions are also similar. The side actions of therapeutic doses are detailed by Seifert, *Nebenwirk.*, 1915, p. 196. Death has occurred after 7 Gm. (Schulze, 1894). Hypodermically, guaiacol produces dangerous collapse and cardiac depression. The *excretion*, as with phenol, is mainly in combination with glycuronic and sulphuric acid (Knapp, 1911). Guaiacol (but not its carbonate) causes, in very large doses, the appearance of an undetermined, very viscous, substance in the urine, which is supposed to be capable of obstructing the uriniferous tubules.

Guaiacol Carbonate.—The undesirable local effects of guaiacol, the taste and the toxicity, are largely reduced by converting it into esters, on the "salol-principle," *i.e.*, by replacing the H of the OH group by acyl groups. These esters are insoluble and inactive; but in the intestine they are decomposed (saponified), into their constituents, and the OH is thus regenerated. In this way the antiseptic is liberated but slowly; its action extends over the entire intestine; but the amount which can be liberated at any time is too small to be either irritant or toxic. The creosote esters are decomposed even more slowly than salol, perhaps only through putrefactive bacteria. An excess will pass the intestine unabsorbed. As much as 6 Gm. of guaiacol carbonate has been given to phthisical patients, as much as 75 Gm. (2½ ounces) to dogs, without producing toxic symptoms. With these large doses, a great deal of the substance is passed in the feces, without having undergone decomposition.

Other Guaiacol Compounds.—Since the liberated creosote or guaiacol is the active portion of these compounds, the acid with which they are combined is absolutely immaterial. The carbonic acid esters are the cheapest and contain the largest percentage of active principles, and therefore deserve the preference which has been universally accorded to them. Similar compounds have been prepared from all other phenols—from thymol, menthol, etc.

As there are no good reasons for the use of these other guaiacol compounds, they need only be mentioned. They are more fully described in N.N.R.

Compounds formed by replacing the OH by acyl groups (analogous to the carbonate): Benzoate (Benzosol); Cinnamate (Styracol); Salicylate (Guaicol-salol); Methylglycolate (Monotal).

Replacement of the OH by alkyl group: The methyl derivative, Veratrol, is practically inactive because the OH is not regenerated. The glycerin derivative, *Guaimar*, is soluble and active, but has a bitter taste. Guaiasanol is the chloride of diethyl-glycoll-guaicol.

Thiocol is potassium guaiacolsulphonate, analogous to sodium phenolsulphonate. Like the latter, it has very little effect.

PREPARATIONS

Creosotum (Creosot.), U.S.P., B.P.—A mixture of phenols and phenol derivatives, chiefly guaiacol and creosol, obtained during the distillation of wood tar, preferably that derived from beech. Almost colorless or yellowish, highly refractive, oily liquid, having a penetrating, smoky odor; burning, caustic taste. Slightly sol. in water. Miscible with alc. and fixed or volatile oils. *Dose*, 0.25 c.c., 4 minims, U.S.P., 0.06 to 0.3 c.c., 1 to 5 minims, B.P. *Maximum dose*, 0.5 c.c., 8 minims.

Ung. Creosot., B.P.—10 per cent.

Creosoti Carbonas (Creosot. Carb.), U.S.P.—A mixture of the carbonates of various constituents of creosote, chiefly guaiacol and creosol. A clear, colorless or yellowish, viscid liquid, odorless and tasteless, or having a slight odor and taste of creosote. Insol. in water, freely sol. in alc. or fixed oils. *Dose*, 1 Gm., 15 gr., U.S.P.

Guaicol, U.S.P., B.P., $C_6H_4(OH)(OCH_3)$.—Nearly colorless refractive liquid, crystalline at low temperatures. Odor aromatic; sharp taste. Sol. in water (1 : 60 to 70); freely miscible with glyc., alc. or oils. *Dose*, 0.5 c.c., 8 minims, U.S.P., 0.06 to 0.3 c.c.; 1 to 5 minims, B.P. *Maximum dose*, 0.5 c.c., 8 minims.

Guaicolis Carbonas (Guaicol. Carb.), U.S.P., B.P.; (Duotol), $(C_6H_4(OCH_3)O)_2CO_3$. White crystalline powder, almost without odor or taste. Practically insol. in water, sol. in alc. (1 : 60). *Dose*, 1 Gm., 15 gr., U.S.P.; 0.3 to 1 Gm., 5 to 15 gr., B.P.; in powder or capsules. *Maximum dose*, 1 Gm., 15 gr.

TAR

This is a complex product obtained by the destructive distillation of pine woods, especially *Pinus palustris*. It contains phenols and other aromatic derivatives, resin acids, acetic acid, etc. Tar is strongly irritant to the skin; it is used in scabies and other parasitic skin diseases, chronic dry eczema, itching, etc.; but has now been displaced largely by the less disagreeable naphthol and resorcin. Internally, it has been employed in chronic bronchitis and cystitis, acting similarly to turpentine and copaiba. The official syrup is little more than a flavoring vehicle. Toxic doses of tar produce effects similar to phenol: vomiting, colic, diarrhea and collapse.

Oil of Tar.—When tar is subjected to redistillation, it can be separated into a fixed portion—pitch—consisting mainly of rosin; and a volatile portion which separates into *Oil of Tar* (*Oleum Picis Liquidæ*, U.S.P.) and pyroligneous (crude acetic) acid. The oil of tar consists of various coal-tar derivatives, mainly Cresols, Guaicol, Phenol, Xylol, Toluol, and Pyrocatechin. It also contains methyl alcohol and acetone.

PREPARATIONS

Pix Pini, U.S.P., *Pix Liquida* (Pix. Liq.), B.P.; *Pine Tar*.—A viscid blackish-brown substance, obtained by the destructive distillation of Pine wood. Empyreumatic odor and sharp taste. Miscible with alc. and fixed or volatile oils, only partly sol. in water. *Dose*, 0.5 Gm., 8 gr., U.S.P.

Ol. Pic. Rect., U.S.P.; *Oil Tar*.—A volatile oil distilled from Tar. An almost colorless liquid when freshly distilled, but soon acquires a dark reddish-brown color, and has a strong, tarry odor and taste. *Dose*, 0.2 c.c., 3 minims, U.S.P.

Syr. Pic. Pin., U.S.P.—0.1 per cent oil of tar. *Dose*, 10 c.c., 2½ drachm, U.S.P. Used as flavor for cough mixtures.

* *Unguentum Picis Pini*, U.S.P., *Ung. Pic. Liq.*, B.P.; *Tar Ointment*.—50 per cent. U.S.P.; 70 per cent., B.P.

Oleum Cadinum (Ol. Cadin.), U.S.P., B.P.; Oil of Cade (Oil of Juniper Tar; Ol. Junip. Empyreumaticum).—An empyreumatic oil obtained by the dry distillation of the wood of *Juniperus Oxycedrus*. A dark brown, clear, thick liquid, having a, tarry empyreumatic odor and a warm, faintly aromatic, and bitter taste. Used externally like tar, having a less unpleasant odor.

Pix Carbonis Præparata (Pix Carbon. Prep.), B.P.—Prepared Coal-tar.—Commercial Coal-tar is heated for an hour at 50°C. to expel ammonia. It is employed as antiseptic and antipruritic in the form of *Liq. Picis Carb.*

Liq. Pic. Carbon., B.P.—20 per cent. in alcoholic solution of Quillaja.

CHEMICAL CARCINOMAS

Tar and Paraffin Epitheliomas.—It has been observed clinically that workers whose skin comes into frequent contact with coal-tar and with crude paraffin may develop chronic dermatitis, eczema, eruptions and papillomas, which may eventually turn into true epithelioma. The susceptibility varies considerably. True carcinoma with metastases has also been produced by these means in animals (Yamagiwa and Ichikawa, 1916; Yamagiwa, 1921; Bierich, 1922; Deelman, 1922). The application has to be continued for 2 to 13 months.

Pure paraffin does not produce this effect, but paraffinomas may sometimes take a cancerous direction.

Presumably any of the irritant constituents may contribute to the action, although some may be more actively "auxetic." Norris, 1914, considered the anthracene fraction most effective, and this stimulates cell division in vitro (Ross, Cropper and Ross, 1912). Kennaway, 1924, believed that anthracene itself, and a number of the other constituents, may be excluded. Bayet and Slosse, 1919, make the improbable suggestion that the soot, tar and aniline cancers are due to arsenic.

Paraffin Dermatis and Cancer.—These were first described by Volkmann, 1895. The acute stage begins with eruptions and abscesses, "wax boils." These last several months, and then pass into a chronic dermatitis, with seborrhea resembling psoriasis, pigmentation, dry fissures, horny thickening, resembling ichthyosis, etc. In the terminal stage, multiple warts or papillomas develop, turning finally to true epithelioma (Davis, 1915). The wax-cancer affects only a fraction of the workers, and is therefore influenced by predisposition (B. F. Davis, 1920).

Bladder Tumors of Aniline-workers.—A very high incidence of papillomas and cancers of the urinary bladder is noted in workers employed in the manufacture of aniline dyes, especially fuchsin, benzidine, and naphthohydramine. H. Curschmann, 1920, estimates the incidence as high as 1:500. People living in the vicinity of the factories do not show an abnormal cancer rate.

The tumors are discovered from $\frac{1}{2}$ to 28 years after starting the employment (Nassauer, 1919; Schwerin, 1920; Oppenheimer, 1920). The prognosis is the same as for bladder tumors of other origin.

Maisin and Picard, 1924 claim to have produced experimental cancer of the bladder of rats by the application of paraffin, tar and scarlet red.

BENZOL

Benzol, C_6H_6 , has been used for the treatment of leukemia. It often causes temporary improvement, but is rather unreliable and sometimes dangerous. Industrial acute and chronic poisoning is also common, from its use in the arts (as solvent for rubber). It is somewhat antiseptic.

Blood Changes in Animals.—Subcutaneous injections of benzol (2 to 40 c.c.) into rabbits or dogs produce death in three to twenty days, with marked destructive changes in the hematopoietic organs, especially the myeloid tissue. There is a corresponding diminution of the leucocytes and blood platelets. With large doses, the platelets show a preliminary increase in rabbits, not in dogs (Duke, 1915).

Recovery from this fall may be followed by a second fall (Weiskotten, et al., 1916).

There is little change in the red cells (Neumann, 1915). The prothrombin is also decreased (Hurwitz and Drinker, 1915). The production of antibodies is diminished (Hektoen, 1916). The changes vary quantitatively in different individuals (v. Neumann, 1915).

Use in Leukemia.—The destructive action of benzol on leucocytes led to its introduction by v. Koranyi, 1912. Numerous reporters (Királyfi, 1912; Stein, 1912; Stern, 1913; Billings, 1913; Morawitz, 1914; Hahn, 1914, etc.) have described more or less favorable, but rather inconstant results. The changes are noticed only after continued administration, often requiring some weeks. The leucocyte count falls, more profoundly and persistently than with arsenic, but never to normal, as in X-ray treatment. The general condition is also improved. The best results are obtained when benzol is preceded by or continued with ray-treatment. In a considerable number of cases, especially the advanced, the benzol is unsuccessful. In others, toxic effects supervene.

Mechanism of Action.—Urinary changes indicate metabolic disturbances; increase of neutral sulphur; decrease of Urea $\div$ N, slight increase of ammonia, in most cases albuminuria (Sohn, 1913). The uric acid is not increased, and this speaks against destruction of leucocytes. Pappenheim, 1913, believes the decrease to be only apparent, asserting that the leucocytes accumulate in the dilated capillaries of the liver and other internal organs. He found marked hepatic and renal lesions in rabbits after repeated large doses. Duke, 1915, attributes the platelet changes to irritant, then toxic action on the bone-marrow.

Toxic Effects.—Ordinary doses cause eructations, but the appetite is not disturbed. There may be some dizziness, sometimes bronchitis. Occasionally, late symptoms of chronic benzol poisoning develop, which may be fatal (Neumann, 1913; Klemperer and Hirschfeld). It is therefore advised to discontinue the benzol as soon as the leucocytes start to decline (Királyfi, 1913); or at least when they have fallen to 20,000. Liver, kidney and intestinal disturbances contraindicate benzol (Hahn, 1914).

Administration.—Billings uses the benzol in extemporaneous capsules, 5 minims, increasing to 15 minims, after meals and at bedtime.

Acute Benzol Poisoning.—Fairly large doses of benzol are tolerated by mouth; 9 to 12 Gm. have caused serious collapse (Perrin, 1861; Averill, 1889). The acute symptoms are restlessness, excitement, high rise of temperature, narcosis, and death by paralysis of respiration. Sublethal doses are followed by good recovery. The technical article is somewhat more toxic than the pure (Lehmann, 1911).

Benzol Vapor.—This causes intoxication by absorption through the lungs. Dilute vapors produce headache, vertigo, ataxia, twitchings, convulsions and coma. Fuehner, 1913, finds benzol about as narcotic as chloroform. Concentrated vapor is markedly toxic, sometimes producing acute death. There are no characteristic anatomic lesions, except that the blood remains fluid for a long time; there are often small hemorrhages in various organs. Patients who recover sometimes develop skin changes (Lewin, 1907; Wolf, 1911; Heffter, 1915). The entire symptoms are produced, also on animals, by pure as well as impure benzol.

Chronic Poisoning by Vapor.—This causes hemorrhage (purpura), leucopenia, anemia, and finally death under high fever (Santesson, 1897; Selling, 1912). These effects are attributed to destruction of leucocytes in the circulating blood, and to damage of the bone-marrow, lymph glands, spleen, and the whole hematopoietic system. The formation of blood platelets is first stimulated, then depressed (Duke, 1913).

Industrial Poisoning from Benzene-vapors.—This occurs especially in the rubber-industry. Workers gradually (after 2 or 3 months or later) develop leucopenia, aplastic anemia and purpura hemolytica, without other marked symptoms. They generally recover slowly but completely when removed from exposure. The susceptibility varies greatly, and some workers show no apparent effects (Newton, 1920; Legge, 1920). Corresponding phenomena are produced by dilute vapors in animals. Their susceptibility increases with repeated exposure, thus explaining the deferred outbreak in workers. The effects are greatly diminished by dilution, i.e. by liberal ventilation. Contact of the liquid benzol with the skin adds greatly to the danger. Leucocyte counts should be made periodically on exposed workers, to detect the poisoning at its inception. The toxicity of the vapors of pure benzol is as high, if not higher, than that of the impure (Pugliese, 1922).

Distribution of Benzol after Poisoning.—The brain and spinal cord contain more than other organs (Joachimoglu, 1915).

Fate.—Benzol is partly oxidized in the body to phenol (15 to 30 per cent.), catechol and quinone and excreted as phenol-sulphates (Baumann and Herter, 1877); a part is completely destroyed to muconic acid (Jaffe, 1909), and a considerable portion is excreted unchanged by the lungs.

Benzenum, B.P.; Benzene (Benzol); C_6H_6 .—Not to be confused with *Benzinum Purificatum*, U.S.P., Benzin. The latter is Petroleum Ether, a gasoline fraction.

TOLUOL

Toluol, $C_6H_5.CH_3$, is used as a laboratory antiseptic, especially to preserve ferments. Its toxicity is low (Baumann and Herter, 1877; Schultzen and Naunyn, 1867). Its effects and those of xylol are similar to benzol (Lehmann, 1911).

It also produces complex effects on the antibodies and leucocytes (Hektoen, 1916).

NAPHTHALENE

This represents the union of two benzol rings: It is practically insoluble in water; and is employed mainly as insecticide (moth-balls); as antiseptic dusting powder in skin diseases and as intestinal antiseptic and anthelmintic, especially against oxyuris.

Naphthalene, $C_{10}H_8$

Fumigations have also been tried against pertussis. It has usually a relatively low toxicity for mammals because but little is absorbed, the greater part being eliminated unchanged by the feces. That absorbed is excreted as naphthol, naphthoquinone, etc., and produces renal and vesical irritation and hemorrhage, and damages the blood forming organs, resulting in anemia (S. Mayer, 1920). However, the absorption is sometimes greater (Kaminer, 1920), especially in the presence of oil: 2 Gm., administered in the course of two days, has proven fatal to a six year old child (Prochownik, 1911). Heine, 1913, reports poisoning in a woman after 2.8 Gm., distributed over three days. Retinal changes may occur, similar to those produced by naphthol (Takamura, 1912). Further references to the side actions are given by Seifert, Nebenwirk, 1915, p. 140.

PREPARATIONS

Naphthalenum, $C_{10}H_8$.—Colorless, crystalline powder; coal-tar odor; hot taste. Insol. in water; sol. in alc. (1:13). *Dose*, 0.1 to 0.5 Gm. (2 to 8 gr.). For children, 0.05 Gm., 1 gr., at 1½ years; to 0.2 Gm., 3 gr., at twelve years, three times daily.

NAPHTHOL

The naphthols are compounds analogous to phenol, formed by the introduction of an OH group into naphthalene: Alpha-naphthol is the

more toxic of the isomers and is not employed in medicine. Beta-naphthol acts similarly to phenol, but is more germicidal. It has a special irritant action on the kidneys, and severe nephritis has been caused by its absorption from the intact skin in the therapeutic use (Koposi, 1881; Baatz, 1894). Even death has been reported from its external application in scabies (L. Burger, 1919). It is especially contraindicated in the presence of renal diseases. Changes in the retina and opacity of the lens have also

been described after its use (e.g., Howe, 1913). Further references to the side actions are given by Seifert, *Nebenwirk.*, 1915, p. 186.

It is almost insoluble, and is employed as an ointment in psoriasis, acne, parasitic skin diseases, pruritus; and to deodorize ozena. Internally, it is used as an intestinal antiseptic and anthelmintic. It is effective in hook-worm disease but inferior to thymol (Freeman, 1908). The local irritation and toxicity may be lessened on the salol-principle, by transforming it into esters. The benzoate, salicylate (Betol) and oxytoluate (Epicarine) are described in N.N.R.

PREPARATIONS—NAPHTHOL

Betanaphthol, U.S.P.; *Naphthol*, B.P., $C_{10}H_7OH$.—Colorless or buff-colored, crystalline laminae or powder; faint phenol odor; pungent taste. Very slightly sol. in water (1:1,000); very sol. in alc. (1:0.8) and in oils, glycerin and alkalies. *Dose*, 0.25 Gm., 4 gr. U.S.P.; 0.2 to 0.6 Gm., 3 to 10 gr., B.P.; against hook-worm, 1 to 4 Gm., by special technic (Freeman, 1908). Externally, 1 to 10 per cent. ointment or 2 to 5 per cent. solution in oil or alcohol; in alopecia, 1 to 2 per cent.

QUINOLINE

Quinoline, C_9H_7N , is derived from naphthalene by the substitution of a N for a CH group. It is highly toxic and strongly antiseptic, but does not inhibit the growth of yeast (Donath, 1881). In rabbits, the hypodermic or intravenous injection of 0.2 Gm. per kilogram produces retinitis, similar to naphthalene; the lens, however, remaining clear (Jess, 1916).

Oxyquinoline Sulphate (C_9H_7ON) $_2$.H $_2$ SO $_4$, is very strongly antiseptic, but feebly germicidal. It seems to be non-toxic and is used as an antiseptic lotion for mucous membranes, etc., under the name of **chinosol** (N.N.R.). Its fate was studied by Brahm, 1899.

ANILINE

Aniline $C_6H_5NH_2$, is used extensively in the arts and therefore gives rise to industrial poisoning, with methemoglobin formation, headache, weakness, dyspnea, cyanosis, convulsions, and psychic disturbances. Its excretion has been studied by Rambousek, 1913.

Bibliography and history of industrial aniline poisoning, Alice Hamilton, 1915; Luce and Hamilton, 1916.

It has been suggested that impurities may play a large share in industrial poisoning.

Unusual frequency of bladder papillomas and cancer has been recorded repeatedly amongst workers in aniline dyes (Rehn, 1895; Seyberth, 1907; Edit., J.A.M.A., 1917, vol. 69, page 204).

PHENYL HYDRAZINE

Phenyl hydrazine, $C_6H_5.NH.NH_2$, alters hemoglobin more profoundly than aniline. Its administration also results in irritation of the skin (eczema, erythema nodosum and papulosum) and of the alimentary canal (gastroenteritis).

NITROBENZOL

Nitrobenzol, $C_6H_5NO_2$, is used extensively in the manufacture of aniline. Its odor resembles that of hydrocyanic acid, and it has therefore been used in cheap perfumery and soaps, under the name of Artificial Oil of Almonds or Oil of Mirbane; but it is highly toxic; 1 Gm. may be fatal.

Toxic Symptoms.—These are usually rather delayed, sometimes for hours. They resemble aniline poisoning; and consist in nausea and prostration, burning, headache, intense cyanosis, vomiting with characteristic odor, convulsions, and coma, ending in death after a few hours. The mortality is high; but 30 c.c. with prompt treatment were survived, (Zuccola, 1918). In protracted cases, temporary improvement and relapses occur.

The cyanosis is a very striking feature, the face turning almost black; the blood, when withdrawn, is also very dark, due to the formation of methemoglobin. The blood

corpuscles undergo rapid and intensive destruction. In case of recovery, this is followed by active regeneration, with marked hyperactivity of the bone-marrow (Zuccola).

The other symptoms result largely from the asphyxia; but the motor centers are probably affected directly. The respiration and circulation undergo relatively little disturbance.

Nitrobenzol has been taken to produce *abortion*, but even large doses are ineffective. (Spinner, 1917).

Subacute and chronic poisoning show icterus and cyanosis, the clinical picture resembling pernicious anemia.

The reported cases of nitrobenzol poisoning are reviewed by S. S. Adams, 1912.

Shoe-dye Poisoning.—The use of shoe-dyes flavored with nitrobenzol resulted in numerous cases of temporary cyanosis in the Army; fortunately all recovered (Stifel, 1919). It is not certain, however, whether the effects were due to nitrobenzol proper, or to aniline or some other nitration product (Jour. Amer. Med. Assoc. 1919, v. 72, p. 593).

Treatment.—This consists in evacuation and stimulation. No fat should be given. Transfusion of blood results in marked improvement (Zuccola).

Inhalation of Nitrobenzol Vapor.—The symptoms differ in detail with the species of animals. They generally begin 3 or 4 days after exposure, with vomiting and marked digestive disturbance; then loss of muscular coordination, generally starting with the hind-legs; forced movements or extensor rigidity. Consciousness is preserved. Death occurs through respiratory failure (Dresbach and Chandler, 1917).

The motor symptoms are of cerebellar type; and histologic examination shows changes in the cerebellar Purkinje cells, whilst other nerve cells are unaffected (Dresbach and Chandler, 1918).

PICRIC ACID

The saturated aqueous solution is used as a dressing for burns and superficial wounds, weeping eczemas, etc.; exerting anesthetic, antiseptic, astringent and protective actions, and stimulating the reproduction of epithelium, in contrast to most other antiseptics (Ehrenfried, 1911). Stronger alcoholic solutions are irritant; and being absorbed, become toxic. By mouth, 1 to 2 Gm. produce severe poisoning, generally with recovery under treatment (Lewin). It stains the skin, conjunctiva and tissues yellow, even on systemic administration, simulating icterus. This may persist for two weeks after taking 1 Gm. The urine is colored a peculiar red (Walko, 1901).

Picric acid is trinitrophenol, $C_6H_2(NO_2)_3.OH$. Its toxic effects were investigated on dogs by Rapp and Foehr, 1827. Braconnet, 1830, introduced it against intermittent fever; it was also used as anthelmintic; but its internal administration was soon considered too dangerous. It was employed in surgery by Cheron, 1876.

Application.—Picric acid is soluble to 10 per cent. in alcohol, to 20 per cent. in ether, to 1.2 per cent. in water. In burns, etc., it is used as a saturated aqueous solution, whose antiseptic efficiency is about seven times that of 1 per cent. phenol. (Picric acid has a phenol coefficient = 6; so that 0.165 per cent. picric acid would equal 1 per cent. phenol; Tidy, 1915.) Stronger alcoholic solutions should not be used. An ointment would be illogical. The water solution is said to be free from danger, but should not be applied over large surfaces. It is prepared by dissolving $1\frac{1}{2}$ 5 in a pint of hot water and filtering when cold. Cloths saturated with this solution are applied, covered with dry cotton, and left in place for several days.

Picric Stains.—These may be removed from the skin by applying powdered potassium sulphate for a minute, then washing with soap; or by a paste of magnesium carbonate (Mankiewicz, 1916).

Toxicology.—This is practically important, especially in munition factories, (Alice Hamilton, 1917). The common belief of its use in beers seems to be unfounded (Gadamer).

Locally, the handling of the dry powder produces eczematous dermatitis, "picric itch." A measles rash also occurs sometimes in poisoning. Systematically, toxic doses destroy the red corpuscles and produce gastro-enteritis, hemorrhagic nephritis and acute hepatitis. There may thus be a true icterus, although the yellow coloration is mainly due to picric staining (Malmejac, 1917).

The toxic effect on rabbits and dogs are described by Koizumi, 1914; those on frogs by E. D. Brown, Ahlfs and Howard, 1920.

Fate.—A part of the picric acid may be excreted unchanged by the urine, but most is transformed by the liver into picramic acid. This confers the diazo-reaction on the urine (Pecker, 1916).

Trinitrophenol (Trinitrophen.). U.S.P.; *Acidum Picricum* (Acid. Picr.), B.P.; Picric Acid, $C_6H_2(NO_2)_3OH$.—Yellow crystalline powder, odorless, of very bitter taste and intense staining power. Sol. in water (1:78) or alc. (1:12). *Dose*, 0.03 Gm., $\frac{1}{2}$ gr., U.S.P.

DINITROPHENOL

This produces toxic hepatitis and jaundice, similar to picric acid or trinitrotoluol. It is one of the dangerous occupational poisons (Warthin, 1918).

TRINITROTOLUENE

This is important as an explosive ("T.N.T."). It is $C_6H_2(NO_2)_3CH_3$. Other nitro- and amino-derivatives of benzene which are also used as explosives, produce similar effects with differences in detail (Alice Hamilton, 1917). Poisoning arises by the inhalation of the dust, in a proportion of the munition workers, generally between the 5th and 6th week of the employment; young and old subjects being more susceptible than vigorous adults (Martland, 1917).

The poison is absorbed mainly through the skin (Moore, 1918).

The symptoms take two directions: local irritation of the skin and mucous membranes; and degenerative hepatitis similar to phosphorus poisoning (Livingstone, Learmouth and Cunningham, 1916).

Minor ailments (digestive disturbances, etc.) are much more frequent than toxic jaundice; but the latter may develop after a long interval; for instance in one extreme case, seven months after stopping work on the poison (J.A.M.A. 7: 678, 1918).

The *local irritations* effect the eyes and nose; then produce cough, bitter taste, gastralgia, eructations and colic, vomiting. At first there is obstinate constipation, later diarrhea and tenesmus. The skin is eczematous.

The *systemic effects* consist of nausea, vomiting, anorexia, jaundice, mental depression, blurred vision, transitory peripheral neuritis. The condition may terminate in delirium, coma and convulsions.

Toxic Jaundice, Anemia, Purpura.—The T.N.T. jaundice is of hepatic origin, and leaves the liver tissue so severely damaged that recovery is very exceptional in patients who have reached this stage. There is also destruction of the red marrow, resulting "aplastic anemia," and purpura (Panton, 1917; B. Moore, 1917).

The blood of T.N.T. workers who do not exhibit symptoms, does not show any characteristic changes (L. H. Smith, 1918).

Cyanosis.—Moore describes the immediate effect of the absorption of T.N.T. as a change in the hemoglobin, with diminished oxygen capacity, leading to cyanosis, air-hunger on exertion, etc. This is generally easily recovered from, and its intensity bears no relation to that of the jaundice.

Toxic Effect on Animals.—Rabbits appear to be rather insusceptible (Panton, 1917). Dogs respond by a train of chronic digestive and cachectic symptoms ending in death. These resemble the human symptoms, except that the liver is relatively little affected (Kramer and Meierhof, 1918).

Treatment.—Little can be done for the fully developed disease. The workers should be withdrawn from exposure with the first appearance of any symptoms.

Protection.—This offers the only satisfactory solution of the problem. It involves proper ventilation, cleanliness etc. The subject is discussed by Schereschewsky, 1917.

"*Tetryl*" (Trinitro-phenyl-methyl-nitramine). This is another explosive. It often produces dermatitis; also abdominal symptoms, asthmatic attacks, hemorrhages from mucosae; headaches and giddiness (Cups & Ruxton, 1917).

PARADICHLORBENZENE

This is a by-product of the manufacture of picric acid. It resembles naphthalene in physical properties, and is chemically very indifferent.

It is a powerful insecticide (Konantz, 1918). It is also toxic to worms. Oral administration to dogs produces no apparent deleterious effect, even in the dosage of 1 gm. per Kg. (Sollmann, 1919).

COAL TAR DYES

The quality of permanently dyeing tissues generally implies that the dye has a slight adsorption-affinity, *i.e.* that it accumulates in high concentration on the surfaces. This not only increases the concentration in contact with the cell, but it modifies the surface properties of the cells, and indeed of intra and extracellular colloids, similarly to the albumoses, saponins, etc., as was pointed out under the Allergic Reactions. The actions of the dyes therefore show similarities independent of their chemical composition. They generally have rather high antiseptic value, which often shows specific differences that go parallel with their staining action. Protozoa are more generally susceptible than bacteria. Intravenous injection produces acute anaphylactoid phenomena, which have been employed similarly to the foreign protein injections against septicemias, etc. (see Churchman, 1925). The injected dye often shows a selective concentration in inflamed and injured tissues, for instance, in necrotic tuberculous and cancerous areas (R. Weil, 1916; Cecil and Weil, 1917). The excretion is also generally rather selective, either by the urine or more generally by the bile (Salant and Bengis, 1916). The rate of the excretion is utilized for studying the functional efficiency of the kidneys and liver. Colloidal dyes may leave the blood plasma so slowly that they may be used to estimate the volume of the circulating blood. The greater number of the medicinal dyes belong to a few chemical types. Commercial dyes are generally often impure and indefinite mixtures.

The basic or acid character of the dyes has considerable influence on their toxicity and on their penetration, especially in the living cells; but it is by no means the only determinant factor.

The penetration of dyes into cells presents very interesting problems (A. P. Mathews, 1910). Basic dyes diminish, acid dyes increase the imbibition of gelatin. This may be a factor in the penetration, but is not a complete explanation (Traube and Koehler, 1915). The vital staining and the toxicity of acid and basic dyes are not parallel (Hoeber, 1914). The addition of dyes to other poisons often modifies their toxicity (Sellei, 1913).

Yeast Formation.—Basic dyes (methylene blue) stimulate in dilute solutions and inhibit with moderate concentrations. Acid dyes have little effect (Somogyi, 1916).

PHENOLPHTHALEIN DYES

Two series of dyes of medical importance are formed from phthalic anhydride:

Phenolphthalein is discussed under the Cathartics. *Phenolsulphonphthalein*, which is used as a test of renal function, is formed by substituting SO_2 for the CO in phenolphthalein. In *Phenol-tetrachlor-phthalein*, used as a test for hepatic function, the four H atoms in the phthalic ring have been replaced by Cl. These dyes are injected intramuscularly, and their concentration in the excretions measured colorimetrically, after the addition of alkali which produces a molecular rearrangement that results in the red color. In *Tetrabrom-phenol phthalein*, two Br atoms are introduced into each phenol ring, (not into phthalic ring, as with the tetrachlor compounds). The bromine atoms render this compound opaque to Roentgen rays; and as it is excreted by the bile, it is used to outline the gall bladder.

Phenolsulphonphthalein Test of Renal Function.—If the sodium salt is injected intramuscularly it normally begins to appear in the urine in 5 to 10 minutes, and 60 to 80 per cent. are excreted by the urine within 2 hours. With intravenous injection, 35–45 per cent. are excreted in 15 minutes; 50–65 per cent. in 30 minutes; and 65 to 80 per cent. in an hour. Delayed appearance and diminished excretion indicate the existence and degree of renal impairment (Abel and Rowntree, 1909; Rowntree and Geraghty, 1910; Chesney, Marshall and Rowntree, 1914).

The test is performed as follows (N.N.R.).—"One cubic centimeter of a sterile solution, containing 0.006 Gm. of phenolsulphonphthalein as the monosodium salt, is injected into the lumbar muscles. Great care must be taken that all of the solution is injected.

From twenty minutes to half an hour before administering the test, the patient is given from 200 to 400 c.c. of water in order to insure free urinary secretion; otherwise delayed time of appearance may be due to lack of secretion.

Under aseptic precautions a catheter is introduced and the bladder is completely emptied, or the patient is allowed to empty it voluntarily. The time is noted, and 1 c.c. of a carefully prepared solution of the phenolsulphonphthalein containing 6 mg. to the cubic centimeter is accurately administered intramuscularly or intravenously by means of an accurately graduated syringe.

The urine is allowed to drain into a test tube in which has been placed a drop of 25 per cent. sodium hydroxide solution, and the time of the appearance of the first faint pinkish tinge is noted.

In patients having no urinary obstruction, the catheter is withdrawn at the time of the appearance of the drug in the urine. If injection is made *intramuscularly*, the patient is instructed to void into a receptacle at the end of one hour and ten minutes, and into a second receptacle at the end of the second hour. If injection is made *intravenously*, the patient is instructed to void into a receptacle at the end of fifteen or thirty minutes or one hour.

When the passing of a catheter is disagreeable and no urinary retention is present, its use can be dispensed with and the time of appearance of the drug can be disregarded.

The urine collected is made alkaline with a 25 per cent. solution of sodium hydroxide and then diluted to 1 liter. The solution is thoroughly mixed and a small filtered portion taken, to compare with the standard which is used for all of these estimations. Comparison is made in a colorimeter, a special form of which has been devised for this purpose."

Rate of Excretion.—In dogs, Arbuthnot *et al.*, 1917, found that with intramuscular injection the excretion varies greatly according to the rate of absorption. With intravenous injection, about 80 per cent. is excreted in an hour, regardless of the amount injected (between 3 and 30 mg.). The amount excreted is practically independent of the quantity of urine (beyond a certain minimum). A part is lost in the body by reduction, so that the recovery is not quantitative (Kendall, 1917).

Absorption from Subdural Injections.—Mehrtens and West, 1917, report that these are normally followed by the appearance of the drug in the urine within 10 minutes but that it may be considerably delayed in diseases of the central nervous system, especially when the meninges are involved.

Related Compounds.—Other compounds related to phenolsulphonphthalein are also excreted by the kidneys. These may be somewhat antiseptic (E. J. Davis, 1918).

Phenoltetrachlorphthalein Test of Hepatic Function.—The di-sodium salt (0.05 to 0.4 Gm.) is injected intravenously (not intramuscularly or subcutaneously), and its excretion determined either by the quantity in the stools (Rowntree, Hurwitz and Bloomfield, 1913) or by the duodenal tube (Aaron, Beck and Schneider, 1921); or its

disappearance from the blood-stream (S. M. Rosenthal, 1922). The effect of shock conditions and anaphylactoid drugs on the rates of disappearance of dyes has been studied by Hanzlik and DeEds, 1926.

Tetrabromphenolphthalein for Gall-bladder Roentgenograms.—The sodium salt contains 47 per cent. of bromine; and since it is excreted mainly in the bile, it renders this opaque to the rays. It is necessary to use large doses intravenously (0.1 Gm. per Kg. as 10 per cent. solution in two fractions half an hour apart), and this may not be entirely safe, so that it should not be used indiscriminately. In fact, it is distinctly in the experimental stage.

PREPARATIONS

Phenolsulphonphthaleinum, U.S.P.; (Phenol Red); $(C_6H_4OH)_2CO.C_6H_4SO_3$.—Red crystalline powder. Very slightly sol. in water (1:1,300); slightly sol. in alc. (1:350); almost insol. in chloroform and ether; readily soluble in dilute alkalis. *Dose*, 6 mg., $\frac{1}{10}$ gr., U.S.P.

Phenol Tetrachlorphthalein.—Pink powder. Practically; insoluble in water, sol. in alc. or ether; slightly sol. in chloroform; readily soluble in dilute alkalis. *Dose*, 0.05 to 0.4 Gm., intravenously, as the disodium salt.

Tetrabromphenolphthalein Sodium.—A purple powder, containing about 47 per cent. of bromine. Very sol. in water slightly sol. in alc. insol. in ether.

FLUORESCEINS

The structure of fluorescein and its relation to phenolphthalein is explained in the preceding section. Sodium fluorescein (*uranin*) retains its color in extremely dilute solutions and has an intense fluorescence: This is true also of the tetrabromine compound, *eosin*; and of the tetraiodine compound, *erythrosin*.

Fluorescein is used locally for revealing abrasions and foreign bodies on the cornea and conjunctiva; and by oral administration to test the permeability of the ocular vessels, in the diagnosis of intra-ocular inflammation; and also as a renal-function test. It is not toxic.

The fluorescence of eosin and erythrosin sensitize to the longer light rays, which are irritant and destructive to protoplasm.

Diagnosis of Corneal Injury.—Two per cent. of fluorescein is dissolved in water by the aid of three per cent. of sodium bicarbonate. When dropped on the eye, this does not stain the tissue protected by living epithelium; but where this has been injured by abrasions or ulcers, the dye penetrates and produces a green stain. Foreign bodies appear surrounded by a green ring. Loss of substance in the conjunctiva leads to a yellow stain. These phenomena were discovered by Ehrlich, 1882 and introduced into practice by Hamberger, 1909.

Diagnosis to Intra-ocular Inflammation.—When fluorescein is administered by mouth, the whole body becomes of a jaundice color, which disappears in twenty-four hours. Here also the normal eye is not colored, the dye being retained in the posterior chamber; but in the presence of intraocular disease, glaucoma, iritis, etc., the aqueous humor is colored bright green in about twenty minutes, thus differentiating these diseases from conjunctivitis in which there is no coloration. The *dose* by mouth for adults is 3 to 6 Gm., for children 1.5 to 2 Gm. in water. This presents no danger.

Renal Function Test.—This is described by Strauss, 1913, Sod. Fluorescein, 1 Gm. in a cup of tea, is given on an empty stomach. Normally, it appears in the urine (best seen when alkaline) in ten to twenty minutes, and lasts thirty-five to forty hours. In renal disease, it appears later and lasts longer. The skin may be stained slightly yellow, but there are no other side effects.

Eosin and Erythrosin.—Rost, 1915, found the oral administration of eosin harmless in man and animals. On intravenous injection, the toxic effects of eosin and erythrosin are much higher than those of fluorescein (Salant and Bengis, 1917).

Fluorescent Substances and Light.—V. Tappeiner and Raab, (1903) showed that fluorescent substances are very destructive to all forms of life, and also to ferments and toxins; but that the effects appear only in the presence of the specific light rays which induce the fluorescence (Review, Tappeiner, 1900; Iodlbauer and Haflner, 1921). The powerfully destructive action of fluorescence on toxins was confirmed by Noguèhi, 1900.

Smooth Muscle.—If the excised stomach of a frog is treated with a dilute solution of eosin, it goes into tonus when exposed to light, and relaxes in the dark; mammalian intestine is permanently paralyzed (Kolm and Pick, 1920).

Isolated Heart.—When this is sensitized by small doses of eosin or benzoflavin, its tonus is increased by exposure to light, and relaxed by darkness. Larger doses of the sensitizants or prolonged exposure to light also depresses (Viale, 1923).

Plants.—Eosin and erythrosin are toxic in the light, not in the dark (Shanz, 1923).

PREPARATIONS

Fluoresceinum (Resorcinphthalein).—Orange red powder, insol. in water, ether or chloroform. Sol. in dilute alkalis.

METHYLTHIONINE HYDROCHLORIDE OR METHYLENE BLUE

This dye (tetramethyl-thionine hydrochloride) is of rather doubtful value as an analgetic in neuralgia, neurites, sciatica; as antizymotic and antipyretic in malaria; as antiseptic in cystitis, urethritis, conjunctivitis and skin diseases; and as a test for kidney function. It colors the urine green or blue (also the sweat; Tachau, 1911).

Smooth and cardiac muscle is stimulated by small and depressed by large doses, on direct contact or by intravenous injection.

Urinary Antisepsis.—Methylene blue (1:150,000) is antiseptic for pure cultures; but it is a slow and weak germicide and practically inactive in the leuco form, in which it is excreted in the urine. In doses of 0.4 to 0.6 Gm., four times daily for several days, it perhaps is of some use in staphylococcus cystitis; but useless in urethritis (Hinman, 1915).

Toxic Actions.—Therapeutic doses sometimes cause slight vesical or gastro-intestinal irritation (Seifert, *Nebenwirk.*, 1915, p. 24); but its toxicity is very low, the fatal dose for dogs exceeding 1 Gm. per kilogram. Its continued use is also harmless (Tanfiljeff, 1907). Hypodermically, it may produce ulcers and abscesses.

Fate.—Methylene blue is distributed through all the tissues (localization in kidneys, G. D. Shafer, 1908), but it is rapidly reduced to colorless leuco-compounds. These are oxidized when the tissues are exposed to air (Herter, 1904), or in contact with hydrogen peroxide, thus restoring the blue color. It is excreted in the urine and feces (traces in the sweat and sputum), partly unchanged and partly as "methylene azure." The latter is also present in medicinal methylene blue, being formed from it by alkalis. Both exist in a colored and colorless (reduced) form in the urine (Underhill and Closson, 1905). This is therefore rendered more blue by oxidizing agents, especially in acid reaction; and paler by reducing agents (dextrose, etc.).

Test of Kidney Function.—0.02 to 0.5 Gm. are injected hypodermically. The excretion begins normally between fifteen to twenty-five minutes. Indigocarmine (4 c.c. of 4 per cent., hypodermically) has also been used; as well as phlorhizin. The usefulness of these tests is more limited than that of the phenolsulphonaphthalein test.

Blood-pressure and Respiration.—Intravenous injection of 4 mg. per Kg. produces a marked rise of blood pressure, which has been attributed to cardiac stimulation (Garfoukel and Gautrelet, 1913) and to vasoconstriction (Lundberg, 1922). Larger doses slow the heart. The respiration is stimulated by small and arrested by large doses (Lundberg).

Heart.—C. Heymans, 1922, found methylene blue antagonistic to the drugs that stimulate the vagus mechanism, but less effective than atropine. Lundberg believed that it stimulates both the sympathetic and the vagus mechanism.

Intestine.—This is stimulated by 1:10⁶; with 1:10⁴ this is followed by inhibition. Atropine antagonized the stimulation only imperfectly (Lundberg).

Uterus.—This is also stimulated. It can then be inhibited by large doses of atropine, but not by ergotoxine (Lundberg).

PREPARATIONS

Methylthioninm Chloridæ (Methylthionin. Chlor.), U.S.P. (Methylene Blue; Tetramethylthionine Chloride).—*Not to be confused with methyl blue!* A dark green, crystalline powder, or prismatic crystals having a bronze-like luster. Freely sol. in water and alc. *Dose*, 0.15 Gm., 2½ gr., U.S.P. Externally, 0.5 per cent. solution on mucous membranes, 2 per cent. on skin.

Sodii Indigotindisulphonas (Sod. Indigotin.), U.S.P. (Indigo carmine).—Blue powder or paste, sparingly sol. in water; insol. in alc. Used for coloring Bichloride Poison Tablets.

ACRIDINE DYES (FLAVINES)

A derivative of the coal tar base acridine was introduced by Ehrlich 1912, as a trypanocide, under the name of "trypaflavine." This is now, generally called acriflavine and is used as a local and urinary antiseptic, as is also its neutral base, and the closely related proflavine.

Structure.—*Acriflavine* is diaminomethylacridine chloride hydrochloride.

Proflavine is diamino-acridine sulphate: It differs by the

absence of the methyl group. It also is used as *proflavine base*.

Many other acridine dyes have been studied, but are not bactericidal. The preparation and properties of acri- and proflavine were described by Benda, 1912.

The literature, to 1919, was reviewed by the Council on Pharmacy and Chemistry in the Journal of the American Medical Association, 1919, vol. 73, p. 1542.

Clinical Uses.—Acriflavine and proflavine are actively antiseptic even in the presence of wound-secretions. They are relatively not very toxic to phagocytes and epithelium and therefore interfere relatively little with wound repair (Browning et al, 1917, 1919). It may be doubted whether their germicidal power under these conditions is materially superior (Dakin and Dunham, 1917). They are used to check infection of wounds and mucous membranes. Acriflavine is more antiseptic and more toxic than proflavine, but acts more slowly. Neutral acriflavine may be preferred on sensitive mucous membranes where the acidity of the others is objectionable.

Application to Wounds.—After trimming the wound, it is washed and flooded with acriflavine, 1:1,000 in normal saline. As much as possible of the solution (up to 100 c.c.) is left in the wound. The application is not painful. Fresh wounds may be sutured at once. Suppurating wounds are packed with gauze soaked in the solution, and covered with oiled dressings, to check evaporation. Proflavine may be used as a 1 per cent. ointment.

The flavines seem to have a distinct field for temporarily checking bacterial growth whilst a wound is awaiting operation; as in transportation with war-wounds; or in the interval of two-stage operations. They are not advisable for long continued treatment (Crile).

Application Gonorrhoea.—The concentration for injections is 1:1,000; for irrigation, 1:4,000 to 8,000. There is a slight burning sensation in the urethra.

Urinary Antisepsis.—The oral administration of the flavines tends to render urine antiseptic; and with some organisms, the efficiency was much better in alkaline urine. The efficiency in animal experiments was inconstant; perhaps because of differences in reaction, (Davis and White, 1919).

Intravenous Injections.—These have been tried, like other dyes, against influenzal pneumonia, rheumatism, pyelo-nephritis, etc. (Bohland, 1919). Ruhnau, 1920 found them ineffective.

Toxicity.—Tubby et al., 1910, found that rapid intravenous injections kill cats by paralysis of respiration. For rabbits, 10 to 20 mg. of acridine by vein are non-fatal; proflavine is half as toxic.

Diphtheria Toxin.—Reinhardt, 1922 claims that this is destroyed by acriflavine, 1:100.

PREPARATIONS

Acriflavina, acriflavine, N.N.R.; *Acriflavina neutra*, neutral Acriflavine, N.N.R.; and *Proflavina*, proflavine, N.N.R. These occur as reddish-brown, odorless powders, of bitter taste, forming fluorescent solutions in water. These are not injured by boiling, but are sensitive to light. One per cent. solutions may be stored in amber bottles for a week. Dilute solutions must be freshly prepared. The flavines are also soluble in alcohol, but insoluble in fat solvents.

Stains.—These may be removed from the *skin* by soap and water, followed if necessary by 3 per cent. HCl in 95 per cent. alcohol; or hydrogen peroxide may be added to the soap solution. Linen may be boiled for several hours in a 3.5 per cent. solution of sodium borborate.

TRIPHENYLAMINE (ROSANILINE) DYES

The basic dyes of this group, especially gentian violet, crystal violet and methyl violet have a selective toxicity for Gram-positive bacteria, especially staphylococcus, *b. pyocyaneus* and *b. diphtheriae*; and a very much weaker action on the Gram-negative species. They have a low toxicity for tissues, and penetrate them readily. They are being tried chiefly against staphylococcus infections, locally and intravenously. The response on intravenous injection is probably allergic. The acid dyes (acid fuchsine) act selectively on Gram-negative organisms.

Composition.—These dyes are derived from triphenyl methane, $\text{H.C.}:(\text{C}_6\text{H}_5)_3$. *Para-rosaniline* is triamine-triphenyl-carbinol, $(\text{C}_6\text{H}_4\text{NH}_2)_3\text{COH}$, and *rosaniline* is triamino-diphenyltolyl-carbinol, $(\text{C}_6\text{H}_4\text{NH}_2)_2(\text{C}_6\text{H}_3\text{CH}_3\text{NH}_2)\text{COH}$. *Fuchsine* (magenta, aniline red) is a mixture of rosaniline and pararosaniline chloride. *Basic fuchsine* is a corresponding acetate; and *Acid fuchsine* (ruby S) is the acid sodium salt of fuchsine disulphonic and trisulphonic acids. The introduction of methyl groups into pararosaniline-fuchsine results in a series of violet dyes: *Gentian violet* is a mixture of penta- and hexa-methyl pararosaniline chloride; *methyl violet* consists mostly of the pentamethyl, and *crystal violet* of the hexa-derivative. Crystal violet is most readily obtained in pure form; but so far gentian violet has been most extensively used. In fact, many of the statements refer to dyes that had been diluted with indefinite quantities of dextrin. *Brilliant green* (malachite green) also belongs to the triphenylamine group.

Gentian Violet.—The selective action on bacteria has been investigated especially by Churchman, 1914. Its relative harmlessness to tissues is illustrated by the observations of Russel, 1914, that tissue-cultures are not injured by the concentrations which kill bacteria.

Local Application.—Gentian violet (1:10,000 to 1:500) has been used mainly in pleural empyema and in arthrites, especially against staphylococcus infections.

Intravenous Injection.—Young and Hill, 1924, claim good results in septicemia, in chronic cystitis and in osteomyelitis, when caused by staphylococcus. They inject 5 mg. per Kg. of the body weight, as 0.5 per cent. dilution, repeated in 5 hours if necessary. The skin immediately takes a markedly blue tint from the dye, which disappears in a few hours.

It has been shown on animals that the intravenous injection of gentian violet produces a marked but brief fall of blood pressure, which may be preceded by a sharp rise. These effects occur also after pithing, so that they are peripheral (presumably of the allergic type). The respiration is not affected (Pindar and Donnelly, 1925).

Brilliant Green.—Leitch, 1917 claimed high antiseptic power and satisfactory results in wounds.

Acid Fuchsine.—Churchman found that this killed Gram-negative organisms (*b. prodigiosus*) in concentrations that had no effect on the Gram-positive (*b. anthracis*); but this selective action occurred only at a temperature (50°C.) materially above that of the body.

Basic Fuchsine (Gruebler), para-rosaniline acetate. This was advised by May, 1912, and Donnelly, 1914, as a lotion or ointment (1 per cent.) for ulcers and burns. It

is antiseptic, non-irritant, non-toxic, and seems to encourage epithelial growth and granulation. The color may be removed from the skin by alcohol.

PREPARATIONS

Gentian Violet Medicinal, N.N.R.—Dark green powder or pieces, with metallic lustre. Soluble in alcohol and chloroform, insoluble in ether.

BENZIDINE DYES

Trypan red and trypan blue are complex derivatives of benzidine (paradiamino diphenyl),

Ehrlich found that these have a high toxicity for trypanosomes. The dye "Bayer 205" probably belongs to this group. It is said to be the most active trypanocide, and to be successful even in advanced clinical sleeping-sickness. Its composition is secret.

AZO-DYES

"Scarlet R." is a rather complex toluyl-naphthol derivative with two azo ($-N:N-$) links. It is used as 4 to 8 per cent. ointment, to stimulate the growth of epithelium on clean granulating wounds, especially on burns and on clean ulcers (Schmieden, 1908; Morawitz, 1909). It may also be employed as solution in oil and as dusting powder (diluted with talcum). Its application should be confined to the areas of active epithelial proliferation. The 8 per cent. ointment often produces irritation and even erosion and should therefore be alternated with a soothing ointment. Systemic effects (violent gastroenteritis, Lyle, 1912) have been reported.

Although scarlet R. has been in use for many years, clinical opinions as to its value are still divided. It is conceded to be ineffective in chronic ulcers, if the local circulation is impaired. O. Sachs, 1911, claims that a number of other aniline dyes also stimulate epithelial growth but the property is especially prominent in the compounds allied to amido-azo-benzene (Martinotti, 1914).

In *cancer*, the necrotic areas accumulate diazo-dyes, but no therapeutic effects have been attained (R. Weil, 1916).

PREPARATIONS

Rubrum Scarlatinum, Scarlet R Medicinal Biebrich; N.N.R.—Toluylazotoluy-azobetanaphthol.—Dark reddish-brown powder, nearly insoluble in water, soluble in chloroform, oils and fats.

MISCELLANEOUS ANTISEPTICS

FORMALDEHYDE

The aldehydes react chemically with an exceptionally large number and variety of organic substances, amongst others with proteins. This probably explains their actions (Liebreich, 1893). Formaldehyde, $HCHO$, especially is very strongly germicidal and is largely used as a disinfectant. It hardens the tissues on local contact and thus produces irritation, especially of mucous membranes. Its systemic toxicity is relatively low.

Formaldehyde is a colorless, irritant gas, prepared by the oxidation of methyl alcohol. It is freely soluble in water, and is found on the market

in the form of a 40 per cent. solution (*Formalin*).¹ The solutions tend gradually to become inactive by the formation of the insoluble, polymeric, *trioxymethylene* or *paraform*, $(\text{HCHO})_3$, especially on heating, but some-what also on standing. The latter may be prevented by chemic means (calcium salts, methyl alcohol). Trioxymethylene again yields formaldehyde by dry heat.

Formaldehyde is converted into *methenamine* (hexamethylene tetramine) by ammonia.

Other Aldehydes.—Aldehydes contain the CHO group linked with organic radicals. Acetaldehyde and paraldehyde are somewhat antiseptic, but more markedly narcotic. This narcotic action is especially prominent in trichloraldehyde (chloral).

Acroleine, $\text{CH}_2:\text{CH}.\text{CHO}$, resulting from the decomposition of glycerin by excessive heat, is highly irritating and but little antiseptic (Fraenkel, *Arzeimittel-synth.*, p. 628).

Historical.—Formaldehyde was discovered by von Hoffmann, 1867; its antiseptic action by Loew and Fischer, 1886. Aronson, 1894, showed that it also destroys toxins.

Reaction of Formaldehyde with Proteins.—Formaldehyde enters into rather peculiar compounds, which are precipitated under suitable conditions, from which the formaldehyde and the original proteins may be completely regenerated under other conditions. The literature to 1897 is given by Benedicenti. With albumoses (Sollmann, 1902) and presumably with other proteins the compound contains definite proportions of formaldehyde, albumose and alkali. It is precipitated in weakly alkaline solutions, dissolved without decomposition by stronger alkalies, and is decomposed, or its formation prevented, by weak acids and by excess of neutral salts. Even under the most favorable conditions the combination is completed slowly. It is hastened by increased concentration of formaldehyde, protein or alkalinity, and by heat. (This combination has also been investigated by Schryver, 1911.) The precipitate also contains a further quantity of formaldehyde mechanically.

Other Chemic Actions.—Formaldehyde retards or prevents the coagulation and spontaneous laking of shed blood, when added in the proportion of 1:200 to 400. *Uric acid* and *urates* are dissolved, or their precipitation is prevented, by the formation of soluble compounds. *Urea*, on the other hand, forms an insoluble compound with formaldehyde.

Digestive Ferments.—The digestibility of fibrin and the coagulability of casein are diminished. Formaldehyde also lessens the activity of certain *ferments*, namely, papain, trypsin, ptyalin, and amylopsin; whilst pepsin, rennin, and malt diastase are but little altered.

Antiseptic Action.—Formaldehyde is one of the most powerful disinfectants, of relatively high penetrating power, harmless to metals, fabrics and colors and of relatively low toxicity. On account of its irritant effects, its use on the body is generally inadvisable. Venereal warts may be touched with the 40 per cent. solution. It is employed particularly for the disinfection of rooms and excreta.

Antiseptic Efficiency.—Formaldehyde is very much more effective as an antiseptic than as a germicide. Its activity varies for different organisms. Typhoid bacilli, with exposure of twenty-four hours, are killed by 1:6,000, completely restrained by 1:16,000; partly restrained by 1:30,000. 1:40,000 is practically ineffective (Hyman, 1914); all the concentrations refer to absolute HCHO . Solutions of $1\frac{1}{2}$ to $2\frac{1}{2}$ per cent. destroy all bacteria, spores and toxins, in six to twenty-four hours. The gas is similarly antiseptic, especially when it is moist. The activity is increased by acids, presumably by preventing combination with the proteins of the medium. (Further details, J. F. Anderson, 1897, *Hyg. Bull.*, 39; Hinman, 1913.)

The germicidal efficiency against *spirochetes* is low (1:1,800, absolute; Akatsu, 1917).

Practical Application.—*Feces* are mixed with 10 per cent. of the commercial solution. This destroys the odor almost immediately, but to insure complete disinfection, they should be left in contact for an hour. *Tubercular sputum* should be disinfected with 5 per cent. of the commercial solution for an hour. *Instruments* and other articles may be placed in $1\frac{1}{2}$ to 5 per cent. solutions of formalin.

Fumigation of Rooms.—No method of fumigation is absolutely reliable. Moist formaldehyde vapor is the most efficient fumigant against bacterial

¹ In making solutions of a given strength, it is therefore necessary to take $2\frac{1}{2}$ times as much of the commercial solution as would be required of absolute formaldehyde.

diseases, but has little penetrative power. It does not destroy mosquitoes or other insects, and is therefore inferior to sulphur dioxide against malaria or yellow fever (McClintock, *et. al.*, 1911).

Formaldehyde vapor is usually generated by the heat evolved by the interaction of formaldehyde solution with permanganate or cheaper oxidizing agents. This is somewhat wasteful, but convenient.

It may also be formed by special apparatus involving the incomplete combustion of methyl alcohol or the vaporization of trioxymethylene.

Simple spraying with formaldehyde solution (8 c.c. per cubic meter) is also used. Evaporation of formaldehyde solution by heat is wasteful, but may be employed (150 c.c. for 1,000 cubic feet).

A 1:20 dilution, allowed to stand about a room in saucers, is said to kill *flies*.

Permanganate Method.—This was introduced by Evans and Russel, 1915. For a room of 2,000 cubic feet, 2 pounds of potassium permanganate are placed in a 3-gallon pail and this is set in a large tin can containing water. When everything is ready, 2 quarts of 40 per cent. formaldehyde are poured on the permanganate, the room is vacated immediately and left closed for at least twelve hours, then thoroughly aired (Hoxie).

With this and the following methods, about 40 to 80 per cent. of the formaldehyde is effectively volatilized (Base, 1916; Hamilton, 1917; Storm, 1918).

Chromate Method.—This was introduced by S. G. Dixon, 1914, at the suggestion of Rosengarten. A solution of $1\frac{1}{2}$ fluidounces of concentrated sulphuric acid and 1 pint of U.S.P. Formaldehyde Sol. is prepared in advance and keeps perfectly. When needed, it is poured on 10 ounces of sod. dichromate crystals, which have been spread in a thin layer in a vessel of ten times the capacity of the ingredients. The gas is liberated more rapidly than with permanganate; the operator must therefore withdraw promptly.

Chlorate Method.—Storm, 1918, suggests a mixture of 1 part sodium chlorate and 4 parts of formaldehyde solution. The reaction starts only at 65°C.

Applications to the Body.—This is not recommended on account of the local irritant action. It has been employed, however, for the *disinfection of hands* (1 per cent.); as a *mouth wash and gargle* ($\frac{1}{2}$ per cent.); in *skin diseases and hyperidrosis* (2.5 per cent.); for painting the throat in *diphtheria or tonsillitis* ($2\frac{1}{2}$ to 5 per cent.). The *evaporation* of a small amount of the solution in the room has also been used in *tuberculosis*. Maguire, 1900, suggested intravenous injections of 1:20,000. They were quickly abandoned.

Formaldehyde as Food Preservative.—Concentrations of 1:33,000 to 1:10,000 have been used, especially for milk. It is both ineffective and dangerous, and is therefore properly prohibited. The ordinary concentration for milk (1:10,000) checks lactic fermentation, but does not kill the tubercle bacilli and is therefore of questionable utility. Whilst it may not interfere with digestion *in vitro* (Price, 1904), in life it may produce intestinal ulcers (Schaps, 1905). It probably causes cumulative effects. Even the local application is said to lead to inflammatory changes in the liver and kidneys (Fischer, 1905). The effects on digestion and general health are described by Wiley, 1908.

Salkowski, 1915, states that formaldehyde, 0.6 to 1 Gm. per day, added to the food of a 12 kilogram dog, was well tolerated and did not impair the utilization of protein.

Local Actions.—Formaldehyde solutions or vapor, even when very dilute, produce very strong irritation of all *mucous membranes*. The susceptibility to this irritation is diminished by *habituation*. Applied to the unbroken *skin*, it hardens the epidermis, renders it rough and whitish, and produces anesthesia. Repeated application of strong solutions leads to superficial *necrosis* of the skin and nails and to persistent eczema (Galewsky, 1905). Its application to broken surfaces is very painful. Isolated tissues are promptly hardened. Formaldehyde is therefore used in *histologic technic* in strengths of $1\frac{1}{2}$ to 10 per cent. These effects are produced by the *coagulation of proteins*. They are influenced by the concentration and by the time of contact (Meneguzzi, 1913).

Urticaria.—The endermic application of formaldehyde (2 per cent.) produces wheals (Sollmann, 1917). General urticaria is also sometimes seen from the systemic use of

formaldehyde, in mouthwash (Heidingsfeld, 1916) or formamint tablets (Glaser-Lipehne).

Use on Perspiring Feet.—Althof, 1914, claims relief by painting the skin with 20 per cent. formaldehyde, daily for 3 days. The effect is said to persist 4 to 6 weeks, when the treatment is repeated. It is doubtful whether the method is harmless.

Red Corpuscles.—These are fixed by dilute solutions similarly to other tissues; strong solutions of commercial (not of pure) formaldehyde may produce laking, by their formic acid (Franchi, 1913).

Systemic Actions.—The *inhalation* of formaldehyde vapors, even for a long time, produces but small effects, beyond the local actions, causing bronchitis and pneumonia. The *intravenous injection* of solutions in normal saline of a strength of 1:5,000 also produce no immediate effects, even in man. The fatal dose for mammals intravenously, is about 0.07 to 0.09 Gm. per kilogram; the hypodermic dose is approximately ten times as much.

When applied directly to the mucosa of the upper intestine (not the lower), the irritation of the formaldehyde produces an increased flow of pancreatic juice. The most favorable concentration is 1 to 2 per cent., 8 to 10 per cent. being ineffective (Delezenne and Pozerski, 1915).

The contractibility of *heart muscle*, in frogs, is lowered by formaldehyde and acetaldehyde. The irritability is not changed (Sasaki, 1921).

Poisoning by Swallowing Formaldehyde.—A number of such cases have been reported. As summarized by MacLachlan, 1909, the symptoms consist of immediate and severe abdominal pain; often sudden and prolonged loss of consciousness, and collapse. Death occurs in twenty-four to forty-eight hours. The autopsy shows severe gastritis with erosions. In non-fatal cases, the urine is suppressed for twelve to twenty-four hours, and then generally contains blood and casts. There is often diarrhea and tenesmus, sore mouth and dysphagia. The recovery is curiously rapid, the patients being well within a week. The fatal cases all took over 3 ounces of the commercial solution. The largest quantity from which recovery is reported is 60 c.c.

The *treatment* should consist in the administration of dilute ammonia and in lavage.

Fate of Formaldehyde.—Formaldehyde is absorbed from all parts of the alimentary tract and lungs (McGuigan, 1914). It is not excreted as such (Blum; Pohl, 1893), even with intravenous injection; unless very large doses are given (McGuigan, 1912; Impens and Rosenberg; Salkowski, 1915). It is mainly oxidized in the tissues, especially the liver (Pohl), to formic acid. The oxidation of aldehydes is not direct, but through the "Cannizzaro reaction," commonly observed *in vitro* when aldehydes are treated with alkalis, $2\text{HCHO} + \text{H}_2\text{O} = \text{CH}_3\text{OH} + \text{HCOOH}$. A part of the formic acid may appear in the urine (Pohl; Klueber and Gerlasch); but small quantities of formic acid are also completely destroyed (Sollmann, 1908). Some of the formaldehyde may be transformed into methenamine (McGuigan).

PREPARATIONS

* *Liquor Formaldehydi* (Liq. Formaldehyd.), U.S.P., B.P.; Solution of Formaldehyde (Formalin).—A watery solution containing not less than 37 per cent. of HCOH . Clear, colorless liquid; pungent odor and caustic taste. Miscible with water and alcohol. A tablespoon in a quart of water makes about 1 per cent. of absolute formaldehyde.

Liquor Formaldehydi Saponatus (Liq. Formaldehyd. Sap), B.P.—20 per cent. of Liq. Formaldehyde, 40 per cent. of Soft Soap; 30 per cent. of Alcohol.

Paraformaldehydum (Paraform.), U.S.P. (Paraform, Trioxymethylene), $(\text{HCOH})_3$.—White friable masses, or as a powder, having a slight odor of formaldehyde. Slowly sol. in cold water; insol. in alc. or eth. Dose, 0.5 Gm., 8 gr.

It sublimes slowly at 100°C . and melts at 171°C . Heated under proper conditions, it is decomposed into formaldehyde and is used for the *disinfection of rooms*. Two Gm. of paraform are required per cubic meter (35 cubic feet of space). Formaldehyde is also slowly liberated at body temperature: paraform has therefore been suggested as an *intestinal antiseptic* (0.05 to 0.1 Gm. every two hours, for children), but its irritant actions renders it objectionable. Larger doses (3 to 4 Gm.) are *cathartic*, small doses are rather constipating. It will not cause serious poisoning even in large doses.

FORMALDEHYDE COMPOUNDS

These are generally inactive and non-irritant in themselves, but regenerate formaldehyde under suitable conditions. It was therefore thought that they would prove valuable antiseptics. However, most of them

liberate it either too slowly or too readily. Methenamine alone has proved really valuable.

Glutol (Schleich, 1896) is an insoluble compound of formaldehyde and gelatin, which holds the greater part of the formaldehyde so firmly that it is practically useless (Sollmann, 1908). Other protein compounds were also disappointing. Classen introduced compounds with **carbohydrates**: Starch (amyloform), dextrin, milk-sugar, etc. Their fate was studied by Jacobson, 1906. There were also combinations with phenols, urea (Cohn, 1897), etc. Anhydromethylencitrate (*citarin*) splits off CH_2O too readily (Nicolaiër, 1906); whilst methylendisalicyclic acid is not decomposed in its passage through the body (Sollmann, 1908).

METHENAMINE (HEXAMETHYLENAMINE)

Methenamine or hexamethylene-tetramine, $\text{N}_4(\text{CH}_2)_6$, is formed by the action of ammonia on formaldehyde. It is itself quite devoid of antiseptic, irritant or toxic actions. Its solutions, however, dissociate slowly with the evolution of formaldehyde. This decomposition is favored by the presence of free acid; it becomes practically negligible at neutral reaction and is arrested by relatively mild alkalinity.

From one-sixth to one-third of the methenamine is decomposed by the acid reactions of the digestive tract, especially of the stomach. The absorption of the remainder starts promptly and the methenamine is distributed rapidly through the tissues and secretions, and excreted unchanged mainly in the urine.

The acid reaction of the urine sets free a small quantity of formaldehyde, sufficient to be more or less antiseptic, so that methenamine is used in the prophylaxis and treatment of urinary infections (introduced by Nicolaier, 1895, 1899). It would be useless if the urine is alkaline. Occasionally, especially in susceptible individuals, it may produce irritation of the bladder and hematuria. This is minimized by liberal dilution. Even large doses do not cause systemic poisoning.

Insignificant traces of formaldehyde are liberated in the blood and tissues; even under optimal conditions the concentration would remain far below the antiseptic level. Before this limitation was realized, methenamine was tried against infections of the bile-passages, meninges, respiratory tract, accessory sinuses etc. The liberated formaldehyde is oxidized to formic acid.

Formation of Formaldehyde.—This occurs according to the reversible reaction: $\text{N}_4(\text{CH}_2)_6 + 6\text{H}_2\text{O} \rightleftharpoons 4\text{NH}_3 + 6\text{HCHO}$. The end point depends on the hydrogen-ion concentration, and the speed of the adjustment on the temperature. At body temperature the following percentages of methenamine is hydrolyzed to formaldehyde, in watery solutions:

pH	(Equivalent to)	(In 2 hours)	(In 6 hours)
2 to 1	(gastric juice)	60-100	100
5	(maximum acidity of urine)	25	35
6.8	(asphyxial blood)	0.8	1.0
7.2	(normal blood)	0.35	0.8
9			0

(De Eds, 1924; P. Trendelenburg, 1910; Jordan, 1911; Hanzlik and Collins, 1913.) Proteins interfere with the liberation of formaldehyde, so that none could be demonstrated with alkaline reactions.

Time of Excretion and Distribution.—Methenamine appears in the urine within eleven minutes after oral, rectal or hypodermic administration, reaches its maximum in one to three hours, and practically ceases in four to eight hours, according to the dose. After twelve hours only very small amounts are excreted, although the blood may contain faint traces after twenty-four hours (Sollmann, 1908; Crowe, 1908; Burnam, 1912; Falk and Sugiura, 1916). Approximately the same time relations obtain for its concentration and disappearance from the other secretions and tissues. Its distribution is universal, since it has been demonstrated in all parts of the body in which it was sought.

Quantitative Excretion.—With doses of 1 to 5 Gm., from 32 to 85 per cent. of the methenamine are excreted by the urine. The percentage is independent of the dose (within these limits), of diuresis, and of clinical conditions. It is determined mainly by the reaction that the methenamine encounters in the digestive tract, and the excretion can therefore generally be increased by the administration of alkali (De Eds 1924).

The Concentration of Methenamine.—This depends on the dose, the time, and in the case of urine very largely on the ingestion of fluid.

With continued administration three times daily, the concentration in the urine ranged from 1:1,400 to 2,800 for doses of 0.67 Gm.; between 1:2,400 to 14,000 for 0.33 Gm. (Falk and Sugiura, 1916). In other secretions and in the tissues the concentration is probably lower.

Excretion in Eye.—Gradle, 1911, found methenamine in the anterior chamber, its excretion being hastened by mydriatics; however, its concentration is not sufficient to be antiseptic. In cats Remelé, 1916, found it in the aqueous humor shortly after the intravenous injection of 2 Gm.

Excretion in Milk.—This was announced by Bucura, 1905, and confirmed by Crowe, 1908, Woldewijn, 1910, and by J. Schmid and Schroeter, 1910. Reider, 1912, found that the highest concentration was reached after an hour.

Excretion in Saliva.—The excretion reaches its maximum in half an hour (Hanzlik).

Presence of Free Formaldehyde in the Urine.—The amount of formaldehyde liberated depends upon the acidity, the concentration, the time of standing, and perhaps on other unknown conditions. The liberation may occur in the kidney (Burnam) and increases in the bladder (Sollmann; Hinman, 1913). Burnam found it often absent with small doses, but believes that with larger doses the concentration of free formaldehyde may exceed 1:5,000. Smith found that 0.5 Gm. always gave formaldehyde in acid urines, while 0.3 Gm. was inconstant. Alkaline urines do not liberate formaldehyde; but the formaldehyde liberated in the acid kidney may persist for a short time in the alkaline bladder. Kidney disease does not modify the liberation (Hinman).

L'Esperance and H. Cabot, 1912, found free formaldehyde in about half the methenamine urines examined. They believe that the liberation is not affected by the dosage or by the reaction of the urine. This conclusion can only have been based on faulty methods of estimating the acidity; for G. G. Smith, 1913, and Hanzlik and Collins showed definitely that all acid urines liberate formaldehyde. Smith and Jennes, 1913, also found it in about half the cases.

Concentration of Formaldehyde in Urine.—With the present rather unreliable methods, Hinman, 1913, claims that this is below 1:40,000 in half the cases; 1:16,000 in 25 per cent.; and over 1:7,000 in 2 per cent. of the urines.

Antiseptic Action.—*Methenamine itself is not at all antiseptic*, if the liberation of formaldehyde is prevented by alkalis (Hanzlik, 1913). A concentration of 5 per cent. is required to check the growth of staphylococcus in neutral broth cultures; and this may be attributed to the free formaldehyde (Jordan). The antiseptic action is always parallel to the concentration of free formaldehyde (Hanzlik and Collins). Formaldehyde in concentration of 1:50,000 to 30,000 has a distinct though limited antiseptic effect (Mossa and Paleotti).

Antiseptic Effects after Administration.—These are especially marked in acid urines, as might be expected. However, Crowe, 1908, claims that the administration of 5 Gm. per day also renders the bile and other body-fluids antiseptic. Exact observations have not confirmed this (Hanzlik and Collins), and the idea of producing a "tissue-antiseptis" by its use must be abandoned.

Therapeutic Use as Urinary Antiseptic.—Methenamine is by far the most effective urinary antiseptic, provided that the reaction of the urine is acid. In neutral or alkaline urine, its efficiency is practically nil (Jordan, 1911). In ammoniacal urines it would be useless. It would therefore be especially valuable as a prophylactic, *f.i.*, in catheterization (Hinman, 1915). It has also been advised to prevent the spread of typhoid bacilli (Richardson, 1898); but its efficiency is doubtful. It may be used in inflammation or suppuration of the renal pelvis, bladder or urethra. The dosage should be from 0.25 to 0.5 Gm. (4 to 8 gr.) in half a glass of water, four or five times a day. Burnam, 1912, recommends increasing the dosage until free formaldehyde appears in the urine. In typhoid fever, the same dosage would be employed continuously, from the time when the diagnosis is made. If the urine is alkaline, acid sodium phosphate (NaH_2PO_4) should be administered, 1 to 2 Gm. every one to four hours, as a separate prescription, until the urine is acid. This often causes diarrhea.

Relative Value of Other Urinary Antiseptics.—Using the ordinary therapeutic doses in a normal subject, Sollmann, 1905, found that urinary decomposition was prevented, at incubator temperature, with methenamine, for three days to three weeks; after salicylates for a day; benzoate, phenolsulphonate and boric acid had no discernible effect. Churchman, 1906, concludes that methenamine surpasses methylene blue. Jordan, 1911, found it much superior to salicylic acid and santal oil. The difference is of course most marked in acid urines, although this increases the efficiency of all the antiseptics. The greatest effect of santal oil was on staphylococcus. He found boric acid the best antiseptic for alkaline urines (1913).

Solvent Action on Uric Acid.—Methenamine has been proposed as a remedy for gout and urate calculism. It, as well as formaldehyde, dissolves uric acid, with the formation of a series of paired compounds (Nicolai, 1906). However, the solvent action is really very slight (Stevens and May, 1911), and the experimental and clinical results have been disappointing (Hanzlik, 1916).

Haskins, 1915, found that the administration of methenamine in doses of 1 to 2 Gm. does not confer any solvent action on the urine. Doses of 4 Gm. made the urine distinctly more solvent; but equal results are secured by making the urine slightly alkaline ($\text{p. H.} = 7.1$ to 7.4) as may be easily done by administering sodium bicarbonate or acetate. These results were also confirmed by adding methenamine directly to water, urine and phosphate mixtures.

Presence of Free Formaldehyde in the Tissues.—Methenamine must continuously liberate small quantities of formaldehyde in the tissues; but this is probably rapidly bound by the proteins and oxidized to formate, so that it has been impossible to detect its presence by the most delicate tests in any of the tissues and secretions, other than the gastric juice and urine: Negative results were reported for the milk, Schmid and Schroeter; saliva, Hanzlik; bile, cerebro-spinal fluid and sputum, Burnam, 1912; various situations, McGuigan, 1912; blood and cerebro-spinal fluid, Voit, 1923; blood, de Eds, 1924. The very small excretion of formate is an index to the very small quantity of formaldehyde that is liberated (De Eds, 1924).

Administration for Systemic Disinfection.—Large doses, 5 to 20 Gm. per day, were formerly administered against infections of the biliary and respiratory tracts, meninges, etc.; but more critical observations failed to show any antiseptic action (biliary tract, Burnham; infantile paralysis, Fraser, 1914; empyema, Shattuck, 1911).

Hematuria.—Methenamine itself is non-irritant, so that it may be given hypodermically (Gundrum, 1911) or injected into the bladder in 50 per cent. solution (Burnham). After the liberation of formaldehyde, this becomes irritant, but only in specially susceptible individuals or with

large doses. This results in painful micturition and eventually cystitis and hematuria. In Crowe's cases the hemorrhage was from the bladder. The kidneys may probably also be irritated. The cystoscope shows hemorrhagic cystitis; and post-mortem examination also hyperemia of the pelvis (D. L. Simon, 1914). The hematuria has been used by malingerers (Marie and Behague, 1920). These irritant effects are quite exceptional if the drug is given in sufficient dilution. They disappear promptly and without any permanent damage, if it is discontinued.

I. A. Abt, 1917, believes that its use has caused severe and fatal nephritis; this still requires confirmation.

In dogs, Wiggs, 1910, obtained marked nephritis from relatively small doses. Rabbits show hematuria only with 8 Gm. per day (D. L. Simon, 1914). In guinea pigs, hypodermic injections (Frothingham, 1910) produce local necrosis, and gastric congestion, hemorrhage and ulceration.

Other Undesirable Actions.—Rubeolar skin rashes, catarrhs of various mucosae, and digestive disturbances have been reported (Coleman, 1903), but they are rare.

Intravenous Injections.—This does not seem necessary or justified in view of the rapid absorption of methenamine; but it has been used (1.5 to 2 Gm. as 25 per cent. solution; Loeper and Grosdidier, 1918). Very large doses may be injected without direct toxicity (Crowe, 1908; Burnham, 1913); occasional anaphylactoid reactions may be expected.

Incompatibilities.—Methenamine is a fairly strong base, gradually displacing ammonia from its salts. It is decomposed by acids (even acetyl-salicylic acid) and by acid salts with the liberation of the irritant formaldehyde. It is also incompatible with tannin, mercuric chloride and oxidizing agents (J.A.M.A., Feb. 8, 1913, p. 465).

PREPARATIONS

**Methenamina* (Methenam.), U.S.P.; *Hexamina*, B.P. Hexamethylenamine, Hexamethylenetetramine, $(\text{CH}_2)_6\text{N}_4$.—It was introduced as *urotropin* and is also marketed under other numerous and confusing trade names. These commercial brands are in no way superior to the official substance (Base, 1907). It occurs as colorless, lustrous, odorless crystals, of sweet, then bitter taste. Solutions react alkaline to litmus. It is freely sol. in water (1:1.5), and alc. (1:2.5). *Dose*, 0.3 Gm., 5 gr., U.S.P.; 0.3 to 1 Gm., 5 to 15 gr., B.P.

Salts.—A number of these are described in N.N.R. but they have no serious advantage. Boruttau, 1914, claims that the urinary antiseptic action is somewhat greater with salicylate or camphorate; and that the urate solvency is higher with the citrate, borate or sulposalicylate.

Jacobs and Heidelberg, 1915, report experiments with some quaternary derivatives that appear promising. The activity of these does not seem to depend on the liberation of formaldehyde, so that they are not inhibited by protein and do not require acid.

OXIDIZING AGENTS

OZONE

This is a polymeric form of oxygen (O_3), which decomposes very readily with the liberation of active oxygen. It is therefore strongly oxidizing, deodorant and antiseptic; but is too easily destroyed in the presence of organic or other oxidizable matter. Efficient concentrations are also highly irritant and produce toxic depressant systemic effects. It is being used for the sterilization of water. Traces of ozone are contained in the air, especially after thunder storms, but the quantity is much too small to have any effect whatever; in fact, concentrations far beyond

human tolerance are of uncertain efficiency (J.A.M.A., 57: 1370, 1911). At most, its persistent presence is an indicator of the absence of organic matter in the air. The odor of ozone is characteristic and disguises other odors.

Effects of Inhalation.—The older methods of preparing ozone developed irritant nitrogen oxides. The modern machines are free from this defect. By their use, concentrations of 5 to 10 per million, inhaled for a short time, produce in man increased amplitude of the pulse, drowsiness, and persistent headache—the latter probably by irritation of the sinuses. Ten per million inhaled for fifteen minutes produces sore throat. One per million diminishes the oxygen intake and the CO₂ output. *Prolonged exposure* to concentrations below 1 per million does not produce noticeable disturbance; but with higher concentrations there is irritation of the respiratory tract and other mucous membranes, leading to fatal pulmonary edema; or in acute toxic concentrations to initial restlessness followed by depression and coma (Jordan and Carlson, 1913; Hill and Flack, 1911; Sigmund, 1905; Du Mont, 1891). Exposure for two hours to 10 or 15 per million is dangerous to life, but the irritant effects, cough, headache, etc., give ample warning to avoid the danger. For an antiseptic action, at least 13 per million would be necessary (L. Hill and Flack, 1911). The air contains at most 0.00015 to 0.158 per million. Its seasonal occurrence is discussed by Holmes, 1912.

HYDROGEN PEROXIDE

The peroxides are fairly stable in pure solutions, but on contact with catalyzers, inorganic or organic (catalase), tissues, etc., they split off active oxygen and are therefore strongly antiseptic and deodorant. The action lasts only so long as oxygen is being evolved, and is therefore brief and superficial. In deep and closed cavities, the rapid evolution of gas presents danger of mechanical injury and embolism.

Uses.—Hydrogen peroxide is employed for washing fetid wounds and ulcers; as injection for gonorrhea; as mouth wash, etc. It is non-toxic and scarcely irritant, but is best diluted with 2 to 10 parts of water. A stronger (30 per cent.) preparation is caustic. In contact with pus it foams, and this aids mechanically in cleansing the wound. Hydrogen peroxide is also a chemic *antidote* for cyanide and phosphorus poisoning. It is often used for *bleaching* the hair and fabrics. The concentration of 0.35 per cent. (absolute) in *milk* inhibits the development of pathogenic bacteria (Budde, 1903) but it also destroys the ferments of milk and is of questionable utility (Heinemann, 1913). Sieber, 1901, claims that it destroys toxins. The germicidal action is feeble (Albert and Taylor, 1918).

Phagocytosis.—This is stimulated *in vitro* by hydrogen peroxide; whereas free oxygen is generally depressant (H. J. Hamburger, 1915). Potassium chlorate and ferricyanide proved inactive.

PREPARATIONS

* *Liquor Hydrogenii Dioxidii* (Liq. Hydrog. Diox.), U.S.P.; *Liq. Hydrog. Perox.*, B.P.; Solution of Hydrogen Dioxide (Peroxide).—A slightly acid aqueous solution of H₂O₂ (approximately 3 per cent.) corresponding to about 10 per cent. (volumes) of available oxygen. Stronger solutions are also marketed. It occurs as a colorless liquid, odorless, of slightly acid taste, producing a peculiar sensation and soapy froth in the mouth. It keeps best in bottles stoppered merely with a plug of cotton, and standing in a cool place. It is incompatible with easily oxidizable substances. It decomposes gradually. This is not due to impurities (Clover, 1913). The decomposition is retarded by small quantities of acid or acetanilid. The latter is used in most brands (Kehler, 1910), but in time these acquire a yellow tint and an odor of nitro-benzol, and should then not be used. *Dose*, 4 c.c., 1 drachm, U.S.P.; 2 to 8 c.c., $\frac{1}{2}$ to 2 drachms, B.P.

"*Solid Peroxide*" consists of easily soluble compounds with urea, containing about 35 per cent. of absolute peroxide.

PEROXIDES OF METALS

These may be conceived as compounds in which the H of H_2O_2 has been replaced by metals, and which are readily decomposed with the formation of H_2O_2 or of active oxygen. They have been suggested at substitutes for hydrogen peroxide. The commercial products are usually mixtures containing 15 to 75 per cent. of the real peroxide. The compounds of the different metals vary considerably in their stability and solubility, and in the ease with which their solutions are decomposed. Acids convert them rapidly into hydrogen peroxide, *f.i.*, $\text{MgO}_2 + \text{H}_2\text{SO}_4 = \text{MgSO}_4 + \text{H}_2\text{O}_2$. In this way the oxygen is made promptly available. Water decomposes them more slowly, inversely to their solubility; *f.i.*, $\text{ZnO}_2 + 2\text{H}_2\text{O} = \text{Zn(OH)}_2 + \text{H}_2\text{O}_2$. Their action is therefore more prolonged. The therapeutic effect is also modified by the nature of the base; thus sodium peroxide would yield a solution sufficiently alkaline to be caustic. Magnesium or zinc peroxide is therefore generally preferred.

Uses.—The antiseptic effects are utilized in skin diseases (ZnO_2); dentifrices (MgO_2); and against gastro-intestinal fermentation (CaO_2). These compounds are described in N.N.R.

Sodium Perborate.—This also yields hydrogen peroxide on contact with water, being transformed into metaborate which acts as a mild alkali, $\text{NaBO}_3 + \text{H}_2\text{O} = \text{H}_2\text{O}_2 + \text{NaBO}_2$. It is used as a dusting powder or 2 per cent. solution, as a substitute for peroxide. The substance is described in N.N.R.

ORGANIC PEROXIDES

These were introduced by Novy and Freer, 1902. Acetyl-benzoyl peroxide (Acetozone) and succinic dioxide (Alphozone) are described in N.N.R. They may be considered as H_2O_2 in which the H has been replaced by organic radicals. In the presence of water they are slowly hydrolyzed, forming organic per-acids, with very active oxidizing and germicidal properties, *f.i.*, the acetyl benzoyl peroxide decomposes into acetyl per-acid, acetic acid, and the insoluble dibenzoyl peroxide, according to the equation $2\text{C}_6\text{H}_5\text{CO.OO.COCH}_3 + \text{H}_2\text{O} = \text{C}_6\text{H}_5\text{CO.OO.COC}_6\text{H}_5 + \text{CH}_3\text{CO}_2\text{H} + \text{CH}_3\text{CO.OOH}$.

They are somewhat used as local and intestinal antiseptics, but are of doubtful efficiency for the latter purpose. They should not be mixed with organic liquids, nor kept in a warm place, as they tend to explode. They are described in N.N.R.

IODOXYBENZOIC ACID

This is being tried in chronic arthritis, with promising results. It appears to arrest the progress of the disease, and to remove the functional disturbances; to relieve the pain, diminish the swelling and tenderness of the joints, to increase their mobility and functional use, and to improve the general health (A. G. Young and Youmans, 1926). The ammonium salt is administered intravenously; 1 Gm. in 100 c.c., injected slowly (ten minutes), once or twice a week, for 6 to 8 doses. The toxicity is low, and is determined mainly by the rate of injection. At most, there may be temporary apnea. The solution is irritant, and may produce fibrosis of the vein; if it escapes into the subcutaneous tissue, it is painful, but not escharotic. The mechanism of action is not understood. The injections are often followed by irritation of the mucous membranes and presumably of other tissues; and it is possible that it sets up acute inflammatory reaction in the joints, which may lead to improvement of the chronic process.

Iodoxybenzoic acid was investigated by Heinz, 1899. It has a strong oxidizing action, even in the body, and is therefore of considerable scientific interest. Loevenhart and Grove, 1911, have investigated the sodium salts of the three compounds:

- (1) Iodbenzoic acid, $\text{C}_6\text{H}_4.\text{CO}_2\text{H.I}$.
- (2) Iodosbenzoic acid, $\text{C}_6\text{H}_4.\text{CO}_2\text{H.I} = \text{O}$.
- (3) Iodoxybenzoic acid, $\text{C}_6\text{H}_4.\text{CO}_2\text{H.I} \begin{smallmatrix} \text{O} \\ \parallel \\ \text{O} \end{smallmatrix}$.

(2) and (3) have a metallic taste, resembling hydrogen peroxide, presumably due to the active oxygen. They oxidize hemoglobine to oxyhemoglobine. (2) is irritating, (1) and (3) very mildly. The systemic effects were studied by intravenous injection. (1) has very little action. The oxygenated compounds (2) and (3) produce the phenomena of apnea; marked and continued fall of blood pressure by depression of the vasomotor center; brief arrest of respiration, also by depression of the medullary center. The vagus center is not affected. These actions are due to the active oxygen. (This can not replace ordinary molecular oxygen for maintaining the cardiac activity; Loevenhart and Eyster, 1913.)

Antiseptic Action.—The oxidizing property promises an antiseptic effect, perhaps even in the tissues, since it is not inhibited by serum. (2) and (3) are much more

bactericidal than (1) (Arkin, 1911). Iodoxybenzoate increased the production of antibodies in dogs (Hektoen, 1911); also the production of hemolysin and agglutinin in rabbits, when injected intravenously shortly after immunization. It stimulates phagocytosis (Arkin, 1915). Its injection also lessens inflammation by mustard oil or allergy, whilst this is increased by cyanide, indicating that edema is lessened by oxidation and increased by asphyxia (Amberg and Knox, 1912; Amberg, 1913). Iodosobenzoic acid has also been studied by Jahn, 1914. It reduces the toxicity of tuberculin *in vitro* (Arkin, 1916).

POTASSIUM PERMANGANATE

In the presence of organic matter, this splits very readily into MnO_2 (forming a brown precipitate), and into oxygen. It is therefore an effective oxidizing agent and disinfectant; but its efficiency is limited by any excess of organic matter. Its action is only superficial, and it is markedly irritant. It is used as an antiseptic for mucous membranes, especially the urethra (1:4,000 to 1:1,000). A 1:5,000 solution is said to be a satisfactory anesthetic for introducing urethral sounds (Barton, 1913). Beck, 1913, recommends it against burns (1:4,000 to 1:3,000 on gauze and as lotion).

It is an antidote to organic poisons, especially morphine, hydrocyanic acid, and phosphorus (1:1,000 to 1:500). A saturated solution may be employed for disinfecting the hands, the color being removed by oxalic acid. Large doses by mouth cause death by gastroenteritis.

In snake-bite, it is effective, but only if used within 5 minutes (1 per cent., applied to free incisions after double ligature, if possible; Weidenmann, 1915).

PREPARATIONS

**Potassii Permanganas* (Pot. Permang.), U.S.P., B.P.; $KMnO_4$.—Slender, dark purple prisms; odorless; astringent taste. Sol. in water (1:13.5); decomposed by alc. and all organic matter; explosive. *Dose*, 0.06 Gm., 1 gr., U.S.P.; 0.06 to 0.2 Gm., 1 to 3 gr., B.P.; diluted.

Liq. Pot. Permang., B.P.—1 per cent. *Dose*, 7 to 15 c.c., 2 to 4 drachms, B.P.

BORIC ACID AND BORAX

These combine a fair antiseptic power with a low toxicity to higher animals. They are also less irritant than most other antiseptics. Boric acid is employed in surgery as dusting powder, as saturated (4 per cent.) aqueous solution, as boroglycerite, and in collyria (1 to 2 per cent. of boric acid or sodium borate). Boric acid is a mild acid, and increases the acidity of the urine; borax acts as a weak alkali. It dissolves mucus, lessens the urinary acidity, and is used for cleansing. The acid and alkali characters are very weak. The borate ion has no other *therapeutic uses*.

Boric acid and borax have been extensively employed as food preservatives. Small single doses are generally innocuous; but their continued use produces slight but cumulative effects, so that their employment is not advisable.

Directly harmful effects follow doses of 2 to 5 Gm. of boric acid or borax, and 15 to 30 Gms. may be fatal (Schwyzer; C. Potter, 1921.)

Antiseptic Efficiency.—Boric acid is not a disinfectant. Even saturated solutions do not kill bacteria, but solutions of 0.3 per cent. check putrefaction and decomposition (but not the growth of pathogenic organisms, Bernstein, 1910).

The antiseptic efficiency varies for different bacterial cultures. It begins with about $\frac{1}{10}$ saturated; and for most is complete with about $\frac{1}{6}$ saturated (Tanner and Funk, 1919). Borax is somewhat less efficient. Their popularity as food preservatives is attributable to the absence of distinctive odor and taste, and to their relatively low

toxicity. The acid is used in meats in the concentration of 0.5 per cent.; in milk of 0.2 per cent.

Action of Small Doses.—This has been investigated extensively. It may be premised that boric acid and borax behave exactly alike. A man living largely on preserved food may ingest as much as 0.5 Gm. of boric acid (or its equivalent in borax) per day; the consumption would generally fall below this figure, but could rise to several grams. All investigators agree that quantities to 0.5 Gm. have no immediate action of any kind in healthy individuals. When, however, the consumption is continued for a long time, quite marked effects are produced (Forster, 1883; Heffter, 1902; Rubner, 1902; Rost, 1902, 1903, 1905; Wiley, 1904). The digestion becomes somewhat deranged; the body weight lessens; the feces become more watery (but there is no diarrhea even with larger doses). The absorption of fat and of nitrogen is somewhat diminished. The urinary nitrogen is slightly decreased, whilst the phosphates rise distinctly. The quantity of urine is scarcely altered. If a slight albuminuria was present, this is increased (Wiley). Boric acid therefore seems to have a *cumulative action* on digestion and absorption, metabolism, and the kidneys. The cumulative effect may be explained by the observation that the **excretion** of boric acid is slow, requiring several days. (However, it begins within ten minutes, and reaches its maximum in the second hour.) On the average, 15 per cent. is retained, the other 85 per cent. being excreted mainly by the urine, to a slight extent by sweat and milk, and practically none by the feces (Wiley). The excretion is not hastened by diuresis (Rost, 1905). Traces occur normally in milk and eggs (Bertrand and Agulhon, 1913).

The effects of such doses as are actually consumed would therefore not be very serious, even if the consumption of preserved food were continued for a long time. However, the results are somewhat deleterious, even in normal individuals; and they would probably be very undesirable in patients with digestive or renal disturbance.

Toxic Doses.—Somewhat larger doses, 1 to 3 Gm. per day, produce the described effects more rapidly and more severely. Headaches appear. With 5 Gm., the subject soon becomes unable to do any work. Quantities above 2 Gm. per day may be condemned as distinctly harmful, without any hesitation. (Some investigators hold the opposite opinion, for instance Liebreich, 1903 and 1904. Their results may perhaps be explained by individual differences of susceptibility, which were also noticed by Wiley.) Harrington, 1904, has observed that the continued administration of borax to cats leads to very severe kidney lesions. Very large doses cause **acute poisoning**; this may also occur from local administration (van Dort Krom, 1906); especially from flushing serous cavities and from the use of powdered boric acid on extensive burns (Savariaud, 1914). The symptoms consist ordinarily in gastroenteritis, congestion of the abdominal viscera, nephritis (granular degeneration), scarlatinal skin eruptions; very commonly visual disturbances, muscular debility and incoördination, fall of temperature, collapse. The autopsy shows fatty degeneration (Rinehart, 1901; Best, 1904).

The action on the *uterus*, which are not very marked, have been investigated by J. W. C. Gunn, 1920.

Boric Acid Hemolysis.—Blood corpuscles suspended in 1 per cent. boric acid do not undergo any visible change; but their osmotic properties are altered, so that they become laked if transferred to isotonic salt solutions. This alteration is due to the presence of boric acid within the cells, for laking does not occur if the corpuscles are washed in hypertonic salt solutions (Kosakai, 1919).

Borax and the insoluble calcium borate kill *house-fly larvæ* in manure etc. (Cook and Wilson, 1917).

With *plants*, even low concentrations in the soil or culture solution causes spotting of the leaves (Haselhoff, 1913).

Minute traces of boron occur in all animals, most abundantly in the oceanic (Bertrand and Agulhon, 1912). Plants also take it up readily from the soil (Cook, 1916).

PREPARATIONS

**Acidum Boricum* (Acid. Bor.), U.S.P., B.P.; Boric Acid (Boracic Acid), H_3BO_3 . Translucent colorless scales, or light very fine bulky powder, unctuous to the touch; odorless; of slightly saline taste. Slowly sol. in water (1:18); sol. in alc. (1:18); freely sol. in glyc. (1:4). *Dose*, 0.5 Gm., 8 gr., U.S.P.; 0.3 to 1 Gm., 5 to 15 gr., B.P.; as urinary antiseptic. Locally, in lotions, injections, gargles, etc., 2 to 4 per cent. (1½ to 3 teaspoons per pint.) A saturated watery solution contains about 4 per cent., or 25 gr. per ounce.

Glyceritum Boroglycerini (Glycer. Boroglyc.), U.S.P.; *Glycer. Acid. Bor.*, B.P.—31 per cent. For external use, diluted ten times.

**Unguentum Acidi Borici* (Ung. Acid Bor.), U.S.P., B.P.—10 per cent.; in Petrolatum and Yellow Wax, U.S.P.; in Paraffin Ointment, B.P.

Liquor Antisepticus, N.F.—A mild antiseptic, containing in 1,000 : 20. Boric acid; 1. Benzoic acid; 1. Thymol; 0.25 Eucalyptol; 0.5 Oil Peppermint; 0.25 Oil Gaultheria; 0.1 Oil Thyme; 250 Alcohol. A number of proprietary mixtures, e.g., "Isterine," have a similar composition. Their antiseptic efficiency is very slight (Verhoeff and Ellis, 1907).

**Sodii Boras* (Sod. Bor.), U.S.P.; *Borax Pur.*, B.P.; Sodium Borate (baborate or tetraborate), Borax, $\text{Na}_2\text{B}_4\text{O}_7 + 10\text{H}_2\text{O}$.—Colorless, transparent crystals, or white powder, odorless, of sweetish alkaline taste. Sol. in water (1:15), very sol. in glyc. (1:1); practically insol. in alc. *Incompatible* with alkaloids, acids, mucilage of acacia. (Free boric acid is not incompatible with most alkaloids.) *Dose*, 0.75 Gm., 12 gr., U.S.P.; 0.3 to 1 Gm., 5 to 15 gr., B.P.

Glycer. Borax., B.P.—20 per cent.

Mel. Borac., B.P.—10 per cent.

Sodii Perboras (Sod. Perbor.), $\text{NaBO}_3 + 4\text{H}_2\text{O}$.—Sol. in water. Used for making oxygen.

GENERAL CONSIDERATION OF ANTISEPTICS

Toxicity and Resistance.—The protoplasm of bacteria is fairly readily injured by many substances and by physical changes. The conditions under which it exists are, however, somewhat peculiar: By virtue of a highly impenetrable cell wall, and by the formation of very resistant spores, bacteria are able to survive conditions which would kill other cells. Under these adverse conditions the microorganisms are indeed unable to grow and multiply; but by passing into a dormant state, particularly by spore formation, they are able to preserve their vitality for a considerable time, and to recover their power of growth as soon as the conditions become more favorable. Substances which merely suspend the vitality of bacteria are called *antiseptics*; whilst those which kill them outright are *germicides*. A third class of disinfectants is formed by the *deodorants*, which obscure or destroy the odorous bacterial products, but which have little action on the bacteria themselves.

Factors Determining Usefulness.—The nature of the antiseptic substance, or the strength in which it is used, are by no means the only factors determining its efficiency and usefulness. Among the other more important factors may be mentioned:

The nature, peculiarities and number of microorganisms; the time of exposure; the influence of organic matter; the penetration, toxic and corrosive actions of the agent; and in some cases, its cost. Widely advertised antiseptics especially present a very striking disproportion between cost and efficiency.

The Influence of Proteins and Other Organic Matter.—Many substances which are strongly germicidal when acting on the bacteria alone are much weakened by entering into chemic reactions with the medium.

Thus, potassium permanganate is *destroyed* by all organic matter; mercuric chloride is *precipitated* by proteins; silver nitrate by chlorides, etc. These insoluble combinations are no longer germicidal. Further they *hinder the penetration* of the antiseptic, a condition of considerable surgical importance. The antiseptics of the aromatic series are relatively little affected. From the standpoint of antiseptic efficiency and penetration, the phenols stand highest, experimentally (Keilty and Packer, 1915; for relative place of other antiseptics, the original paper must be consulted). However, even these are markedly impeded by serum, even when there is no precipitation (Bechhold and Ehrlich, 1906). Indeed, serum and body fluids in general interfere very much with the activity of almost all antiseptics (Verhoeff and Ellis, 1907); but the flavine dyes are said to be more effective in serum.

The Disinfecting Power of the Commonly Used Antiseptics.—On account of the different resisting power of different bacteria, and the ease with which the antiseptic action is modified by circumstances, the results of experiments directed to comparing the different antiseptics can not be generalized. Tables of antiseptic values are therefore unsatisfactory. In a general way, it may be said that mercuric chloride and silver nitrate are the most powerful. Then come copper and zinc salts, then formaldehyde, chlorine, and hydrogen peroxide, then the cresols, then carbolic acid. Salicylic acid, boric acid, sulphurous acid, and the essential oils are antiseptics rather than germicides. Iodoform manifests its action only under special conditions. Ferrous sulphate is merely deodorant. Lepine, 1886, claims that mixtures of antiseptics are often more efficient than would be expected from their ingredients.

Specificity of Antiseptics.—Some antiseptics act fairly uniformly on all bacteria; others, especially the dyes, show a high degree of specificity (see, for instance, K. Taylor, 1917; P. A. Lewis, 1917).

The relative susceptibility of bacteria and cells has been investigated on tissue cultures by R. A. Lambert, 1916.

The Preservation of Food.—The liability of organic food-stuffs, especially meat and milk, to bacterial decomposition, often renders their chemical preservation a matter of economic necessity. Asepsis, refrigeration, or sterilization by heat, are not always applicable. That the use of chemic preservatives is theoretically undesirable, on account of their possible deleterious action, is universally granted; in practice, however, this evil may be less than those resulting from the consumption of partly decomposed foods. The time-honored use of sugar or salt-cured, corned, and smoked meats, of vinegar, spices, etc., is a sufficient proof of the comparative innocuousness of some of the preservative measures. More recently there have been introduced a number of preservatives which are more powerful, and which can not be detected by the taste. These offer a special interest, and they have accordingly given rise to much discussion.

It is self-evident that markedly toxic and irritant substances, such as formaldehyde, should be entirely excluded. The principal difference of opinion is in regard to substances, such as benzoates, borates, sulphites, saccharin, etc., which do not produce marked effects in the quantities ordinarily used. Their opponents rest their objections mainly on their action on weak or diseased individuals, on infants, nephritics, and dyspeptics; and to the cumulative effects of their continued administration. There is, however, no evidence as to the degree of danger from their intermittent use, under the actual conditions. At all events, the consumer should be made aware of the addition of the preservative, and of any possible dangers.

Urinary Antiseptics.—The urine and the bladder may be disinfected to a considerable degree by drugs administered through the mouth. The efficiency of urinary antiseptics is naturally limited by the brief contacts. It is therefore not necessarily reflected in the phenol-coefficient (Hinman, 1915). Methenamine is effective in acid urine. Hexyl resorcinol is active in all reactions. The antiseptics of the aromatic series are sufficiently concentrated, in the course of their excretion, to be effective, *e.g.*, in gonorrhea. Sodium salicylate or benzoate or salol are used for this purpose, as also copaiba, cubeba, sandal-wood, methylene blue, etc. Santal is especially useful against staphylococci; but none of these antiseptics are very powerful (Hinman, 1915). Increased acidity of the urine also destroys bacteria. Dilute mineral acids, or acid sodium phosphate, may be used (Jordan, 1911). Alkalinity interferes greatly with the activity of benzoates, salicylates and methenamine, not so much with borates or santal (Jordan, 1913).

Intestinal Antiseptics.—The disinfection of the alimentary canal might be useful in various dyspepsias, intestinal putrefaction, in typhoid fever, cholera, etc. Many experiments have been directed to this end. As a result, it may be concluded that *complete asepsis is impossible* in this situation.

This is easily comprehended if one stops to consider the large number of bacteria present, especially in the colon; the large mass of material in the intestine, tending to weaken the antiseptic and to prevent its access; the ready absorption and consequent danger of general poisoning; the sensitiveness of the intestinal canal to irritating agencies; the fact that ferment action is diminished by all antiseptics, etc.

When the antiseptics are used in such an amount as to injure the mucosa, they may even increase the number of bacteria. It was also argued, at one time, that antiseptics would be injurious by checking the saprophytic bacteria, which were supposed to be necessary for digestion. This theory has been disproved; nor do they appear to hinder the digestive ferments materially, although they tend in this direction (Heineberg and Bachmann, 1909).

Although a complete intestinal asepsis is an impossibility, a relative asepsis, a limitation of an abnormally increased bacterial action, is not inconceivable; but it has not been satisfactorily demonstrated (Harris, 1912).

The bacteria in the lumen of the intestine would be much more readily acted upon than those which have already obtained a nidus in the intestinal walls.

The antiseptics, at best, seem to be inferior to suitable modifications of diet and evacuation of the intestines (Friedenwald and Leitz, 1909). For antiseptics, more strictly speaking, the preference is given to those which are only sparingly soluble, so that they will not be absorbed before reaching the colon. Comparative experiments with the so-called intestinal antiseptics were made by Hirata, 1910.

Intravenous Injections of Antiseptics.—Improvement of staphylococcus, gonococcus, and other infections may occur after the intravenous injection of antiseptic dyes, arsphenamine, mercurochrome, mercuric chloride, formaldehyde, and a number of other antiseptics (H. H. Young et al., 1924). All these agents tend to alter the colloidal equilibrium of the blood, and therefore produce more or less allergic reaction, which may be responsible for the improvement, but which also implies an element of danger.

SERUMS, VACCINES AND ALLERGIC PREPARATIONS

The consideration of these immunologic agents will be restricted to those whose value appears well established, and to that information which is most essential to their practical application. Assuming that the reader is familiar with the general phenomena of immunology, it will suffice to recall that the presence of antigens stimulates the tissues to the production of specific antibodies and that the reaction of these with the antigen gives rise to characteristic phenomena that have diagnostic significance. The antibodies are also the mechanism that determines resistance to the invasion. Therapeutically, they may be administered directly for preventing or combatting infection, *i.e.* for "passive immunization;" or the antigen may be administered to the patient, to prompt the manufacture of antigen in his tissue; *i.e.* for "active immunization."

Active immunity requires some days to develop, but it persists for years or months; it utilizes and immunizes the tissues as well as the blood; and it can be secured against a much greater variety of infections than can passive immunization. The agents used for active immunization consist of attenuated living virus, vaccines of killed bacteria, toxins and other bacterial products and proteins. Their curative application is limited by their delayed action, and by the fact that they may increase the toxicity of the antigens of the disease more than the formation of antibodies. They may possibly be useful in chronic, stationary and localized infections. Their principal field is in prophylactic protection. They do not produce serum-disease, but their injection is generally followed by more or less allergic reaction, fever, leucocytosis, etc.; and with intravenous injection there may be serious collapse, analogous to the anaphylactoid reactions produced by injection of foreign protein, which are described in another section.

Passive immunization is secured by the injection of the serum of animals, generally horses, that have been immunized to the disease; and which have thereby developed antibodies to the toxins—the "antitoxic serums"—or to the bacteria themselves—the "antibacterial serums." The effects of these serums occur immediately on injection; but the protection lasts only for a few days or weeks, and their potency is often rather limited. It is therefore necessary to inject large doses of serum, and these often produce serum disease (see index), and more rarely a grave acute collapse. These reactions are due to the serum-proteins, and not the antitoxins as such. The latter are usually attached to a definite globulin fraction, which can be separated by fractional salt precipitation from the remaining and larger part of the protein, and the serum reactions diminished in a corresponding degree. The official (U.S.P.) diphtheria and tetanus antitoxins are "purified" in this manner.

Antibodies in general have colloidal properties, and are therefore not easily absorbed from mucous membranes. Effective doses require subcutaneous, intravenous, or intraspinal administration.

Standardization.—This, as well as the production of serums and vaccines is efficiently supervised by the U. S. Public Health Service. The packages must bear an "*expiration date*," that insures the full activity of the preparations, provided that they have been properly stored.

Preservatives.—Serums and vaccines tend to deteriorate. Their preservation requires the addition of some antiseptic, which must be fairly non-

toxic. Those most commonly used are cresol, 0.4 per cent.; phenol, 0.5 per cent., and glycerol.

Normal Horse Serum (see index).—This is used in hemorrhagic conditions, to increase the coagulability of the blood.

ANTITOXINS

These consist of the serum of horses that have been immunized by the injection of increasing doses of the specific toxins, and which have thus been stimulated to the production of antibodies that inactivate these toxins. The more important antitoxins are those against diphtheria, tetanus and the scarlet fever streptococci.

DIPHTHERIA ANTITOXIN

This was discovered by Behring in 1890, and applied therapeutically to man by Roux in 1891. It confers perfect although brief protection; its therapeutic use has reduced the mortality of the disease to about one-fourth. It should be administered in adequate doses, as early as possible; for the mortality increases from 4 to 5 per cent. if it is given on the first day, to over 20 per cent. if delayed beyond four days (Park, 1906). Seriously detrimental effects from the serum are so infrequent and can be so greatly reduced by proper precautions as to be practically negligible in view of the great benefits.

The antitoxin is not directly bactericidal; but by inactivating the toxin, it arrests promptly both the systemic and local phenomena of the disease, the more strikingly and promptly the earlier it is used. The exudation ceases to spread and clears more rapidly; it rarely extends to the larynx; the swelling of the cervical glands subsides; the fever falls promptly, and the general condition improves quickly. The occurrence of paralysis is not affected.

Only the "purified" antitoxin, which is official in the U.S.P., should be used. For the phenomena of Serum Disease, see Index.

Failure to Prevent Paralysis.—H. Meyer, 1905, attributes this to the absorption of part of the toxin through the nerve sheaths, where it would be protected against the antitoxin.

Circulatory Collapse.—This is prevented if the antitoxin is administered before the blood pressure has started to fall; after this, antitoxin is useless (H. Meyer, 1909), the toxin being presumably fixed in the cells.

Administration.—All immunizing sera are practically inactive when taken by the alimentary canal (McClintock and King, 1909, p. 294). They are therefore injected into the loose subcutaneous tissue of the abdomen, back or flank. The skin and needle should be cleansed with alcohol. The injection is made slowly. Intravenous injection has been advised in urgent cases. It is not especially dangerous if proper precautions are observed (Levin, 1909; Park, 1912); but it is sometimes followed by purpura and hemorrhages from the mucous membranes (Osgood, 1923).

Absorption.—This is quite slow, the maximum concentration of antitoxin in the blood being reached only after a day with intramuscular, and in three days with hypodermic injection (Levin, Part). The *distribution* has been studied by Hektoen and Carlson, 1910.

The concentration of antibodies generally, both in active and passive immunity, decreases in the order of serum (highest), thoracic lymph, neck lymph, pericardial fluid, aqueous humor, cerebro-spinal fluid (least). This indicates that they pass from the blood into the lymph (Becht and Luckhardt, 1916).

Dosage.—This varies with the stage and severity of the disease; the age of the patient need not be considered. The *immunizing dose* is 1,500 units. The *curative dose* is usually 10,000 units in ordinary, and 20,000 in malignant cases. Larger doses do no further good (Park, 1914). Half the initial dose may be repeated two or three times at intervals of about twelve hours, according to the progress of the disease; but it is better to make the initial dose sufficiently large, since experiments have shown that this insures a higher concentration in the blood (Park, 1913).

Production.—The antitoxin is produced by injecting healthy horses hypodermically, at four-day intervals with diphtheria toxin, *i.e.*, with filtered sterile broth cultures; beginning with very small doses, which are increased at varying intervals, according to the amount of reaction. This treatment is continued for from four to six months, until a high antitoxic power has been reached (as determined on small samples of blood, withdrawn from time to time). The horse is then bled from the external jugular vein, with strict asepsis. This can be easily done without anesthesia. Seven to 12 liters are collected in sterile bottles. When the serum or plasma has separated, it is purified, through Berkefeld filters, and an antiseptic (phenol or cresol), is added. The antitoxic strength is determined, and the appropriate doses are marketed in aseptic glass syringes, to obviate contamination during administration.

"Purified Antitoxin."—If the proteins of antitoxic serum are separated by fractional precipitation with salts, the antitoxin is found practically completely in the pseudoglobulin portion (Gibson and Collins, 1907; Banzhaf and Gibson, 1907). The non-antitoxin proteins may thus be largely eliminated. These "refined" serums permit reducing the bulk of the injection and are said to lessen the liability to rashes but not to anaphylactic shock (Park, 1913).

The *Gibson process* of purification consists in precipitating all the globulins by an equal volume of saturated ammonium sulphate solution (other sulphates may be used); the precipitate is treated with saturated solution of sodium chloride, which dissolves the pseudoglobulin. This is again precipitated by acetic acid, and this precipitate is dialyzed to reduce the salt to 0.8 per cent. The pseudoglobulin fraction of normal serum is about 40 per cent. of the total proteins; in immunized serum it is about 78 per cent.; so that this process eliminates only about one-fifth of the total proteins. The proportion can be raised by heating the serum for several hours to 57°C., before proceeding to Gibson's process (Banzhaf, 1911). This *Banzhaf process* eliminates about 50 per cent. of the proteins, without material loss of antitoxin (Park, 1910).

All attempts to separate this antitoxin from the globulin have been unsuccessful (Crawford, 1918); perhaps the globulin is itself the antitoxic constituents.

Standardization.—The activity of antitoxins is determined by comparison with a standard antitoxin issued by the U. S. Public Health Service to manufacturers. This is used for determining the "*test dose*" of the toxin to be employed in the actual standardization. This test dose is the *largest quantity of toxin which can be completely neutralized by the unit of standard antitoxin*, so that a 250-gram guinea pig will survive for four days. This toxin is then used in standardizing the serum to be tested; the *smallest quantity of serum which neutralizes a test-dose of the toxin contains one unit of antitoxin*. This new unit, which is now employed universally, is approximately equivalent to the original unit, but is more uniform.

Deterioration.—The antitoxic power of serum, plain or purified, declines gradually, the loss averaging between 10 and 30 per cent. per year. If kept on ice, the yearly loss is only about 6 per cent. (Anderson, 1909). If aged serums are used, allowance must be made for the deterioration; in other respects their use is quite safe. *Dried serum* does not deteriorate, but is inconvenient to dissolve.

Active Immunization with Diphtheria Toxin-antitoxin Mixture.—The slow development but long duration of active immunization is particularly useful for the permanent protection of children in asylums and schools. It is not applicable in the presence of an actual outbreak of the disease; in such case the immunizing dose of antitoxin is used alone. The addition of antitoxin has the object of preventing severe local reaction (Schroder and Park, 1923). The mixtures as marketed by the manufacturers are so

neutralized with antitoxin that five human doses are fatal to a guinea pig, in five days. Three doses of 1 c.c. each are usually given a week apart. This suffices to produce immunity in more than three-fourths of the instances. It is but little developed in four to six weeks, but continues to increase for a year or longer (Park *et al.*, 1914, 1915). The success is checked about six months later by the Schick test, and if necessary the treatment is repeated.

PREPARATIONS

**Antitoxinum Diphthericum*, (Antitox. Diph.), U.S.P.; Diphtheria Antitoxin (Purified Antidiphtheric Serum; Antidiphtheric Globulins).—A sterile saline solution of the antitoxin-bearing globulins of the serum or plasma of healthy horses properly immunized against diphtheria toxin; of a potency of not less than 350 antitoxin units per c.c.: containing not more than 0.5 per cent. of phenol or 0.4 per cent. of cresol. That marketed in the United States must be manufactured in establishments licensed by the government. It must bear an expiration date beyond which the contents cannot be expected to possess the specified potency. It should be preserved between 4.5 and 20°C., preferably at the lower limit. *Dose*, curative, 10,000 units; protective, 1,000 units; U.S.P.

TETANUS ANTITOXIN

This is prepared in the same manner as Diphtheria Antitoxin, except that tetanus toxin is used for the immunization. It has a high protective value if used early; and it would be desirable to administer it in every suspicious case, but without neglecting thorough disinfection. Its curative value, after the symptoms have set in, is doubtful and at best limited. It does not affect the toxin which is fixed in the nerve cells, and could only reach that which is still free or being formed. The latter can generally be prevented more effectively by surgical procedures.

For protection, 1,500 units may be injected hypodermically at once, or four injections, each of 500 units, may be made at intervals of a week (McCoy, 1917). The protection lasts two or three weeks.

If symptoms have appeared, hypodermic administration alone is insufficient. Large doses must be introduced by several channels. Park, 1910, 1912 and 1914, advocates the subdural injection of 3,000 to 5,000 units, followed by 10,000 to 15,000 units intravenously; the spinal injection is repeated in twenty-four hours, and a hypodermic injection of 10,000 units is given three days later (Park and Nicoll, 1914; Nicoll, 1915). Dreyfus, 1914, urges daily injections, combining vein, lumbar, endoneural and local.

Intraneural injection was advised by Meyer and Ransom, 1903, since they found that the toxin travels largely by nerve sheaths. It has not maintained itself in practice, but is again advocated by v. Behring, 1914.

Subdural injection, according to Park and Nicoll, is more effective than intravenous, and vastly better than hypodermic. The antitoxin disappears in twenty-four hours, so that the administration must be daily if this channel is used alone (Dreyfus).

Official Unit (U.S.P.H.S.).—This is ten times the least quantity of serum necessary to save the life of a 350-Gm. guinea pig for ninety-six hours against the official test-dose of standard toxin furnished by the U.S.P.H.S. (Rosenau and Anderson).

**Antitoxinum Tetanicum*, (Antitox. Tet.), U.S.P.; Tetanus Antitoxin (Purified Antitetanic Serum, Antitetanic Globulins).—A sterile saline solution of the antitoxin-bearing globulins of the serum or plasma of healthy horses properly immunized against tetanus toxin; of a potency of not less than 300 units per c.c. Other conditions as for Diphtheria Antitoxin. *Dose*, curative, 10,000 units; protective, 1,500 units.

Antitoxinum Tetanicum Crudum, U.S.P.—This is used mainly in veterinary practice.

SCARLET FEVER STREPTOCOCCUS ANTITOXIN

Antitoxic serums are obtained from horses immunized against the toxin of the hemolytic streptococcus of scarlet fever (Moser, 1902). Two

methods of immunizing the horses were introduced independently; that of the Drs. Dick consists in the injection of the soluble toxins of strains of the specific streptococci; whilst in the method of Dochez, the living streptococci are inoculated in the subcutaneous agar nodule. The Dochez serum may therefor also contain bactericidal antibodies. Both methods yield effective serums, which may be concentrated by the same methods as other antitoxins and which are standardized against the toxin skin-reaction, so that 1 c.c. of the serum neutralizes 1,000 to 10,000 "skin-test doses." The prophylactic dose is 10 c.c.; the therapeutic dose is 20 to 50 c.c., intramuscularly. In many patients, the injection is followed by blanching of the rash, lowering of the febrile temperature, and improvement of the general condition. If the antitoxin is given early, the course of the disease is shortened and the incidence of complications and sequels is greatly diminished (Dick and Dick, 1924, 1925; Dochez and Sherman, 1924; F. G. Blake, 1924).

The Dick Test.—The susceptibility to scarlet fever may be judged by the reaction to the intradermal injection of the toxin, which is marketed in suitable form for this purpose.

ANTIBACTERIAL SERUMS

These act directly on the bacteria, which they may either disorganize, or precipitate or agglutinate, or render more subject to phagocytosis. Their therapeutic value is generally less striking than that of the antitoxic serums and reports as to the results vary greatly. This indicates that their effects are so limited that they leave a large field to interpretation; but there are also wide and uncontrollable difference in activity, which cannot be accurately estimated. The concentration of the antibacterial substances is generally low, so that it would be difficult to introduce effective doses, except by large intravenous injections, which give rise to serious serum diseases. The high specificity of the serums also limits their use, since they are often effective only against limited strains. This difficulty is partly met by the use of "polyvalent serums" from horses immunized simultaneously against several strains.

Antibacterial serums are used especially against meningococcus, pneumococcus, dysentery, and streptococcus infections.

Antimeningococcus Serum.—This is markedly successful against epidemic cerebrospinal meningitis due to *Diplococcus intracellularis*, especially if used early. It reduces all the symptoms, clears the cerebro-spinal fluid, lessens the duration and sequels, and diminishes the mortality (Dunn, 1908; Ladd, 1909; Flexner, 1913). The mechanism of its action has not been decided.

Action.—The serum does not kill the bacteria directly, but causes their disappearance, perhaps by stimulating phagocytosis and intraleucocytic digestion.

Administration.—The action being mainly local, the serum must be injected into the subdural canal, early, and in efficient dosage. As it is absorbed, several injections are generally needed. The usual dose is 15 to 30 c.c.; for young infants 10 c.c. Cerebrospinal fluid is first withdrawn, if possible the same bulk as the serum to be injected. The blood pressure should be watched during injection to guard against excessive pressure. A drop in pressure of more than 10 mm. should cause withdrawal of the needle. The administration should be repeated every twelve to twenty-four hours, for at least four injections; and longer if the fluid and symptoms have not cleared. The occurrence of accidents is discussed by Flexner, 1913. They consist in sudden collapse with stoppage of respiration and fall of blood pressure. The effects have been attributed to the preservative (Voegtlin, 1914); but this is probably not the usual cause (Auer, 1914).

Antipneumococcus Serum.—In lobar pneumonia due to Type I pneumococcus careful clinical observers report encouraging results from the early intravenous injection of 50 to 100 c.c. of highly potent serum (Cole, 1917).

Antidysenteric Serums.—The polyvalent serum has given variable results, differing probably according to the strain of the bacteria. The prophylactic dose is 10 c.c.; for treatment, 50 to 100 c.c. are injected, preferably by vein, as early as possible and repeated at 4 to 10 hour intervals, as needed.

Antistreptococcus Serum.—Polyvalent sera have been used against streptococcus infection; but critical observers have found them of little if any value (Novak, 1926). The prophylactic dose is stated as 10 c.c.; the therapeutic dose as 50 to 100 c.c., intravenously, repeated in 4 to 24 hours as needed.

ATTENUATED LIVING VIRUS

The injection of living organisms of vaccine and of rabies confers a high and lasting protection. The virulence is restrained by passage through a suitable animal species.

VACCINE VIRUS

This consists of the scrapings from the pustules or vesicles of vaccinia or cowpox, of vaccinated, but otherwise healthy calves. It must be removed aseptically, is further sterilized by standing with glycerin, tested for the absence of bacteria, and marketed in tubes or "points." It is used by inoculation (vaccination) to produce active immunity against smallpox, the protection lasting four to ten years.

Preparation.—The "pulp" is curetted from the typical vaccinia vesicles. The "lymph" which flows afterward was formerly used for making "dry points;" but as it is less potent and generally septic, it should not be used. The pulp is ground with 50 to 60 per cent. of glycerin, and allowed to "ripen." This preserves the virus, but kills most of the bacteria. The establishments must be conducted under federal supervision and license.

PREPARATIONS

* *Vaccinum Variolæ* (Vaccin, Var.) U.S.P.; Vaccine Virus (Glycerinated Vaccine Virus; Jennerian Vaccine).—The pustules of vaccinia or cowpox removed, under aseptic conditions, from vaccinated animals of the bovine species. Preserved at a temperature preferably below 0° and never above 5°C., protected from light. The vaccine pulp is thoroughly rubbed up in a mortar or passed through a special grinder, strained to remove coarse particles, and made into a smooth emulsion with a glycerin solution. Vaccine Virus gradually loses in potency, the loss being more rapid at high temperatures than at low temperatures.

ANTIRABIC VACCINE

This consists of emulsions of the spinal cords of rabbits, which have died as the result of subdural injection of "fixed" rabies virus. By its use, immunity is usually established before the incubation period of the disease is completed, and rabies is thus prevented. The mortality is less than 1 per cent., against 15 or 20 per cent. in untreated cases (Stimson, 1910). In a small percentage of cases, the treatment is followed by paralysis, which is usually transient; but it may be permanent.

Fixed virus is obtained by the passage of rabies virus through a long series of rabbits, till it acquires a fixed incubation period. This fixed virus is less capable of producing rabies on subcutaneous injection. The spinal cords of the infected rabbits are further attenuated by graduated drying. In the treatment, emulsions of increasing virulence are daily injected into the subcutaneous tissue of the anterior abdominal wall, the scheme of dosage varying according to circumstances; but generally beginning with cord dried for eight to twelve days and gradually increasing till "two-day" cord is used.

BACTERIAL EMULSIONS AND EXTRACTS

Bacterial vaccines ("bacterins") are usually suspensions of the killed bacteria in physiologic salt solution, containing an antiseptic. They may be modified by the partial disintegration of the bacteria by antiserums, "serobacterins," or by autolysis or chemical agents, or mechanical means, and may then contain more or less of the soluble bacterial products. The old tuberculin is a filtrate. Suspensions of killed bacteria in oil ("lipo-vaccines") have also been tried, but they appear to be less effective.

These antigens are injected for diagnosis, or to generate antibodies for protection or treatment. The results vary widely with the organisms, the reaction of the patient, the condition of the disease and the adaptation of dosage, which is partly a matter of experience, but as yet, with a considerable element of chance.

Prophylactic inoculations have been tried extensively for a great variety of infections; but in many of these the results are unconvincing. Protection against typhoid with vaccines has been very notably successful; immunization with diphtheria and scarlet fever toxins was discussed under the antitoxins.

Treatment by vaccine injections appears rational in the case of localized infections, especially if they have become stationary. In case of generalized infections, chance of harm by increasing the toxic condition is probably greater than the benefits.

The possibility of success, in any case, demands an exact diagnosis of the bacteria, and often of the very strain. Autogenous vaccines are therefore much more effective than stock vaccines. Manufacturers have tried to obviate the need of diagnosis by marketing bacterial mixtures on the type of the discredited shot-gun prescriptions, with this difference: that the bacterial injections are much more potent for mischief. Intravenous injections of bacterial suspensions or solutions are particularly dangerous.

The grading and spacing of the dosage of vaccines is a matter of judgment, which cannot be effectively checked by observation; even experience does not give security. In general, the severe infections permit only small doses, and these should be repeated more frequently; mild infections require larger doses, generally to the point of systemic reaction.

The status of the more important vaccines is as follows (N.N.R., 1925):

Acne Bacillus Vaccine.—May give good results in acne due to the Unna-Sabouraud bacillus.

Cholera Vaccine.—Favorable results as to prophylaxis have been reported.

Meningococcus Vaccine.—Probably is of no value.

Modified Pneumococcus Antigen.—Some evidence of value in treatment of lobar pneumonia; not intended for prophylaxis.

Pertussis Bacillus Vaccine.—Value very questionable, both as to prevention and treatment.

Plague Bacillus Vaccine.—Promising for prophylaxis; too slow for treatment.

Pneumococcus Vaccine.—Prophylactic use encouraging; value in treatment of pneumonia very doubtful. Apparently useful in *ulcus corneae repens*.

Straphylococcus Vaccine.—Fairly successful, especially the autogenous vaccine.

Tuberculin.—Useful for diagnosis; probably more often harmful than useful in treatment.

Typhoid Vaccine.—Brilliant success in prevention; not advisable for treatment.

TYPHOID VACCINE

This has given successful results for immunization (Russell, 1913 and 1914), lasting at least two years (Harris and Ogan, 1914). The injections are now repeated annually (McCoy). It is of little value in the treatment of typhoid fever or of carriers. Typhoid vaccine consists of a suspension of a special strain of typhoid bacilli, killed by heating for an hour at 55°C., and preserved by 0.25 per cent. cresol. Typhoid-paratyphoid vaccines, which contain *Bac. paratyphosus* A and B in addition to the typhosus, are also widely used.

The vaccine should be injected subcutaneously (not intramuscularly) in the arm, giving 500 million bacteria in the first dose; and two further injections, each of one billion bacteria, at ten-day intervals. It generally causes some local reaction, and sometimes more or less severe but harmless febrile symptoms (Russell, 1912). It is safer to avoid its administration to any but healthy individuals; not to inject it into a vein or intramuscularly; to avoid exposure of the patients to sun, alcohol or exertion; and not to give it during menstruation or pregnancy (Harris and Ogan, 1914).

Intravenous Injection of Typhoid Vaccine.—The typhoid vaccine is a convenient medium for producing non-specific "reactions." Like the foreign protein injections, these are sometimes useful in rheumatic and other fevers; they are always dangerous. Their use is justified, if at all, only on the basis of special experience.

Intravenous typhoid vaccine injections were first introduced for typhoid fever (E. Fraenkel; Gay and Chickering, 1916; Hektoen, 1916); but it was soon recognized that other vaccines and foreign proteins precipitate similar crises, (J. L. Miller and Lusk, 1916; Jobling, 1917), and that therefore the effects were not specific. They were then applied especially to rheumatic fever, often with good results (Cecil, 1917).

The intravenous injection of the vaccine is followed, after one-half to one hour, by a chill, lasting 15 to 30 minutes, with headache and nausea, fast pulse, and sometimes cyanosis. This is followed by sweating and relief of the joint pains. The temperature reaches its maximum in 3 to 4 hours, and returns to normal within 48 hours after injection. The leucocytes show a transient fall, then a marked rise, with its maximum 6 hours after injection. The blood pressure rises during the chill, then falls for 3 or 4 hours. The urine shows no special changes.

In unfavorable cases the chill lasts several hours, and is accompanied by marked collapse (Scully, 1917).

Irons, 1917, warns against the promiscuous use of the method, as tending to careless diagnosis; but especially because of the frequent excessive severity of the reactions. These include cardiac dilation, sometimes fatal; hemorrhages from nose and intestines; etc. (Irons, 1917; Cecil, 1917).

TUBERCULIN PREPARATIONS

These represent the toxic products of the tubercle bacilli; consisting either of solutions, *i.e.*, filtered germ-free cultures (*e.g.*, old tuberculin); or of suspensions of killed and ground tubercle bacilli (tubercle vaccine, new tuberculin emulsion). They are used for the diagnosis and treatment of tuberculosis. The two classes of preparations are practically identical in action, differing only quantitatively and in absorbability. The filtered cultures ("old tuberculin") are more evenly absorbed and therefore permit a better control of dosage, and are thus safer for diagnostic tests and early treatment. The bacilli emulsion, however, is probably more frequently used for treatment.

Diagnostic Use.—Relatively large doses of tuberculin have no effect on normal individuals; but in tuberculous patients, there is a definite inflammatory reaction about each localized tuberculous lesion, with slight febrile symptoms. The test is applied in various ways. It requires special knowledge and experience for its proper performance and interpretation; otherwise it may do much harm (Baldwin, 1910).

Therapeutic Use.—Tuberculin does not produce immunity to tuberculosis; but a course of carefully graduated doses diminishes the sensitiveness to the toxin, and therefore the constitutional phenomena of the disease. The local reaction about the tuberculous foci also tends to their cicatrization and absorption (Trudeau, 1907, Baldwin, 1913). The artificial resistance is gradually lost after the treatment is discontinued.

For therapeutic purposes, the tuberculins must be administered hypodermically; beginning with a very small dosage (0.000.000.01 to 0.000.001 c.c. of old tuberculin), and increasing very cautiously so as to avoid constitutional disturbance. Serious harm may result from severe reactions. Experience and judgment as well as close observation are essential. The temperature, pulse, and other symptoms must be carefully watched. The dose must be reduced to at most one-half when changing to a different laboratory number of the same preparation, as the different lots of tuberculin vary materially.

The following are the more important tuberculin preparations of the N.N.R.:

Old Tuberculin, "O.T.," *Koch's Tuberculin*, Prepared by concentrating a six to eight weeks' glycerin-bouillon culture of tubercle bacilli by evaporating to one-tenth its volume, and filtering through a Berkefeld filter. Contains 50 per cent. of glycerin.

New Tuberculin B.E; *Bacilli-emulsion, Koch, N.N.R.*—A suspension of ground bacteria is 50 per cent. glycerin, 5 mg. in 1 c.c. Any surviving bacteria are killed by heating for an hour to 60°C.

New Tuberculin, T.R.; *Tuberculin Residue, Koch.*—This represents a complex extract of virulent human tubercle bacilli; the dried bacteria are subjected to prolonged grinding and thereby killed. They are then suspended in normal saline, centrifugalized, and the first supernatant fluid is rejected. The sediment is again ground with saline and centrifugalized. This fluid is saved. The process is repeated until almost no sediment remains. The supernatant fluids are united, mixed with 20 per cent. of glycerin and a little formaldehyde and adjusted so that each cubic centimeters represents 10 mg. of dry bacilli.

Tuberculin "Denys"; "B.F." Bouillon Filtrate.—A simply filtered culture, not boiled.

ALLERGIC PROTEIN EXTRACTS

These consist of saline solution of the proteins extracted from substances that may be concerned in allergic hypersusceptibility; especially as manifested in hay-fever, asthmas and food-idiosyncrasies. The extracts are useful for discovering the proteins that provoke the attack, which may then be avoided. They may also be used for desensitization. A great variety of these extracts is listed in N.N.R. They tend to deteriorate with time, especially if they are diluted. The most important use is in "hay-fever."

Hay-fever (Pollinosis).—The diffusion of the light plant-pollens through the air brings them in intimate contact with the mucous membranes of the respiratory tract, and especially of the nose. If the patient is hypersusceptible, they produce a local inflammatory reaction analogous to the urticarial reaction of the skin-tests. The latter may therefore be used to test the susceptibility of the patient. It is often possible to de-sensitize the patient, systemically (Walker, 1921) or locally (Mackenzie, 1922), by a course of gradually increasing doses, before the season. The immunity does not last longer than a year, and the desensitization would therefore need to be repeated annually, which is rather inconvenient, especially as the success is quite variable.

Different patients may exhibit hypersusceptibility toward a great variety of pollens, and several hypersusceptibilities often coexist in the same patient. However, about nine-tenths of all cases are due to a very few pollens; namely the fall hay-fever to ragweed; and the spring hay-fever to grasses; to timothy in the east, and to spring vernal grass and to June grass in the Middle West (J. C. Walker, 1921).

Food-idiosyncrasies.—These result in acute indigestion, urticaria, eczema (Blackfan 1920). Exclusion of the offending food-stuff from the diet is generally more simple than desensitization; but the latter may be necessary in the case of important foods, and especially in children.

THEORIES OF NARCOSIS

The neutral aliphatic compounds or hydrocarbons resemble each other closely in their main actions. Their most conspicuous effect on the higher animals consists in stupefaction, passing with larger doses into insensibility and motor paralysis; *i.e.*, into profound narcosis or anesthesia of central origin. Analogous narcotic or depressant effects are produced on all forms of protoplasm and on unorganized ferments. Hemolysis is also a conspicuous effect.

The term "narcosis" is applied in biology to temporary and reversible decrease or abolition of the normal automatic activity, by agencies that are not highly selective. It may be produced by a variety of physical and chemical conditions: by cold, fatigue, electric inhibition (anelectrotonus), oxygen deficiency, certain ions, and very strikingly by the neutral aliphatic derivatives that are used clinically as general anesthetics, hypnotics and sedatives.

Various attempts have been made to explain the fundamental nature of narcosis, and particularly to correlate it with the composition and with the other chemical and physical properties of the narcotics. The results indicate that the composition and the purely chemical properties are not directly concerned; but that there are very striking quantitative relations between the narcotic strength of the hydrocarbon series, and their lipid and surface affinity. The efficiency increases with their solubility-partition coefficient (Meyer-Overton Law), which is an index of the lipid affinity; and with their depressive effect on the surface tension of water, which is an inverse index of surface affinity (I. Traube). The lipid and surface affinity are generally parallel; when they conflict, the narcotic efficiency appears sometimes to follow the one, sometimes the other. Both properties tend to condense the narcotic agent on the surface of the cell; their relative share in this being determined largely by the amount of lipid in the cell membrane. This concentration of foreign materials on the surface and in the lipoids of the membrane must modify the properties of the surface. At first it decreases the permeability of the membrane, and so interferes with the increase of permeability that is involved in stimulation. This appears to be the essential cause of the narcotic action. If the action progresses too far, the cell may be disorganized, injured or killed, in which case the permeability increases. Other narcotic agents produce analogous changes in permeability, possibly through different mechanisms. Other theories of narcosis will be discussed in the small type. More extensive presentations may be found in the books of Lillie and of Winterstein.

Influence of Chemic Structure.—An historical review of the older theories of narcosis is given in Overton's book. The earlier studies indicated that the actions of this series appear to be influenced by the chemic structure; and much labor was expended on determining the share of various side-chains (Binz, 1881; Baumann and Kast, 1890). The results (summarized in Schmiedeberg, *Grundriss d. Pharmacologic*, 1909, p. 19) seemed to show certain relations, but the generalizations have not stood the test of wider experience (Diehl, 1894; Meyer, 1899; Kionka, 1900). In fact, it has been pretty definitely shown that the chemic structure affects the narcotic action only indirectly, namely by modifying the partition coefficient and the surface affinity, which vary in a definite manner with changes in composition. However, special side-chains may be responsible for side actions. Thus, chlorine compounds are peculiarly toxic to the heart.

These *empiric relations* are practically interesting and important, although they have lost theoretical significance. The following conclusions appear justified: Other things being equal the strength of action increases with the length of the chain. A limit

is soon reached, however, for the drugs become less volatile, less soluble and less absorbable the higher they stand in the series; so that the higher paraffins are entirely insoluble and inactive. The ethyl radical, C_2H_5 , seems to be best adapted to therapeutic purposes. The action may be modified by replacing the H of the group by other elements or groups. The compounds so formed all possess the typical action of the hydrocarbon group; but this may be so overshadowed by other actions as to be scarcely appreciable. A good example of this is the introduction of the group NO_2 . This acts very much more strongly than the hydrocarbon part of the molecule, and consequently the nitrite action is obtained long before there can be any hydrocarbon action. The same is true if we substitute an aromatic radical. The introduction of certain other radicals weakens the hydrocarbon action to a very great extent. We may mention especially the acid-forming radical CO_2H . The introduction of hydrocarbon radicals into an amine molecule destroys their action entirely. The introduction of more than one OH group also weakens or destroys the action. Aldehydes and ketones are more active than the corresponding alcohols. The introduction of the halogens, and especially of Cl, often enhances the action, but this is not proportional to the number of Cl molecules introduced. The introduction of O (ethers) also increases the action. The introduction of acids (esters) weakens it.

Lipoid Affinity of Narcotics.—Bibra and Harless, 1847, immediately after the discovery of the anesthetics, drew attention to the fact that practically all fat-solvents are narcotics, and suggested that they dissolve the fats out of the nerve cells. The difficulty of explaining the rapid recovery proves that this theory can not be correct. It was accordingly abandoned; but later workers continued to point out more or less quantitative relations. Hermann, 1866, *f.i.*, showed that all the aliphatic narcotics dissolve red blood corpuscles, connected this with their lipoid solubility, and first suggested the modern lipoid theory. Conversely, Richet, 1895, argued that the narcotic efficiency is inversely proportional to the solubility in water.

The relations observed by Hermann and by Richet were striking but not conclusive. It was only by their combination than an exact quantitative relation could be demonstrated. This was done, independently and practically simultaneously by H. Meyer and by Overton, 1899 and 1901. They showed a very close parallelism between narcotic efficiency and the "partition coefficient:"

Solubility in fat (S_F). The higher this coefficient, the more powerful **Solubility in water (S_W)**. The parallelism occurs so frequently that it must be assumed that the lipoid affinity as expressed by this coefficient is concerned in some way in the narcosis. There are however exceptions, which indicate that it is not the only factor.

Partition Coefficient. The experimental determination of this factor is described in Hoeber (p. 196). Berthelot and Jungfleisch, 1872, showed that it is constant, independent of the absolute quantity, provided there is no dissociation. For convenience, it has so far been determined mainly with olive oil. A few of the more important data are given as illustrations.

Narcotics (in order of coefficient):	Partition coefficient (olive oil water):	Anesthetic threshold (tadpoles, mols per liter):
Ethyl alcohol.....	0.03	0.29
Choral hydrate.....	0.22	0.020
Sulphonal.....	1.11	0.0020
Acetylene.....	1.39	
Nitrous oxide.....	1.89	
Ether.....	4.5	0.034
Chloroform.....	32.	0.0014

Objection has been made to the olive-oil coefficient (Moore and Roaf, 1906) since the cell lipoids, especially in the nerve tissues, include lipoids of quite different solubility characters, such as cholesterol and the phosphatides, lecithin, kephalin, cerebrin, cerebrosides, etc. (W. Koch, 1911). However, these would affect the degree rather than the direction of the relation.

Evidence for the Meyer-Overton Law.—The narcotic concentrations have been determined mainly on tadpoles; but the law has also been demonstrated on other animals, plants and tissues. According to the theory every absorbable substance which is a fat-solvent should have an anesthetic action; this should be seen in all cells (since every cell contains lipoids); it should occur in the same concentration of solution; the anesthetic action of a mixture should equal the simple sum of the actions of its constituents; the effect should be proportional to the concentration, and not to the absolute dose, etc. The actual observations agree fairly well with these postulates.

The relation of concentration to action is especially interesting. In general, the same concentration of chloroform or ether produces the same degree of anesthesia in all cells (excepting plants and a few invertebrates). For instance, ordinary anesthesia requires in all animals a concentration of anesthetic to serum, of ether, 1:400; of chloroform, 1:4,500 to 6,000; but cold-blooded animals reach the same concentration in the blood with a lesser concentration in the air, on account of their lower temperature. Again, in those cases in which the coefficient changes with temperature, etc., the narcotic power changes in the required direction: Meyer, 1901, showed that rise of temperature increases the coefficient and the narcotic action for hydrated chloral; and depresses both for salicylamide. Fuehner, 1909, investigated the influence of mixed narcotics, and found that the coefficient and narcosis were always modified in the same direction.

Exceptions to the Meyer-Overton Law.—It must not be expected that the agreement will hold for every case, for other complicating factors may enter. For instance, the influence of temperature on narcotic efficiency is not always parallel to the partition coefficient nor to the surface tension. Hoeber, 1919, found that the relation between temperature on narcosis and partition coefficient does not hold for muscle and nerve. In tadpoles, the susceptibility to the narcotics undergoes interesting changes with the development of the animals (Vernon, 1913). The critical concentrations also vary for different tissues, indeed for different functions of the same tissue, so that it is unsafe to generalize very widely. It is also sometimes difficult to differentiate between narcosis and other forms of injury.

The Meyer-Overton Law Applies Only to the Aliphatic Narcotics.—Cushny has pointed out that many benzol derivatives which are not narcotic have a high partition coefficient. In this case, however, the coefficient modifies the antiseptic action. The peripheral nervous system, although rich in lipoids, is not easily attacked by the aliphatic narcotics. Morphine and other basic and saline narcotics do not obey the law, and must act by entirely different mechanisms. This does not of course impair the validity of the law as applied to the aliphatic narcotics.

Influence of Extraneous Fats on Narcosis.—It might be expected that narcosis would be affected by fatty tissue, deflecting a certain amount of the anesthetic; but this does not seem to be the case to a notable degree; presumably the cell-walls of adipose tissue are not easily permeable to lipoids.

Mansfeld, 1905, suggested the low resistance of starved animals to be due to this. The fact is not convincing, for in starvation the resistance is lowered in many other directions. Indeed, Mansfeld's experiments contradict his explanation; for starvation did not increase the susceptibility to the typical lipolytic narcotics, alcohol and urethane; whilst the susceptibility was increased for morphine, which probably does not act as a lipid solvent. Cloetta, 1907, tried the converse experiment, the influence of increasing the fatty tissue; but his results scarcely justified general conclusions.

Nerking, 1908, claimed that anesthesia can be cut short by intravenous injection of lecithin. This has been contradicted by Kramer, 1913, who took the necessary precaution to keep the concentration of the anesthetic constant by intravenous injection. Lattes, 1911, stated that fatty food, or the injection of fat-emulsions into the circulation, increases the narcotic action of chloroform, perhaps by lessening the pulmonary excretion. Hanschmidt, 1913, supports Nerking, and affirms that lecithin has a protective action against narcotics, but also against a number of alkaloids (curare, strychnine, morphine). The results have therefore been contradictory and have little bearing on the lipolytic theory. Salzmann, 1912, reports that cream and other fats delay slightly the absorption and therefore the action of alcohol and other lipolytic narcotics. Murlin

and Riche, 1915, find that the percentage of fat in the blood is lowered proportional to the degree of narcosis; but since this occurs also with morphine, it has no bearing on the lipid theory.

Surface Affinity.—The close parallelism of narcotic concentration and the depressive action on the surface tension to water was pointed out especially by J. Traube, 1904–1915, and Czapek, 1911. There is also a similar parallelism between the surface tension effect and the partition coefficient, so that it would be difficult to generalize as to which property is the determining factor in the narcosis, but there appears to be more exceptions to Traube's rule than to Overton's (Lillie, 1916). Presumably both properties participate, to a varying extent in different tissues.

Fuehner, 1912, has investigated the question with homologous alcohol and finds that for *hemolysis*, and for animals devoid of a nervous system, the efficiency is parallel to the surface tension; but in proportion as the nervous system develops the activity of the higher alcohols becomes relatively greater, and agrees better with the partition coefficient. Ishizaka, 1914, also finds a correspondence between hemolysis and surface tension in a series of terpene alcohols and ketones; but the chemic characters also had an influence. With chlorine derivatives, the hemolytic action increases with the chlorine content and with the molecular weight, without relation to the surface tension (Plotz, 1920).

Changes in the Cell Surface.—The parallelisms with lipid affinity or surface tension do not in themselves explain the narcotic effect. They might merely represent favorable conditions for the entrance of the substance into the cell, as was suggested by Kochmann, 1906; and the real action within, the cell might be altogether different, for instance, chemic (Heymans and DeBuck, 1905). However, the uniformity of the phenomena favors a more direct relation. The lipid affinity early suggested the actual removal of the cell lipoids. This is not tenable in view of the rapid recovery of the functions when the narcotic is removed, and when there has been no opportunity for the reformation or restitution of lipid. Meyer therefore suggested that the agents liquefy the lipoids without displacing them. The changes in permeability suggest that the action occurs mainly in the cell-surface; which is especially plausible since Overton showed that the cell-permeability depends chiefly on the lipoids of the plasma-membrane.

The depression of surface tension is not supposed to be concerned directly in the narcosis; but it is an index of the condensation of the substance at the surface, which would lead to the formation of films over the cell surface as a whole, and over the colloidal protein and lipid particles. These would tend to produce flocculation of the colloids (I. Traube and Klein) and generally to alter the surface properties, the catalytic activities and the permeability. Both surface-affinity and lipid-affinity would therefore lead to surface changes. These may have identical effects on function, so that they would supplement each other. If the surface active substance condenses on a lipid surface in which it is soluble, the liquefaction may play the major part; with surfaces in which the active substance is not soluble, the film would be more important. This would be the case, for instance with unorganized ferments.

Permeability of the Cell Membrane.—This is diminished by narcotic concentrations, and increased by toxic concentrations. In nerve fibers and in muscle, Hoeber, 1915, found that low concentrations of anesthetics decrease permeability, for they prevent the swelling which normally occurs in solutions of potassium salts. High concentrations increase the permea-

bility; this would correspond to a toxic effect. Both phenomena have been confirmed on fish-eggs by McClendon, 1915. Osterhout, 1912, 1913, 1918, showed that anesthetics lessen the electric conductivity, and therefore the permeability, of plants. Fatal concentrations again increase the permeability. Hemolysis also is an instance of increased permeability by toxic concentrations (Hoeber, 1915; Joel, 1915). Autolysis is similarly increased by high concentrations (Chiari).

The relation of depression and stimulation to permeability is well illustrated by the experiments of R. S. Lillie, 1912, on *Arenicola* larvæ. He found that pure solutions of NaCl produce strong stimulation and at the same time increase the permeability, as shown by the diffusion of pigment and the dissolution of cilia. Mg, Ca and aliphatic anesthetics produce depression and lessen the permeability, so that they prevent the effects of NaCl. The Mg ions and the aliphatic anesthetics probably act on different constituents of the membrane. It is therefore all the more striking that in both cases the narcosis is characterized by diminished permeability. Similar phenomena are observed in the effects of anesthetics on the sensitive plant.

Effects of Narcotics on Surface Phenomena in Dead Systems.—Lipolytic agents increase the electrical resistance of artificial membranes impregnated with lecithin, *i.e.* they diminish the permeability to ions (S. Loewe, 1913). They increase the *viscosity of lecithin suspensions*, and the *precipitability* of these by electrolytes (Handovsky and Wagner, 1911; A. Thomas, 1915). However it is not safe to generalize from this, for Hoeber and Gordon, 1914, reported that the anesthetics hinder the precipitation of lipid suspensions by calcium; and W. Koch, 1910, showed that the various lipolytic anesthetics differ in their effects on the aggregation of the phosphatides. The anesthetics affect *lipoid emulsions* so as to promote the continuity of the fatty phase, and this shows a general parallelism with the narcotic phenomena (Clowes; M. Fischer and Hoskin, 1916).

I. Traube and Klein showed that the lipolytic anesthetics exist in watery solutions largely as colloids (as do also other difficultly soluble substances), and as such they tend to accumulate at the interface, and to produce *flocculation and precipitation of other colloids*. The adsorption of the anesthetics on colloids also explains the observation of Moore and Roaf, 1905, that the *solubility of chloroform in serum and tissue extracts* does not obey the ordinary laws of solution. However, the adsorption is not very firm, for Cushny, 1910, found that the *exhalation* of the volatile members of the alkyl series is exactly analogous to their evaporation from watery solutions.

The flocculation and instability of the colloids produced by low concentrations of the anesthetics is probably different from the *coagulative effect* that they produce in high concentration; such as the precipitation of serum by alcohol, etc. These phenomena, however, suggested to Claude Bernard, 1853 and 1875, a coagulation theory of narcosis, *i.e.* that narcosis might be due to a semicoagulation of the protoplasm, analogous to the muscle-rigor produced by chloroform. This theory had no direct experimental foundation; but it was elaborated by Binz (Lectures, 1891), who showed histologically that the cells of fresh brain sections are coagulated by solutions of chloroform or morphine, but he had to employ relatively enormous concentrations, nor could it be supposed that fully coagulated cells could ever resume their activity. The original suggestion, however, is in the direction of the modern views.

Dubois, 1894, observed exudation of water in narcotized plant cells, and suggested that narcosis consists in *dehydration*. Overton, however, showed that the phenomenon is a manifestation of irreparable injury, and not of narcosis.

Unorganized Ferments.—The lipolytic narcotics retard the action of ferments in general; for instance, *zymase* (Warburg and Wiesel, 1912); yeast invertase (Meyerhof, 1914); *oxidases* (Vernon, 1912); of pepsin, rennin, trypsin, etc.; of colloidal platinum (Meyerhof); and other inorganic catalysts. The relative activity is similar to that for protoplasm; but the concentrations required for the unorganized ferments are considerably greater than the concentrations that suffice for the narcosis of living protoplasm, so that they cannot be transferred directly.

Relation of Cell Permeability to Stimulation.—It may be repeated that the lipolytic narcotics alter the interface condition of colloidal systems. This involves in the first place the cell membrane. If the anesthetic penetrates into the protoplasm, this must also be affected, but the nature of the protoplasmic changes can only be surmised. The alterations of

the membrane consist in a definite decrease of permeability, for narcotic concentrations. This interferes with the changes of permeability which are necessary for stimulation; for according to the currently accepted views of Nernst (1899), stimulation depends on a change in the electric polarization of the cell, due to a change in the concentration of the ions at the surface, which is brought about by a sudden increase of the permeability of this membrane at the moment of stimulation. This change is hindered when the permeability is decreased by the narcotics.

Changes in the plasma membrane could also be effected by other means, and the narcotic effects of salts can be explained in this manner. A plausible explanation of the actions of morphine and most of the local anesthetics is still lacking.

Permeability of the Plasma Membranes.—Overton found that cells are generally impermeable to neutral salts, sugars, etc.; but easily permeable to lipolytic substances. This rule is not absolute—there are important exceptions, *f.i.*, for metabolic substances and for some of the dyes, but it is sufficiently general to indicate that cells behave as if they were surrounded by a lipid film. The departures from the rule are perhaps explained by the intermixture of other colloid constituents (A. P. Mathews, 1910). This protective film, the "plasma membrane," is probably formed by the surface condensation—according to the Gibbs-Thomson principle—of substances, which lower surface tension, as do the lipoids.

(A schematic presentation of the plasma-permeability method is given by H. Winterstein, 1916.)

Relation of the Membrane to Stimulation.—This subject is well summarized by R. S. Lilly, 1913. The semipermeability serves to maintain the differences of electrical potential (as shown by the demarcation current) which is essential to life. This potential disappears with death, and is impaired by all poisons which injure the semipermeability; and amongst these by the anesthetics (Walter and Alcock, 1906). Acids, alkalies and certain ions also disturb the potential; but these act presumably on the other colloids of the membrane. Analogous phenomena are observable in artificial systems of phosphatide and salt solutions (J. Loeb and Beutner, 1913).

Excitability and Conductivity of Nerve.—Narcosis of a nerve, however produced, always lowers both these functions in strict parallel (Verworn, *Erregung und Lähmung*, p. 121). While a normal nerve conducts without loss of stimulus, a narcotized nerve shows therefore a decrement during conduction (*ibid.*, p. 127).

Mobilization of Potassium.—Menten, 1912, states that the quantity of potassium ions in medullated nerve fibers is increased by local lipolytic anesthetics and by injury. This is probably an expression of the disturbed permeability; but since potassium depresses the conductivity of the nerves, it is conceivable that this plays a part in narcosis.

Stimulation of Phagocytosis.—Hamburger and de Haan, and Bubanovic, 1911, showed that this is stimulated by minute doses of lipolytic agents, parallel to their partition coefficient. This is probably explained by a lowering of surface tension. Narcotic concentrations paralyze the movements of leucocytes.

Verworn's Theory of Oxygen Deprivation.—Verworn, 1909 (Harvey Lectures, 1911; "Narkose," Jena, 1912), and his pupils have pointed out that narcosis is generally accompanied by diminished oxidation; and that deficiency of oxygen produces anesthetic phenomena. They therefore believe that narcosis is due to interference with oxygenation; to incapacity of the cell substance to undergo oxidation, even in the presence of oxygen, whilst non-oxidative destruction proceeds unchecked.

Verworn's facts do not prove his theory; for since narcosis suppresses irritability, it would naturally depress oxidation; this would be the effect instead of the cause of the narcosis. Conversely, the suppression of irritability by oxygen deprivation does not prove that every narcosis must be due to oxygen deprivation. This could be accepted only if interference with oxidation and narcosis were always strictly parallel. This is not the case, and the theory is therefore not tenable.

Verworn suggested that the transmission of oxygen may be a function of the lipid substances, thus accounting for the Meyer-Overton law, and harmonizing the two theories. Mansfeld, 1909, also assumed that narcotics lessen the solvent power of lipoids for oxygen and so prevent its penetration. This was contradicted by Winterstein, 1913. A. P. Matthews, 1914, believed that the anesthetics fix the oxygen receptors of the protoplasm into a non-irritable anesthetic-protoplasm combination. Traube believed that the oxygen catalyzers are hindered by surface condensation. Batelli and Stern described precipitation of nucleo-proteins in cell extracts, parallel with checking of oxidases. On the other hand, Buercker, 1910, and Baglioni believed that the narcotics combine with the oxygen.

Verworn concedes that high concentrations cause other changes, such as coagulation; but states that these are non-reversible, and therefore not concerned in true narcosis.

Anesthetic Effects of Oxygen Deprivation.—The anesthetic effects of asphyxia have long been familiar. As samples of the evidence for Verworn's theory may be cited the fact that frogs perfused with saline solution become inexcitable; but that the excitability is preserved or reappears if the solution is oxygenated (Verworn, 1900). Similarly, excised nerve loses its excitability in an atmosphere free from oxygen (Froelich, 1904). Mansfeld, 1909, showed that the results are additive; the paraldehyde narcosis in tadpoles being increased by degrees of oxygen deficiency which are in themselves harmless. He also pointed out, 1910, that oxygen deficiency, like narcosis, decreases the current of rest in frogs' skin. Froelich and Heaton, and Ishikawa showed that oxygen deprivation delays recovery from anesthesia.

On the other hand, there are instances (nerve trunks, vorticella, cilia) in which oxygen deprivation acts very slowly, while anesthetics act very promptly. HCN, which is a strong asphyxiant, is a weak anesthetic. Anaerobic organisms are also subject to narcosis, showing at least that this has nothing to do with free oxygen or its penetration into the cells.

Diminished Oxidation in Narcosis.—Herter found that the oxidizing capacity of tissues for methylene blue is greatly diminished in anesthesia. Vernon, 1909, claims a quantitative relation between the hemolytic effect of alcohols and their influence on the respiration of excised kidneys. Tashiro, 1913, found that anesthetics greatly diminish the CO₂ output of nerves. Alexander and Cserna, 1913, claim that anesthetics and morphine diminish the oxygen consumption and CO₂ formation of the brain.

Verworn, 1912, and others have shown that various anesthetics inhibit oxidases parallel to their anesthetic activity. However, the required concentrations are of the toxic rather than of the anesthetic magnitude.

Interference of narcosis with oxidation is the general rule; but there are important exceptions. Winterstein, 1915, points out that anesthesia, even when continued for days, need not increase the acidity of the central nervous system; while asphyxia (oxygen deprivation) always increases the acidity. Anesthesia therefore does not always diminish oxidation. Warburg, 1910, and Loeb and Wasteneys, 1913, find the oxygen consumption normal in narcotized sea-urchin eggs.

Blood-catalase.—Burge, Weill and Ashman, 1918, claim that narcosis is accompanied by a decrease of the catalase content of the blood, roughly parallel to the depth and rapidity of the anesthesia. In deep narcosis, the decrease may reach 30 to 40 per cent. A similar relation was claimed for ether, chloroform, nitrous oxide and magnesium anesthesia.

Burge assumes that narcosis is due to direct destruction of catalase by the anesthetic agent; that this results in diminished oxidation and that this produces anesthesia. He explains recovery by increased catalase output from the liver.

However, this assigns to the catalase a more important role in oxidation than is generally accepted; and Becht, 1919, throws serious doubt on the results. With a more reliable method, he found practically no change of catalase during anesthesia; if anything, there was a slight increase. The catalase was contained entirely in the corpuscles, and the slight variations may be due merely to changes in the corpuscle-plasma ratio. There is still no evidence that the catalases have anything to do with the ordinary processes of the body. More probably, they serve to destroy peroxides that might become harmful (Loew).

Narcosis and Sleep.—The analogies of narcosis in the higher animals, with the phenomena of natural sleep suggested a common origin to the earlier investigators. Since sleep was then explained by *cerebral anemia* (Durham, 1860) the same explanation was adopted for narcosis (Bedford-Brown, 1860). However, it was subsequently found that changes in the cerebral circulation are small and variable (Cl. Bernard, 1875).

All the theories of *deficient nutrition of the brain*—whether through anemia or otherwise—are definitely disproved by the fact that narcosis can be induced in frogs in which all the blood has been displaced by saline solution, or in which the cerebral circulation has been arrested; in excised nerve-muscle preparations; in animals which do not possess blood; in plants; and even in unicellular organisms.

Morphologic Changes.—It may well be supposed that the changes in the physical composition of the cell will produce corresponding changes in their histologic structure. Most of these would probably disappear in the process of fixation, but certain of them appear to persist. A diminution and fusion of the *Nissl granules* have been described by good observers after deep anesthesia; other observers have not been able to confirm this, and the changes may be only artifacts. Kocher, 1916, emphasizes the numerous sources of error and the inconstant results of such observations.

It is also stated that the dendrites of many pyramidal cells show moniliform enlargements; the alterations disappearing completely within forty-eight hours, even when caused by chloroform anesthesia of nine hours' duration. Lépine and Duval attributed anesthesia to retraction of the dendritic processes.

ALCOHOL

Ethyl alcohol is a local irritant. After absorption, it depresses the central nervous system, especially the "higher functions." It stimulates stimulation, chiefly by lowering the normal restraining functions; but there may be some direct facilitation of motor processes and respiration.

Local Action of Alcohol.—Concentrated alcohol "hardens" tissues by abstracting their water and precipitating the proteins. It is therefore irritant and astringent. The effect is proportional to the concentration.

Applied to the skin, it causes some redness and burning, followed by slight anesthesia. It is employed as a *mild rubefacient* and counterirritant in sprains and other minor pains. It may be applied in 10 to 50 per cent. concentration, by friction or embrocation. It is often combined with other mild irritants, as in the *Linimentum Saponis*, *Spiritus Camphoræ*, *Aqua Hamamelidis* ("Witchhazel") and *Tinctura Arnicæ*. The presence of considerable proportions of alcohol in other spirits, tinctures, fluid-extracts, wines and elixirs should be borne in mind, both in their external and internal use.

If the alcohol is sponged on the skin and permitted to evaporate it produces a *cooling effect*. This is utilized in *fever*, and in excessive perspiration ("night-sweats" of phthisis). The cleansing and hardening of the skin is also useful in this connection, and to prevent the development of *bed sores*. The astringent and stimulant action promotes the healing of *ulcers* (25 to 50 per cent.). Breitmann, 1913, recommends its liberal use as an astringent lotion (70 per cent.) in first- and second-degree burns.

On *mucous membranes*, the local action produces hyperemia or inflammation according to the concentration (see the "Effects on Digestion"). Even the minor grades of this irritation produce chronic inflammation on continued use, and this tends to extend beyond the local surface, producing fatty and fibrous changes in the internal organs (see "Habitual Use"). The diuretic action of alcohol indicates that it irritates the renal cells.

Subcutaneous injections of alcohol in concentrations above 50 per cent. are painful; especial care should be used not to inject it near a nerve.

Intraneural injections of alcohol were introduced by Schoesser for the relief of neuralgia and spasms (Ostwald, 1906; Harris, 1914). They are generally effective; but are

frequently followed by toxic degeneration of the nerve. They should therefore be avoided for motor or mixed nerves (sciatica), and find their best field in trigeminal neuralgia, as a substitute for the extirpation of the Gasserian ganglion (Fischler, 1907), which they have largely superseded. Their effect is not permanent, nor are they entirely free from risks; but they have a definite field of usefulness (Harvey Cushing, 1920).

Cadwalader, 1915, has studied the results of various concentrations: 80 per cent. alcohol produces immediate and complete paralysis, followed by absolute histologic degeneration. The paralysis may persist for one to three years, or until regeneration is complete; in case of scar formation, there may be no regeneration. 50 per cent. causes less severe paralysis and degeneration; and 25 per cent. has but little effect in either respect.

Bactericidal Action of Alcohol.—70 per cent. alcohol is a fairly effective germicide. Concentrations above 80 per cent. and below 60 per cent., however, are almost inactive (A. Beyer, 1911; Sottile, 1912), because they do not penetrate proteins as readily (Tijmstra, 1913).

Skin Disinfection.—The usual surgical routine consists in 2 per cent. iodine in 70 per cent. alcohol. In this, the alcohol plays a material part.

When tested by dropping bits of a rat's tail into the solution, 70 per cent. ethyl alcohol sterilized in 5 minutes, 50 per cent. propyl alcohol in one minute. The propyl alcohol is therefore more effective. The following failed to disinfect in five minutes: Phenol, 2 per cent.; mercuric chloride, 0.1 per cent.; formaldehyde, 4 per cent.; Dakin's solution; ether; acetone (Christiansen, 1918).

"Stimulant" Effects of Alcohol.—These are observed in most individuals, after taking "moderate" doses of alcohol—a quantity not easily expressed in cubic centimeters. The phenomena are at first view typical of stimulation. There is an increase in the rate of the *respiration* and of the *heart*; the *blood pressure* rises. The *skin* is reddened, with a grateful sensation of warmth and comfort. There is an increased *vivacity* of motion, action, and speech, which later may acquire a stamp of brilliancy, perhaps of inspiration. The *subjective condition* of the individual generally veers toward self-appreciation. Shyness, if it ordinarily exists, is replaced by self-confidence. The person under the influence of alcohol feels an unlimited confidence in his own powers and accomplishments, both intellectual and physical. He will attempt very difficult, even impossible, tasks, and feel that he accomplishes them. And he similarly overestimates the productions of others.¹

These manifestations are so conspicuous and apparent, that alcohol in proper doses has been considered a typical stimulant. However, the critical study of its actions tends to the conclusion that *most of these actions do not depend upon true direct stimulation* of the nerve-centers; but that they are the indirect result of incoördination, of accessory factors of environment, and of reflex stimulations.

Of the physical phenomena, the *flushing of the cutaneous vessels*—to which the sensation of warmth must be attributed—occurs as the result of a vasomotor paralysis, restricted, it is true, to this area. The *quickenened pulse* results partly from reflexes caused by swallowing and by irritation of the mucous membranes, partly from the emotional excitement and increased movements; not at all from a direct action on the cardiac nervous or muscular mechanism—for it is entirely absent in animals, and very brief

¹ No better description of these effect has been given than that of Horace: "What wonders does not wine! It discloses secrets; ratifies and confirms our hopes; thrusts the coward forth to battle; eases the anxious mind of its burthen; instructs in arts. Whom has not a cheerful glass made eloquent! Whom not quite free and easy from pinching poverty!"

in man if the factor of excitement be eliminated. *The quickening of the respiration* is also largely due to similar causes.

The *psychic phenomena* find their explanation in a dulling of certain mental faculties whilst others are still practically unaffected—in a disturbance of what has been called the “normal balance of the brain.” The first functions to be lost are the finer grades of judgment, reflection, observation, and attention—the faculties which have largely been acquired through education, and which constitute the elements of the restraint and prudence which man usually imposes on his actions. The orator no longer considers that he may be called to account for his utterances; he allows himself to be carried by the impulse of the moment, without reflecting on ultimate consequences, and, as his expressions become freer, they acquire an appearance of warmth, of feeling, of inspiration. Not a little of this inspiration is contributed by the audience, who are often in a similar condition of increased appreciation.

The view that alcohol increases the intellectual and physical powers of the individual is shown by actual experiment to be erroneous, and based almost entirely upon the subjective condition of the individual, his weakened faculty of judgment and premature but faulty or misdirected reactions. The failure of alcohol to produce real stimulation is also attested by common experience. Persons who have to undergo severe exertion, either physical or intellectual, very rarely take alcohol before or during their labor, but only when this is finished. And then not for any stimulating, but really for its depressing, effect; for the feeling of comfort and general relaxation which it induces. The continued use of large doses of alcohol greatly diminishes the activity of the individual, and even moderate doses tend to have the same effect.

Another very characteristic feature, evidently resulting from this paralysis of the higher functions is the *loss of the power to control moods*. There may be causeless merriment or sadness, friendliness or the opposite. It is proverbial how this abolishes self-control: “There is truth in wine.” On the other hand, the habits of self-control, where they have been cultivated, persist to some extent even in intoxication.

Applied Efficiency Tests.—Several independent investigations on type-writing, target-pricking and rifle-practice have shown uniformly that effective doses of alcohol lower the efficiency by decreasing accuracy. This becomes especially conspicuous when the work is rapid, and when it requires close and continuous attention. The mere speed may not be reduced. The deleterious effects are least marked in tasks that are so familiar, or so easy and simple, so “semi-mechanical,” that they do not require much attention.

Doses of 20 to 40 c.c. of alcohol practically double the errors, in close work, and the effect with this dose lasts about two hours. With some individuals, 10 c.c. may produce the effect; whilst habitual drinkers are more resistant. The concentrations in which the alcohol is given does not materially influence the response; but the effect is less if the alcohol is taken with or just after meals, for then it would be more slowly absorbed (Vernon and Greenwold, 1919; W. R. Miles, 1924).

Experimental Analysis of the Psychic Effects of Alcohol.—The most reliable data appear to be those of Dodge and Benedict, 1915, for they aimed to use the simplest methods of a given kind.

They found that moderate doses depress all kinds of neural processes, motor as well as sensory. This diminished efficiency is most conspicuous

in the simpler and unconscious reflex processes, *i.e.*, those that are most independent of the will; for a normal individual even when somewhat alcoholized attempts automatically to compensate for diminished efficiency by greater effort. This in turn, however, is likely to lead to more errors; for the extra effort is often ill directed, since alcohol diminishes caution and inhibitions.

Dosage, Time and Subjects.—Dodge and Benedict employed doses of 30 and 45 c.c. of alcohol, diluted to 20 per cent. The depression reached its maximum in 1 to 2 hours; recovery starting within 3 hours. The responses were essentially similar for abstainers and reformed drinkers.

Quantitative Response.—The results may be arranged in progressive order from those showing the greatest, to those of the least effects:

Reflexes.—Knee-jerk and lid-reflex: Latent period increased by 10 and 7 per cent. Muscle shortening diminished by 46 and 19 per cent.

Sensory Threshold to Electric Stimulation.—Raised by 14 per cent.

Motor Coordinations.—Speed of eye-movements and of reciprocal finger movements: Diminished by 14 and 9 per cent.

Elaborated Reactions.—Reaction time of eye and speech organs; latent period increased by 5 and 3 per cent.

Memory.—No change.

Kraepelin, 1892, also concluded that alcohol is purely depressant to sensory or intellectual processes; but he believed that the generation of motor impulses is first stimulated, and only later depressed. In the light of the more recent work, this "stimulation" of motor processes is apparently an erroneous interpretation; but this does not destroy the value of the actual data of the extensive studies of Kraepelin; namely that the "stimulant" stage of alcohol favors mechanical performances—the "simpler reactions" of memorizing, mechanical reading, repetition, at the expense of the more intellectual processes—association, arithmetical, etc. It favors motor impulsiveness, but produces intellectual dullness and silliness, lowers thought, judgment, resistance to temptation, and thus leads to further abuse. The euphoria probably depends on the deceptive feeling of facilitation and capability.

Psychic Depression.—With doses of 30 to 45 Gm. of alcohol, this lasts thirty to forty-five minutes; with 60 Gm., one to two hours. The phenomena are somewhat analogous to fatigue. In both, mechanical associations predominate. However, the lighter grades of alcohol "fatigue" disappear with exercise, while genuine fatigue is relieved only by rest.

Motor Processes.—The facilitation begins at once and lasts at most twenty to thirty minutes, less with larger doses. It is followed by depression even with the small dose of 7.5 Gm. With 45 to 60 Gm., the initial facilitation is seen only exceptionally. However, the results depend somewhat on circumstances; in excitement, even large doses produce facilitation; and in fatigue, small doses may depress. The more mechanical the function, the more conspicuous is the facilitation. The force measured by the dynamometer is not increased, so that the rate rather than the force of motor impulses is favored. There is also evidence that the muscular contraction proper is not quickened, but that the motor impulses are started more easily.

Perception of Sensory Impressions.—This is impaired for hours, even by $\frac{1}{4}$ oz. of alcohol (Kraepelin, 1916).

The reflexes from the frog's skin are depressed, even with the smallest effective doses (Hyde and pupils, 1913), before there are any grossly visible symptoms.

Color-vision.—H. Schuly, 1916, finds that small doses of alcohol increase the acuteness of vision, both for red and green. Large doses diminish it.

Use as Stimulant.—Even the "stimulant" doses do not increase intellectual efficiency; but they could be employed for facilitating motor functions of short duration; not so much to increase their force, but for overcoming inhibition or hesitancy; to promote decision or resolution,

f.i., in speaking, in psychic dreads, etc. It would be unfavorable to attention, watchfulness or accurate judgment. The stimulant dose should generally not be more than 15 to 20 Gm. of alcohol; or if a longer effect is needed, 5 to 8 Gm. in twenty-minute intervals.

Alcohol on Muscular Work.—*In man*, the ergographic experiments of Lombard, 1892, showed that the muscular force in voluntary contractions is not increased; but the appreciation of fatigue is lessened (Joteyko, 1904; Foerster, 1912), so that the total work may be increased. When a finger is tetanized, by electric stimulation, the total work is rather decreased (Lombard); the favorable effect must therefore be at least partly central (facilitation of cerebral motor processes). However, the voluntary response is modified by the previous state of the muscles as well as by the dosage of alcohol: Hellsten, 1904, found that moderate doses (10 Gm.) at first increase the power of voluntary muscular work (to 9 per cent.), but in one-half hour diminish it to 6 per cent. below normal. Myers, 1912, reports no effects from 5 to 20 c.c.; 30 to 40 c.c. gave irregular results, most commonly a primary increase and secondary decrease of the work. The increase is seen only when the muscle is not too much exhausted, but it is favored by moderate fatigue. The favorable effect therefore appears to be due partly to the direct food-value of the alcohol, somewhat as with sugar; the food effect of alcohol is more prompt, but not as efficient in the long run. The depression of the larger doses is purely central.

On *frog's muscle*, minute quantities have no effect; moderate doses were said to exert a favorable action on all the features of muscular activity; larger quantities are very unfavorable (Lee and Salant, 1902). Crider and Robinson, 1916, attribute the reported favorable effect to experimental error.

The effects on invertebrates and lower vertebrates have been studied by Fuehner, 1912.

The Effects on the Respiration.—"Stimulant" doses of alcohol may increase the rate and depth of the respirations, by reflex and central stimulation. This may aid in the therapeutic use of alcohol as a stimulant. The response, however, is variable and generally small. With narcotic doses, the respiratory center is depressed.

In Higgins' experiments (1917) on man, 30 to 44 c.c. of alcohol taken diluted, produced little change in the rate or type of respiration (unless there was excitement). The threshold to CO₂ was sometimes lowered. The minute-volume was generally diminished, by decreased CO₂ production. The bronchioles were generally unaffected; rarely dilated.

The respiratory stimulation is especially large in fatigue, and is greater with wines and liquors rich in "bouquet," than with dilutions of pure alcohol (Binz, 1903). Wendelstadt, 1899, obtained similar results in man.

The increased respiration is partly due to the general excitement and partly to reflexes from the local irritation (Jacquet, 1895) and from the odor, etc. However, some increase occurs even in sleep, so that the factors of environment are not essential. Nor can it be affirmed that it is due solely to reflex irritation, for other irritants do not produce an equivalent effect (Binz, 1903). Moreover, an immediate increase of respiration occurs if alcohol is injected into the brain through the carotid artery (Wilmanns, 1897).

With *unanesthetized animals*, slow intravenous injection produced only slight respiratory stimulation, even when the injections were repeated beyond the excitement stage (Hyatt and Jensen, 1918).

With a more perfect separate *perfusion* of the brain and medulla. Hooker, 1917, also found that the addition of 0.025 to 0.1 per cent. of alcohol (corresponding to clinical concentrations) produces pure stimulation of the respiration. With 0.2 per cent., the stimulation was transitory, and followed by prolonged inhibition. This would correspond to coma.

It is therefore certain that the respiratory center is stimulated directly. A. Fonteyne, 1906, finds that *large doses* lessen at first the rate, and later also the volume. In *cats*, Pilcher, 1912, found the rate usually increased by all except fatal doses. In decerebrated cats, doses of 0.5 to 5 c.c. per kilogram, dilute or concentrated, caused no change in the respiration (Lieb, 1915).

The *hypodermic injection* of 50 per cent. alcohol (or of whiskey or brandy) produces considerable temporary increase of respiration, by reflex irritation. This occurs also under morphine (Hanzlik, 1913).

The Effects on the Circulation.—These are rather inconstant, varying not only with the dose and concentration and mode of administration, but also with the condition of the individual.

Small therapeutic doses (in man, to perhaps 5 to 25 c.c. of absolute alcohol, diluted at least to 25 per cent.) produce generally (but not always) an insignificant quickening of the pulse rate, due mainly to excitement.

The cutaneous vessels are dilated, and the splanchnic vessels are somewhat constricted leading to a rise of the systolic blood pressure and a fall of the diastolic pressure. The mean aortic pressure rises slightly in most cases, but not always. The normal heart muscle is probably not affected by these doses; but the exhausted heart may be stimulated by the nutrient action of the alcohol.

The actions, taken together, alter the distribution of the blood, so that more is contained in the surface vessels and in the arteries, and less in the splanchnic veins. The amplitude and force of the pulse; the "mass-movement" of the blood; the output of the heart; and the efficiency of the circulation in general, is improved. Cardiac dilation may be decreased. The effects are not very great and not altogether constant in normal individuals; but they suffice to produce decided therapeutic effects, especially in conditions of exhaustion.

The actions reach their maximum in about half an hour, and disappear in an hour or two.

Somewhat larger doses (45 to 90 c.c. of alcohol for man, diluted) produce at first the same effects, followed in an hour or less by decreased amplitude and force of the pulse, with progressive fall of the systolic pressure, and unaltered or rising diastolic pressure. If the alcohol is taken in more concentrated form on an empty stomach, this stage may occur at once, without the preliminary improvement of the pulse. The fall of the pressure is attributable to splanchnic dilation, replacing the constriction of the first stage. The action is therefore comparable to that of the nitrites. The effects reach their maximum in one to one and one-half hours, and last one-half to one hour.

Toxic doses depress the vasomotor center and perhaps also the cardiac muscle, so that the blood pressure falls severely. The heart rate may be slowed through central vagus stimulation, or through the depressant action of the coma; or it may be quickened by the fall of blood pressure.

The hypodermic injection of whiskey, as that of other volatile irritants, often produces a slight and transient rise of blood pressure (Lieb and Herrick, 1917).

Heart Rate.—The effect is greatly modified by the condition of the individual. In man, the rate is generally increased, mainly by the psychic and reflex actions (Dixon, 1907); the increase is often absent, especially if the patient keeps quiet (Zimmermann, 1896; Jacquet, 1891, Dixon).

Dodge and Benedict, 1915, always observed some acceleration, which they attribute to diminished vagus tone. With larger doses, the quickening is the rule (John, 1918; Higgins, 1917), presumably to offset the falling blood pressure. Animals give similar inconstant results (Pilcher, 1912). The intravenous injection into non-anesthetized animals generally causes some slowing (Brooks, 1910).

General Blood Pressure.—In man, Kochmann, 1905, and Bachem, 1905, found a rise of systolic pressure with small doses. Dixon, 1907 (dose not stated) found the systolic pressure unchanged or slightly raised, the diastolic pressure lowered. This

was confirmed by John, 1908. Lieb, 1915, observed practically no effect from diluted whiskey (usually 5 to 10 c.c.). When given concentrated, this dosage usually produced a slight reflex rise (about 5 mm.) of the systolic and diastolic pressure, returning to normal in less than one-half hour. The return of the diastolic pressure is somewhat slower, so that the pulse pressure is decreased. The Tigerstedt formula indicates a very slight decrease of cardiac efficiency. These effects are entirely reflex, and are most pronounced when the reflexes are hyperactive; least in apathetic patients and toxemias. Moderate users are more susceptible to them than drinkers. With larger doses John found a progressive fall of systolic pressure, with unchanged or rising diastolic pressure.

Anesthetized animals are obviously not suited for determining the effects of small doses of alcohol. In *unanesthetized animals* the oral administration produces a slight rise, lasting five to ten minutes; administration through a gastric fistula has no effect. Rapid intravenous injection causes the sharp drop, common to many drugs, followed by rapid recovery. Slow intravenous injection produces no marked change with doses of 0.5 to 5 c.c. per kilogram (Brooks, 1910; Lieb, 1915; Hyatt, 1920).

Blood Flow.—Alcoholic beverages of the strength of wine, administered to normal men in moderate doses, produce a brief preliminary decrease, followed by a more lasting increase of the blood flow in the hand. Both effects are vascular. Alcohol also favors vasodilator reflexes, *i.e.*, the contralateral heat reflex (G. N. Stewart, 1915). Hanzlik and Collins, 1913, found the circulation time in intestinal vessels distinctly slowed by relatively small doses of alcohol, intravenously, even when the carotid pressure was unchanged.

Vasomotor Changes.—Moderate doses of alcohol dilate the *skin capillaries*, and lower the *vein pressure*, without change in the arterial pressure (McDowall, 1925). (Large doses, which injure the heart, increase the vein pressure; Capps and Matthews, 1913.) The cutaneous vasodilation is obvious on mere inspection, and may be confirmed by plethysmograms of the limbs, and by the blood flow. Since the blood pressure does not fall in the early stages, it is evident that this dilation of the surface vessels is compensated, either by the constriction of other vascular areas, or by increased output of the heart. Both factors appear to contribute to the result, according to circumstances.

Splanchnic vasoconstriction in the early stage has been demonstrated by Dixon, 1907, who found that the volume of the intestine decreases while the blood pressure rises.

General vasodilation, presumably in the more advanced stages of the action, is shown by the fact that the blood pressure is practically not increased, notwithstanding considerable increase of the output of the heart, as measured by the stromuhr (Hemmeter, 1889; Wood and Hoyt, 1905), or by the cardiometer (Dixon). If the vasomotor center is excluded by section, the injection of the alcohol causes a more marked rise of pressure (Kochmann; Wood and Hoyt), showing that the vasodilator action of alcohol must be central. (Bachem, however, found less rise after section of the vasomotor center.)

Vasomotor Reflexes.—Porter and Turner, 1915, find that alcohol may suspend vasomotor reflexes even when the general level of the blood pressure is not altered. They conclude from this that separate centers exist for vasomotor tone and reflexes.

Direct Action on Vessels.—These appear to be insignificant. On perfusion, Dixon found in mammals slight dilation with 0.1 to 0.2 per cent.; higher concentrations gave constriction. Perfusion of the frog showed moderate constriction. In surviving arterial rings, Cow, 1911, found very slight response: transient constriction followed by dilation. Plumier, 1905, believes that alcohol has a peripheral constrictor effect.

Improved Nutrition of the Heart.—The *increased output of the heart in situ* is attested by the stromuhr, cardiometer, rise of pressure after destruction of vasomotor center, etc. Since this improvement is not usually noted in excised hearts, it can not be due to a direct action of alcohol on the cardiac muscle. Kochmann, 1905, attributes it to improvement of the coronary circulation by the general vascular changes. Dixon, 1907, believes that the food-value of alcohol plays the most important rôle; for he finds it most effective, in excised hearts, when the nutrient supply has been previously exhausted. Hamill, 1910, then showed directly that perfused hearts are able to metabolize alcohol. C. C. Lieb, 1917, failed to confirm this utilization; but positive results appear more valuable than are negative data.

Isolated Mammalian Heart.—Concentrations below 0.05 per cent. have generally no effect. Occasionally there are indications either of depression or of stimulation; the latter especially if the heart has been exhausted (Dixon, 1907). Between 0.05 and 0.5 per cent., some depression becomes evident. This is first seen as increased volume, in systole and diastole, which progresses with the dosage, and develops into diminished output, rise of venous and pulmonary pressure, slight slowing, and some tendency to arrhythmia. With 2 per cent., the heart is severely damaged, especially the auricles. Four to 5 per cent. arrests the heart in diastole; the auricles stopping before the ventricle. If the alcohol is removed, the heart recovers rapidly, even from severe

depression (Sulzer, 1924; Kochmann, 1904; O. Loeb, 1905; Barry, 1915; BurrIDGE, 1917; Lieb, 1917).

Repeated perfusion confers tolerance (Kuno). Lieb, 1917, failed to find this rather improbable rapid habituation.

Brandini, 1913, found the depressant effect on perfused rabbit's heart increased with rise of temperature.

During the depressant stage of alcohol or the anesthetics, the heart is said to take up less calcium from the perfusing fluid (BurrIDGE, 1917).

The coronary vessels are said to be constricted, and the coronary flow diminished, by 0.1 to 0.2 per cent. of alcohol (Sulzer, 1924).

The concentration of alcohol in the blood of living animals is said to be 0.12 per cent. in "slight confusion," and 0.7 per cent. in deep narcosis. It is therefore improbable that the direct cardiac effects of alcohol play more than a minor part in either the therapeutic or toxic phenomena.

Pressure in Pulmonary Artery.—Dixon, 1907, and Wood, 1911, found this slightly increased, even when the carotid pressure is unchanged. Cloetta and Anderes, 1914, found the effect on the pulmonary vessels inconstant; generally dilation, rarely constriction.

Cerebral Circulation.—Contradictory results were obtained by Aliprandi and Formaroli, 1905; and by E. Weber, 1909. Hirschfelder, 1915, describes dilation of the vessels of the pia mater and retina. Berezin, 1916, also observed dilation.

The frog's heart is stimulated by small, and depressed by higher concentrations (Wood and Hoyt, 1905); according to others, even the smaller doses are depressant (Dreser, 1887).

Turtle Heart.—The concentration required to reduce the height of contraction to one-half was studied for various alcohols by Vernon, 1910.

Hemolytic Action.—Alcohol added in sufficient concentration directly to blood causes hemolysis (C. H. Schulz, 1841). This concentration is not reached in living animals but the resistance to laking agents is noticeably lowered (Liebermann; Fillinger, 1912). Continued administration increases the resistance of the corpuscles (Orban, 1913). If the relative hemolytic effect of different alcohols is compared, it is found to be proportional to their effect on surface tension, rather than to their lipid solvent action (Fuehner, 1912). J. N. Schultz, 1912, has investigated the influence of various substances (including sera in different diseases) on the alcohol hemolysis.

Blood Viscosity.—This is somewhat increased by the administration or inhalation of alcohol or methyl alcohol (Burton-Opitz, 1904, 1914).

Use of Alcohol in Collapse.—The effects of alcohol on the general circulation are utilized in the treatment of collapse and in exhausting fevers.

Its usefulness as a quickly acting ("diffusible") stimulant can scarcely be doubted in the various forms of sudden circulatory collapse—syncope, exhaustion, hemorrhage, traumatic shock, snake venom, strychnine, aconite, veratrum poisoning, etc. The main element in this action is the reflex stimulation, increasing the pulse rate, the blood pressure, and the respiration. However, the stimulation is apt to fail in the severer grades of hemorrhage and shock (Lieb and Herrick, 1917). The narcotic action is also useful. The subsequent vasodilation is theoretically inadvisable, but it is not sufficiently pronounced to have any practical significance.

The reflex action being brief, alcohol acts mainly as a temporary emergency remedy, to tide the patient over the immediate dangers. To secure these reflex effects, 25 c.c. of whiskey or brandy should be given undiluted, and preferably hot, repeated every ten to fifteen minutes, according to effect.

Other Diffusible Stimulants.—A similar reflex stimulation may be secured by ether, aromatic oils, camphor, or ammonia. These may be administered by mouth (*Spiritus Aetheris*; *Spiritus Camphoræ*; *Spiritus Ammoniae Aromaticus*); or by smelling (aromatic ammonia, smelling salts); or hypodermically (brandy, ether, camphorated oil).

Cardiac Disease.—The actions of alcohol are scarcely available except for temporary conditions, such as acute *myocardial insufficiency*. In *chronic lesions*, small doses may be valuable to lessen the worries of the patient, especially if he has been accustomed to its use. The vasodilator effect may be useful in *angina pectoris*, but it is inferior to the nitrites. Alcohol does not influence *pulmonary hemorrhage* (E. Frey, 1909).

Use in Exhausting Fevers (Typhoid, Pneumonia, etc.).—The intelligent and discriminating employment of alcohol should be useful in these conditions; its indiscriminate use would doubtless do more harm than good. The beneficial effects are probably mainly nutrient, due to the direct *food-value of the alcohol*, and to the stimulation of the digestion and absorption of other foods (see below). This not only conserves the general nutrition of the patient, but also *increases the output of the exhausted heart*. The pulse becomes stronger and more regular. The altered distribution of the blood by the mildest degrees of alcohol action would also be beneficial: The *dilation of the cutaneous* vessels removes the blood from the atonic and therefore congested internal organs, and lessens the venous distention of the heart. It would also tend to lower the temperature, although the antipyretic effect is but small. The narcotic action of alcohol is useful by quieting the febrile excitement, thus reducing the demands on the strength of the patient.

On the other hand, if the action of the alcohol proceeds to the point of inducing splanchnic dilation and lowering blood pressure, it will exaggerate the serious circulatory abnormalities of fever. Again, in the acute, stimulant stages of the "sthenic" fevers, alcohol is apt to increase the circulatory excitement, and should be avoided.

The effects of alcohol must therefore be carefully watched, to secure its stimulant effects, when needed, while avoiding both the depressant and excitant stages. The individual observations on each patient can alone guide its employment: The dose may be increased or maintained so long as it improves the prominent symptoms, quiets the patient, regulates and strengthens the pulse, and lowers the temperature. When it ceases to have these effects—particularly when the pulse becomes "excited," or when the odor of alcohol remains on the breath—it should be diminished or stopped.

The amount must be governed by the previous habits of the patient; but astonishingly large quantities can often be given to fever patients without producing "intoxication" even if they are unaccustomed to its use; the febrile organism probably oxidizing the alcohol more rapidly.

Ordinarily, one may begin with $\frac{1}{2}$ to 2 tablespoons of brandy in half a glass of milk, every three hours, increasing the frequency as needed.

Diuresis.—Dilute alcoholic beverages (wine, and especially beer) increase the flow of urine; but the effect is mainly that of the excessive ingestion of fluid.

In man, Raphael, 1894, found that a liter of wine or beer had no more effect than the same quantity of water, and less than that of milk. John, 1903, found that the average quantity of urine in four to six hours after taking $1\frac{1}{2}$ liters of water to be 1,500 c.c.; with $1\frac{1}{2}$ liters of 3 per cent. alcohol, he averaged 1,800 c.c.; with the same quantity of 6 per cent. alcohol he averaged 2,000 c.c. of urine. The effect was relatively greater in a case of renal insufficiency from hypertonus; in this $1\frac{1}{2}$ liters of water gave only 625 c.c. of urine, while the same quantity of 3 per cent. alcohol yielded 1,600 c.c.

This suggests that the greater diuretic action may be due to a dilator effect on the renal vessels. Moreover, alcohol irritates the urinary passages (and is therefore *contraindicated in cystitis and urethritis*); this may increase the desire to micturate, and make the diuretic effect appear greater than it really is. "*Gin*," which contains juniper, has a more direct diuretic effect, from the renal irritation produced by the oil. Dogs fail

to show more than the water-diuresis, on the oral administration of any dosage of alcohol (Januskiewicz, 1911). (Intravenous injection would arrest the urine flow, as do other hypotonic solutions.)

Temperature.—The ingestion of alcohol causes a sensation of warmth, due to the increased blood flow to the temperature-nerves of the stomach and skin. This sensation, however, is deceptive; for this increased blood flow to the surface and the *diaphoresis* increase the heat loss, so that the internal temperature tends to fall. With small doses, this tendency may be overcome by the increased movements of the patient; but with larger doses the heat loss becomes pronounced (Pilcher, 1912), and is exaggerated by the depressant action on the temperature-regulating centers impairing the compensatory heat production. The fall of temperature is especially great if the external temperature is cold, and also if the heat dissipation was previously low, as in fevers.

Use of Alcohol in Chills and Exposures.—It is evident that this would be detrimental *during* exposure to cold; the temporary relief and feeling of warmth is obtained at the expense of an increased loss of heat, and consequently diminished power of resistance. But if taken *after* the exposure, the dilatation of the cutaneous vessels favors the absorption of external heat, and also prevents the tendency to congestion of internal organs, and thereby the tendency to “catch cold.”

Another effect may be important: Constriction of the cutaneous vessels, such as is produced by chilling, lead to reflex constriction of the vessels of certain internal surfaces and organs, especially the respiratory tract and perhaps the kidneys; and these are rendered less resistant to infection and injury. Cutaneous vasodilation by alcohol, the nitrites or by counterirritation may prevent or arrest the damage.

Influence of Alcohol on Digestion.—This varies with the quantity and concentration; with the state of the digestive functions; with the habits of the individual, and probably also with the flavor and extractives of the beverage. In general, moderate doses act as “condiment” or stimulant to digestion. In this the flavor and the hyperemia coöperate to increase the appetite, the flow of digestive juices, the movements of the stomach, and absorption. The action of ferments is also accelerated.

Small quantities of alcohol, taken with meals, therefore, tend to have a favorable action on digestion. If digestion is perfectly normal, these effects are quite superfluous; the utilization of food, and the total time of digestion, is scarcely influenced by these doses of alcohol. In pathological conditions, in depressive emotional states, and perhaps in overheating, the effects may be beneficial. The best results would usually be secured with wine. The alcohol should not be taken in strength greater than perhaps 20 per cent.: even this would be too strong did it remain for any length of time; but it is absorbed so rapidly that this strength would very soon reach the favorable limit.

Large quantities of alcohol, however—and especially when in concentrated form or in the empty stomach—produce an irritation which surpasses the physiologic limit and interferes with the functions. This is seen most markedly in the habitual use, when the inflammatory changes become chronic, and extend to the portal system.

Hunger Contractions.—These are inhibited by alcohol, as by many other chemic and mechanic stimuli (Carlson, 1913).

Excised Intestine of Rabbit.—The movements are mainly depressed by monovalent alcohols; very dilute solutions produce a primary stimulation (Kuno, 1914).

Action on Ferments.—Since alcohol is very readily absorbed, and no great amount of it reaches the intestine, it can only influence the ferments of the stomach, and its action on pepsin is alone of practical interest. It is found that *in vitro*—and there is no reason to suppose that it acts any differently *intra vitam*—1 to 2 per cent. of alcohol increases the rapidity of peptic digestion. Up to 15 per cent., it causes no perceptible retardation. With 15 to 18 per cent., the digestion is reduced by one-fourth to one-third. With 20 per cent., the digestion is strongly inhibited (Chittenden, Mendel, and Jackson, 1898).

Beers and wines have a slightly more unfavorable effect on account of the extractive matter contained in them.

Secretion of Saliva.—The presence of alcohol, strong or dilute, in the mouth increases reflexly the amount and the solids of the saliva, just as do many other substances (acetic acid, ether, etc.). This increased secretion does not take place if the alcohol is introduced directly into the stomach through a fistula or if it is given subcutaneously.

Secretion of Gastric Juice.—The quantity, the acidity, the absolute quantity of ferments, and the total solids (but not the mucus) are markedly increased (Chittenden, Mendel and Jackson, 1898; Chiari, 1915). The increase occurs also if the local action of the alcohol on the stomach is excluded, as in the "Pawlow stomach" (Zitowitsch, 1905); or if the alcohol is placed into the intestine (Chittenden) or rectum (Kast, 1906).

With oral administration, in man as well as in animals, the favorable effect obtains with concentrations up to 10 per cent.; with 10 to 20 per cent., the mucus is increased, as well as the juice. Above 20 per cent., the mucus is further increased, but the secretion is decreased.

Pancreatic Juice.—Gizelt, 1906, claims that the pancreatic secretion is stimulated when alcohol is administered by mouth, intestine, or subcutaneously; but only if the vagi are intact.

Bile.—Salant, 1906, found that alcohol by mouth (but not intravenously) increases the flow of bile by 50 to 350 per cent.; the solids are also increased. Increased bile secretion was confirmed for large doses by Okada, 1915.

Effects on Absorption.—Alcohol itself is rapidly absorbed (see below).

It also increases the absorption of other substances under certain conditions (Riem-schneider, Strychnine, 1900), but not under some other conditions (Ryan, Strychnine, 1912). Brequet, 1912, found only a slight effect on the gastric absorption of strychnine, salicylate or iodide. Tschekounow, 1914, observed no increase for saccharose, iodine or NaCl. Hanzlik found the absorption of phenol and iodide diminished by strong alcohol.

Alcohol intended as antidote may therefore even increase the toxicity of poisons, if both are taken by the stomach, and this is not evacuated.

Use of Alcohol in Indigestion.—Alcohol, in the form of wine or diluted spirits, taken with meals, is clinically of value in some forms, and harmful in others. It would be useful as a "counterirritant" in functional "colic" and gastralgia, and harmful in acute gastritis. The euphoristic and calmative actions tend to prevent and remove the unfavorable inhibitory effects of depressed and weakened, or harassed and irritable mental conditions; so that alcohol may be valuable in the course or convalescence from fevers or exhausting illness, phthisis, etc; and it may a useful adjunct in nervous dyspepsia. Sometimes, however, it is harmful by increasing the hyperchlorhydria.

Champagne is also used as an *antemeti-c*. Its action in this case depends perhaps more on the carbon dioxide and cold and on the psychical effect, than on direct actions of the alcohol.

The Absorption of Alcohol.—This occurs rapidly, mainly from the small intestine, and is practically independent of the quantity.

Chittenden, Mendel and Jackson, 1898, found that 50 c.c. of a 20 per cent. alcohol disappear from the stomach of a dog in less than half an hour; and with the duodenum ligated, 200 c.c. of a 37 per cent. alcohol are completely absorbed from the stomach in three to three and a half hours. Vollmering, 1912, found absorption practically completed in an hour. Voeltz and Dietrich, 1913, found the absorption materially faster in habituated animals, but in either case practically completed in two and one-half hours. Nemser, 1907, investigated the relative rôle of the successive portions of the ali-

mentary tract in the absorption of alcohol, under normal conditions. Administering 20 per cent. alcohol to dogs with fistulæ at different levels, he finds that the amount absorbed at each level depends mainly upon the time during which the fluid naturally sojourns at this level: Very little of the alcohol is therefore absorbed from the mouth; about a fifth from the stomach; very little from the duodenum; the greatest quantity from the jejunum, and the remaining fifth from the ileum.

Hanzlik and Collins, 1913, have studied the *absorption from intestinal loops* in living animals. It was rather better from the colon than from the stomach or small intestines; the length of the loop had little influence; 10 per cent. solutions were absorbed slightly better than stronger or weaker concentrations. The intestinal wall retains a certain amount of alcohol very firmly, thus apparently arresting its absorption. Voeltz, Baudrexel and Dietrich, 1912, found rather similar phenomena in the absorption of alcohol by the *urinary bladder*, which is fairly extensive (Nicloux and Nowicka, 1913).

Excretion of Alcohol.—Only a very small proportion of the ingested alcohol is excreted, by the kidneys and lungs, generally less than 2 per cent., and probably never more than 10 per cent. (Strassmann, 1891; Benedicenti, 1896). The remainder is completely oxidized in the tissues.

The proportion excreted depends upon the dose and other conditions. It is greater if the respiration is increased as by muscular work; or if the absorption is more rapid, as when the alcohol is taken on an empty stomach (Voeltz, Baudrexel and Dietrich, 1911, 1912).

The percentage of alcohol in the urine in man, is said to be about the same as that in the blood (Widmark, 1915).

Channel of Excretion.—This occurs mainly by the kidneys and lungs; a small amount is excreted and reabsorbed from the urinary bladder. The pulmonary excretion is fairly constant; that by the urine varies between one and one-half and 13 per cent., depending largely on the sojourn and reabsorption in the bladder (Nicloux and Nowicka, 1913). The milk may contain a small amount if large quantities are ingested, but not with ordinary doses (Klingemann; Koldewijn, 1910; Schottmueller and Schumm, 1912). The maximum amount would be too small to affect sucklings (Voeltz and Paechtner, 1913). It is also excreted into the *cerebro-spinal fluid* (also acetone and chloroform, Hald, 1911). This has been proposed as a test for alcoholic psychoses (Selig, 1913; Vorkastner and Neue, 1913, caution against hasty conclusions).

Lenoble and Daniel, 1917, find that after ordinary alcoholic intoxication, it appears promptly in the cerebro-spinal fluid, and persists there for an average of ten days. The excretion curve is similar to that of the urine. It is *not* excreted in the sweat or feces (slight traces by intestinal loops, Hanzlik and Collins, 1913).

The excretions do not contain an appreciable amount of acetone or other intermediate decomposition products (Masing, 1854).

Percentage of Alcohol in Blood.—This maximum concentration is about the same as the quantity of alcohol administered, divided by the body weight (Mellanby, 1919); *i.e.*, if a 60 Kg. subject were to take 30 c.c. of alcohol, the concentration in the blood would reach about 0.05 per cent. It would be somewhat lower if the alcohol is taken on a full stomach, so that the absorption is slowed. The concentration in which the alcohol is administered does not affect its concentration in the blood (Widmark, 1915).

Alcohol passes across the placenta to the fetus, so that the concentration in the fetal blood is about the same as in the maternal (Kostitch, 1922).

Relation of Symptoms to the Alcohol Concentration in the Blood.—According to the old work of Schulinus, 1866, the blood was said to contain 0.12 per cent. in the stage of slight confusion, and 0.72 per cent. in deep narcosis. This agrees quite well with the modern data:

Schweisheimer, 1913, found that symptoms may begin with 0.02 per cent., and are generally quite pronounced with 0.05 per cent. A liter of wine containing 10 per cent. of alcohol may raise the concentration in the blood to 0.1–0.15 per cent. Larger doses gave 0.12 to 0.23 per cent. With dogs, 0.446 per cent. produced only slight intoxication; 0.468 resulted in profound collapse (Mellanby, 1919).

Course of the Alcohol Concentration of the Blood.—Schweisheimer, 1913, finds that the concentration in the human blood corresponds with the degree of intoxication. With *those unaccustomed to alcohol*, the maximum concentration in the blood was reached 1½ hours after a liter of wine containing 10 per cent. of alcohol. The concentration then remained nearly level for 5 or 6 hours. The alcohol had practically disappeared in 12 hours.

With *habitual drunkards*, receiving the same dose the maximum concentration in the blood was reached more promptly, but did not rise as high, and was maintained for only two hours; and the final disappearance from the blood was also more rapid.

Existence of Alcohol in Normal Tissues.—A trifling quantity of alcohol appears to be produced in the tissues in the course of normal metabolism. Its presence was claimed by W. H. Ford, 1872, and confirmed qualitatively by Landsberg, 1904. Reach, 1907, finds that fresh rabbit's muscle contains to 0.0017 per cent. of alcohol; the liver may contain 0.02 to 0.14 per cent. Voeltz and Dietrich, 1915, recovered a total of about 0.1 c.c. from normal dogs. Dakin believed that this "normal" alcohol is not formed in the tissues, but by intestinal fermentation; but Taylor, 1913, finds it even after the removal of the entire digestive tract. Schweisheimer, 1913, claims that normal human blood contains about 0.03 per cent. of alcohol. In *drunkards*, the concentration may rise to $2\frac{1}{4}$ per mille; but after the ingestion of alcohol the excess disappears more rapidly from the blood of drunkards than from non-habituated individuals.

Distribution of Ingested Alcohol in Tissues.—Vollmering, 1912, found that soon after absorption the ratio was blood > liver > muscle > brain. Later, the brain contained the most. Fatty tissue was slow to take it up, but retained it longer. Voeltz and Dietrich, 1912, found 3 to 12 per cent. still present in the body fifteen hours after doses of 2 c.c. per kilogram; 2 to 4 per cent. had been excreted by the respiration, 0.4 to 4 per cent. by the urine, and 90 per cent. has been oxidized. Messner, 1913, could not demonstrate destruction of alcohol by emulsions of tissues or by blood *in vitro*.

The Fate of Alcohol in the Tissues; Effect on Metabolism.—Over 90 per cent. of the ingested alcohol disappears in the body, being completely oxidized to carbon dioxide and water (Atwater and Benedict, 1902); probably with acetic acid as an intermediate stage. By the chemical energy thus liberated (about 7 calories for 1 Gm. of alcohol, or 4 calories for 1 c.c. of whiskey) alcohol can perfectly replace carbohydrates and fats in the diet, and is a *typical non-nitrogenous food*. It is even superior to most other foods in one particular, viz., in that it does not require digestion. By its poisonous side actions, however, it may at first cause an increased nitrogen excretion in individuals not accustomed to its use; but this action disappears in a few days, and it then *saves nitrogen* like any other food.

When added to an ordinary diet, the CO₂ excretion, the oxygen consumption, and the output of heat are not materially changed (Higgins, 1917). The alcohol therefore saves the other constituents of the diet from decomposition, and the body shows a corresponding gain in weight. If it is added to a diet deficient in carbohydrates or fats, the metabolism is the same as if an isodynamic quantity of these foods were added. It spares carbohydrates in man even when large amounts of sugar are supplied (Toegel and coworkers, 1913). It can be used up in muscular work (Krieger, 1913). In dogs receiving 2 c.c. of alcohol per kilogram, this supplies about 40 per cent. of the energy (Voeltz and Dietrich, 1915). (The literature of this subject is summarized by Rosemann, 1901, Pflueger's Archiv, 86:307.)

By observing the respiratory quotient, Higgins, 1916, showed that in man, with doses of 30 c.c. of alcohol, appreciable quantities begin to be burned in five to eleven minutes after administration. Sucrose, lactose and levulose gave similar results: whereas glucose and maltose began to be oxidized only after twenty to thirty minutes.

Man can oxidize alcohol at the rate of about 10 c.c. per hour; dogs about 0.185 c.c. per kilogram per hour (Mellanby, 1919). The oxidation of the alcohol is completed rather slowly; with 2 c.c. per kilogram, it requires about eighteen hours (Voeltz and Dietrich, 1915).

In man, the combustion of 30 c.c. requires about 8 hours; of 45 c.c. 12 hours (Higgins, 1917). It is not materially faster in habituated individuals, as claimed by Pringsheim, 1908.

Likewise, liver emulsions from habituated animals do not destroy alcohol faster than those from non-habituated animals (J. Hirsch, 1916). The destruction is said to be hastened by fever. Increase of external temperature is said to lessen its oxidation and to promote its excretion (thus 90 per cent. oxidized at 16 C.; 92 per cent. at 26 ; Voeltz and Baudrexel, 1913).

Alcohol can also be utilized in the form of rectal injection. Thus, T. M. Carpenter, 1917, found the respiratory quotient (in man) generally lowered in 2 to 3 hours after the injection of 25 c.c. of alcohol diluted to 5 or 10 per cent.

Blood Catalase.—In dogs, this is usually increased by gastric administration of alcohol, presumable through increased output by the liver. Intravenous injections diminish the catalase content by direct destruction (Burge, 1917).

Effect on Nitrogen Metabolism.—Mendel and Hilditch, 1910, have investigated the effects of moderate quantities on man and dogs. Giving, in man, large quantities, corresponding to 96 c.c. of 95 per cent. alcohol (500 calories), divided into six doses per day, with constant diet, they found no pronounced disturbance in the alimentary utilization of food. These doses spared protein; the partition of the urinary nitrogen was unchanged, except that the *purine excretion*, both endogenous and exogenous, was increased. Larger doses caused a loss of nitrogen and a relative increase of urinary ammonia.

With smaller doses (40 c.c. of rum, three times daily) and in individuals accustomed to its use, Hammett, 1916, found no increase of uric acid.

Stehle, 1915, found no increase in the excretion of endogenous uric acid. Winterstein, 1914, claims that alcohol increases the gas-metabolism of the spinal cord of pigs.

Subacute Alcoholic Intoxication.—Salant and Hinkel, 1910, found that this caused, in well-fed dogs, a moderate diminution of the total urinary nitrogen and sulphur; a much greater decrease of the inorganic sulphates and phosphates; a tendency to retention of chlorides; a diminution of indican; and increase of neutral and ethereal sulphur.

Food-value of Alcohol.—Whilst there can be no doubt that alcohol is a food, in the sense of being a source of energy, other factors must be taken into consideration. The increased nutrition may itself be detrimental to the body, either by preventing the complete combustion of metabolites (which may possibly be connected with the origin of gout), or by leading to an abnormal deposition of fat. A still more potent objection to considering alcohol as a generally useful food lies in its toxic action, especially its psychical effects. Alcohol should therefore be employed as a food only when a sufficient supply of energy can not be obtained from an ordinary diet; as, for instance, in *digestive disturbances*, or when the demands on the organism are unusually large, as in *fever*.

The proverbial *obesity* of persons addicted to the overuse of weak alcoholic liquids (in which the nutrient effect is less obscured by the toxic actions), is a striking illustration that too liberal a nutrition is not necessarily beneficial. That alcohol lessens the oxidation of metabolites is shown by an *increased excretion of uric acid and ammonia* nitrogen at the expense of urea (Paton and Eason, 1901; Mendel and Hilditch, 1910). This points to a modification of the functions of the liver.

Excessive doses of alcohol are always detrimental to nutrition, lessening both assimilation and disassimilation. The effects resemble those of the anesthetics.

Alcohol in Diabetes Mellitus.—Alcohol would be expected to act favorably as an easily digestible food, supplying the place of the sugar, and diminishing the excessive draft on proteins, and thus lessening the risk of acidosis. This expectation has been partly verified; Benedict and Förök, 1906, found that the replacement of 50 to 80 Gm. of food-fat by isodynamic quantities of alcohol lessened the excretion of sugar, acetone, and nitrogen. O. Neubauer, 1906, also reports it as useful.

On the other hand, Higgins, Peabody and Fitz, 1916, found that alcohol (100 to 180 c.c. of whiskey per day) did not prevent acidosis in normal persons on carbohydrate-free diet. Mosenthal and Harrop, 1918, also found that alcohol was unable to replace isodynamic quantities of protein or even fat in conserving a nitrogen balance.

Excessive quantities, however, can not be expected to exert an favorable action, since the toxic effects will predominate. Salant, 1906, fed rabbits on alcohol alone, and found no increase of *hepatic glycogen*; nor did large doses retard the disappearance of stored glycogen.

Use of Alcohol in Convalescence and Debility as an "Analeptic," "Restorative" or "Stimulant."—The value of alcohol in these conditions is supported by long experience. Its action must be quite complicated. In the absence of organic lesions a great deal may be expected from improving the symptoms. This, like nursing and hygiene, increases the comfort and well-being of the patient, and starts him on the way to improvement. Alcohol helps to meet these indications in the feeling of

well-being caused by it, the sense of capability, the removal of worry, the enjoyment in the act of taking it, the rest and sleep induced by its narcotic action, its food-value and its beneficial effects upon digestion, all concur in its action. To this may be added its slight effects upon the vascular system—the altered distribution of blood, the diminished resistance to the heart—which may be of benefit in some cases. For these purposes, the alcohol should be taken well-diluted, as light wines or beers.

Use of Alcohol in Depressed Psychological States.—(Hypochondria, Melancholia, Neuralgia, and other obscure nervous diseases.)—This relieves the patient, by its mild narcotic and euphoristic action—but the temporary relief is generally obtained at the expense of a permanent alcohol habit, and is therefore not to be advised.

Use of Alcohol as a Hypnotic.—Alcohol, especially in the form of beer, taken at night and in the absence of excitement, is a fairly efficient hypnotic; but its usefulness is limited by the danger of chronic alcoholism. The hypnotic dosage corresponds to 45 to 60 Gm. of alcohol.

Contraindications to Alcohol.—These may be briefly resummarized as: Danger of habit; states of excitement; sthenic stage of fevers; irritation of the alimentary or genito-urinary tract.

Acute Alcohol Poisoning.—With excessive doses of alcohol the “stimulant stage” passes progressively into the narcotic, anesthetic, and paralytic stages.

The *narcotic stage* may be said to exist when the symptoms of lessened psychic activity assume prominence. *Sensation* and *motion* become impaired. *Speech* is thick and muttering, the *gait* uncertain, the *special senses* blunted. Drowsiness sets in. The face, which was flushed, may become pale. Vomiting occurs.

Consciousness and sensation and muscular tone are gradually lost. This constitutes the *anesthetic stage*.

In the *paralytic stage* proper, the *symptoms* are those of *beginning medullary paralysis*; the *respiration* is slow and stertorous; the pulse scarcely discernible, the *skin* cold and cyanotic; the *pupils* generally dilated; the *reflexes* abolished. The *temperature* falls severely. The *odor* of the breath is diagnostic.

If very large doses have been taken on an empty stomach, these paralytic symptoms may set in at once.

Death is relatively rare. It may occur within half an hour, or the coma may grow deeper and terminate in paralysis of the respiration or the heart, or in pulmonary edema; generally within twenty-four hours. If the coma lasts beyond thirteen hours, recovery is exceptional. Death may also occur later, either from prolonged coma; or after a protracted debauch, as the result of gastric irritation and exhaustion.

The *acute fatal dose* is probably variable. In analogy with animals, it would require about a pint of whisky; and cases of death from such quantities are recorded (Lewin).

Recovery.—The coma—if the intoxication has progressed so far—passes into natural sleep, often with sweating. On awakening there follows a series of symptoms pointing mainly to *acute gastric catarrh*, and perhaps to functional neuritis; and grouped by the Germans under the name of “Katzenjammer:” headache, coated tongue, loss of appetite, irritable stomach, diarrhea, muscular pains, etc.

The *skin*, after severe alcoholic poisoning, may show effects resembling those of contusions or burns; edema, blisters, extravasation of blood, and

gangrene. Bedsores are especially common. These effects are perhaps due to injury to the capillaries, or neurites.

The **treatment of acute alcoholism** consists in evacuation of the stomach preferably by apomorphine, which acts also as a hypnotic; and the administration of stimulants, caffeine or strychnine. The subsequent headache and nervousness are met by bromides and caffeine. Sodium bicarbonate lessens the gastritis.

The Antagonism of Alcohol and Caffeine.—This has been studied by Pilcher, 1912, on cats. The combination of small doses of alcohol and caffeine result in an antagonistic effect, but the combination of larger (half-fatal) doses results in greater depression and greater fatality than if either drug were used alone. The ordinary doses of caffeine would tend somewhat to decrease the narcosis and hasten to recovery from severe, but not fatal alcohol poisoning. With fatal doses of alcohol ordinary doses of caffeine would have no effect, and larger doses would be detrimental.

The Habitual but Moderate Use of Alcohol.—*It may be considered as probable that a certain amount of alcohol (variable in individual cases) may be taken daily without any demonstrable permanently injurious effect.* But it stands equally certain that it is as dispensable to the organism as nicotine or caffeine, and that it must be looked upon purely as a luxury. The injury done by such use of alcohol lies chiefly in the fact that it is so apt to lead to the use of immoderate amounts.

Duration of Life.—It has been claimed, on the basis of life-insurance statistics, that the average duration of life is distinctly less for those who habitually drink alcohol, even in moderate quantity, than for total abstainers. Raymond Pearl, 1924, considers this deduction as mistaken, and that there happens to be rather an increase. Heavy drinkers, of course, present a different problem.

Lessened Resistance.—Perhaps the only positive evidence of injury from small doses of alcohol is in this direction: Hunt, 1907, found that the long-continued administration of small quantities of alcohol to mice or guinea pigs increases their susceptibility to the fatal action of *acetonitrile*. This is attributed to a derangement of metabolism which hastens the decomposition of the non-toxic nitrile into the cyanide. It is not produced by methyl alcohol, chloral, etc. Laitiner, 1907, also claims that very small doses (0.1 c.c. per kilogram, daily) suffice to render the erythrocytes less resistant to hemolysis; and also lessen the resistance to infectious diseases. He asserts that this lessened vitality is transmitted to the offspring.

Mueller, 1904, Wirgin, 1905, and others have found that the *formation of antibodies is lessened*, if rabbits are kept mildly intoxicated for several days after the injection of an antigen.

For human subjects, Reich, 1915, also claims diminished resistance of erythrocytes to hypotonic solutions, and slight decrease of the bactericidal action of serum against typhoid bacilli. The effects, however, varied greatly, so that it is difficult to estimate their importance. Phagocytosis was not affected.

CHRONIC ALCOHOLISM

The excessive habitual use of alcohol leads to effects which may be grouped together under the name of chronic alcoholism, and which depend in part upon the irritant action of the alcohol, in part upon specific injury to the neurons.

Gastro-intestinal Irritation.—The first effects are local, and depend largely upon the concentration of the spirits. They consist of catarrh of the whole alimentary canal, progressing from the pharynx downward, and are characterized by the usual symptoms of catarrhal gastroenteritis: loss of appetite, gastric distress, irregularity of stools, craving for spices, etc. The chronic catarrh leads to malnutrition and emaciation when strong spirits are used. In the case of excessive beer-drinking the habitual overdistention of the stomach leads to chronic dilatation.

Degenerative Changes in Internal Organs.—The continued presence of alcohol in the body sets up a series of irritant and degenerative phenomena in various other organs with which it comes into contact. These changes consist in fatty infiltrations, cellular degenerations, and hypertrophy of connective tissue.

The necrotic changes in the tissue cells must be attributed to the continued irritation from the constant presence of the alcohol; and to this must be added the interference with circulation due to the changes which alcohol causes in the blood vessels. These two—the direct irritant action of alcohol on the cells, and the impaired circulation—are inseparably connected in the production of the degenerations. Of these, the fatty are the most common, since alcohol, by its combustion, prevents the normal consumption of fat. Repeated administration of alcohol to dogs, for several days, uniformly increased the *total fat of the liver*, sometimes to 300 per cent. The *cholesterol content* was also somewhat increased (Ducceschi, 1918).

Connective-tissue formation results as the ordinary consequence of necrosis of the parenchyma.

These changes are proportional to the concentration of the alcohol. Since this is naturally greatest in the liver, kidneys and blood vessels, these organs show the action first and most prominently. In the liver, again, the periphery of the lobules is mainly affected. Chronic alcoholism is probably the most common cause of *hepatic cirrhosis* (perhaps half the cases; but only 5 or 6 per cent. of the alcoholics develop cirrhosis; Baumgarten, 1908). McJunkin, 1917, however, points out that the evidence of the alcohol factor in the human is not quite clear; probably the action is indirect. He fails to obtain cirrhosis in animals by any method of administration. Other workers obtained discordant results (A. L. Grover, 1916; literature). The positive data are perhaps spontaneous (rabbits).

Next in point of time comes the action on the blood vessels. This is of especial import, since it contributes materially to the degenerations in other organs. The principal changes are in the intima; there are fatty degenerations, loss of elasticity and atheroma.¹ These may lead to ruptures (apoplexy, etc.).

The degenerative changes in the kidneys lead to nephritis, with cirrhosis, albuminuria, diminished secretion of urine, secondary weakening of the heart, etc. The heart itself, however, in common with skeletal muscle, shows primary fatty degeneration. This, together with the atheroma, etc., leads to hypertrophy and dilatation of the viscus, and later to dropsies, etc. The heart rate is generally rapid. The fatty changes in voluntary muscle lead to muscular debility, especially in beer-drinkers, in whom there is more material for fat formation. Gout is a common sequence of moderate alcoholism.

The respiratory organs show a chronic catarrhal inflammation of the passages, and a disposition to fatal pneumonia. *Changes in the skin*—vascular ecchymoses, acne rosacea, disposition to furuncles and carbuncles—may be counted among the earlier actions.

Experimental chronic alcoholism, in rabbits, produced fatty changes in the heart, liver and kidneys, and cellular infiltration of the pia (Lissauer, 1913). Hepatic changes occur also on intravenous injection (Schafir, 1913). In the heart, Otto, 1914, found degenerations of ganglion cells, atrophy of muscle, and scar tissue. Large single doses (4 c.c. per kilogram) may also cause changes. Single small doses do not leave any lesions (v. Otto, 1914).

These various anatomic lesions of important organs result in a pronounced lowering of the "powers of resistance," and a high mortality with infectious diseases, operations, etc. It appears that the amount of antitoxic complement is lessened.

Growth.—Daily consumption of alcohol by young rats, in doses of 2.5 to 10 c.c. per kg. for twenty weeks, produced prompt and very marked retardation of growth. The effect was about as marked with the lower dosage as with the higher, and with dilutions of 2½ per cent. as with 10 per cent. (Sollmann, 1920). The duration of life is also shortened, by the lower range of doses (Arlitt, 1919).

Nervous Phenomena.—These differ from the preceding in that they are partly functional.

Ten to 30 per cent. of the cases of insanity are attributed directly to alcoholism; but Heron, 1912, found the proportion of mental defects as high in the recent, as in old cases of alcoholism. Epilepsy, which is a

¹ As a result of an extensive study of autopsy material, Cabot, 1904, disagrees with the common opinion that alcohol is a cause of arteriosclerosis.

hereditary nervous disease, is 70 times as frequent in alcoholics as in the general population. These facts indicate that alcoholism is the effect, rather than the cause, of mental degeneration.

However, alcohol may cause various types of acute delirium and mania.

On the part of the motor system there are *tremors* and later convulsions and paralyzes, the latter partly the result of peripheral *neurites*.

It is difficult to exaggerate the importance of habit and repeated impressions on the psychic activities. The constant repetition of the features of alcoholic excess could not but produce in this manner a permanent moral degeneration. But associated with this functional feature are marked anatomic changes, due to the same causes as similar changes in other organs; and, lastly, it must be remembered that alcohol has a specific action on the nerve cells.

Among the anatomic lesions which have been observed are: Chronic meningitis with thickening; serous effusions into ventricles; softening; tendency to hemorrhages and apoplexy. Histologically, shrinkage and alterations in the staining properties of the cells and changes in the dendritic processes have been averred.

Clinically, the first effects are shown by diminished activity of the individual. This occurs even with very moderate doses. (Nice, 1912, found the activity of white mice, as recorded by a revolving cage, to be reduced by one-fourth through chronic alcoholism.) Later there is a diminished acumen of the special senses and of the reasoning powers, leading, the former to disturbances of vision, the latter to degeneracy and dementia, often suicidal. It is a noteworthy fact that by far the greater proportion of inmates of insane asylums and prisons were addicted to the excessive use of alcohol.

Children of Alcoholic Parents.—The influence of alcoholism of the parents on their offspring is still an unsolved problem, the data as well as opinions being so contradictory that no definite conclusions can be drawn.

Miss Eldeston and Karl Pearson, 1910, in a statistical study covering 3,600 school children, could find no real evidence of either physical or mental deterioration (death rate, mean weight and height, general health, mental and visual defects). They conclude that the danger of alcoholic parents lies in the transmission of the hereditary defects which caused the parental alcoholism. At the other extreme, von Bunge, 1904, claims that chronic *alcoholism on the part of the father* renders the daughter incapable of efficient lactation, and that this incapacity, as well as a tendency to tuberculosis and to caries of the teeth is transmitted to subsequent generations. But if this danger were really as great as it is painted, it is difficult to account for the comparative vigor of populations among whom chronic alcoholism has been fairly common for many centuries, or for the fact that some mothers still nurse their children.

Bertholet, 1909, finds that the testicles of chronic alcoholics generally show atrophy of the parenchyma, and increase of interstitial tissue, with corresponding decrease and abnormalities of the *spermatozoa*. This would lead to more or less impotence. Ivanow, 1913, reports that the addition of 2 per cent. alcohol *in vitro* has practically no effect on the motility of spermatozoa; 12 per cent. has little effect; with 15 per cent. there is marked impairment. Contact for thirty minutes with 10 per cent. alcohol does not hinder their fertilizing action, and the feti are normal.

Arlitt and Wells, 1917, claim that in white rats the spermatic tissue reacts before any other to the daily administration of alcohol. Arlitt, 1919, also reports that chronic alcoholism induced in rats results in partial or complete sterility in both sexes; in a high mortality of the offspring; and that these defects are transmitted for several generations.

Exposure of the ova or spermatozoa of the fish fundulus to alcohol before fertilization produces impaired and abnormal development (Gee, 1917). Of course, the concentrations and other conditions of such experiments are so peculiar that they have little meaning for the human problem.

Pearl, 1916, found the progeny of fowl treated with ethyl or methyl alcohol or ether rather stronger than the controls, although fewer eggs were hatched.

Stockard, 1912, finds that chronic alcoholism, induced in guinea pigs, either parent, diminishes fertility and causes most of the embryos to die before or shortly after birth. The offspring is often defective, sometimes with gross deformities. This degeneration is transmitted for at least three generations; in fact, it rather increases (1914). Stockard

also found (1909) that alcohol and other anesthetics cause various morphologic defects in fish embryos, but this of course is a very different matter. Whitney, 1912, found that cultivation of rotifers in $\frac{1}{4}$ to $\frac{1}{2}$ per cent. alcohol lessens their resistance to copper, the injury increasing with successive cultivations; but if the alcohol was withdrawn, the normal resistance was recovered in the second generation. With these animals therefore the alcohol has no direct influence on the germ-plasm. With female pigeons, the daily inhalation for one to two hours of nearly paralytic doses of alcohol, for two to four months, reduced the size of the egg-yolk quite materially (Riddle and Bassett, 1916). McDowell, 1919, observed lowered efficiency in the solving of maze and similar problems by the non-alcoholic offspring of heavily alcoholized rats.

While it is not proven that ordinary alcoholism has a direct influence on the germ-plasm, it is certain that the embryo is exposed to the influence of the alcohol, since this passes readily through the placenta, and exists in the same concentration in the fetal blood as in that of the mother (Nicloux, 1905). This may be supposed to cause a more or less persistent lowering of the resistance, and account for the high mortality among the children of alcoholics; the usually poor hygienic surroundings would contribute to this result. Moreover, the children will inherit the degeneracy which induces alcoholism in the parents. The statistics of prisons and asylums indicate a tendency to psychic and moral degeneracy amongst the descendants—epilepsy, idiocy, insanity, disposition to crime and to alcoholism; but it is not decided whether the defective inheritance concerns a degeneration induced in the parent by alcohol, or the degeneration underlying the abuse of alcohol. The latter is more probable.

Other Intoxicants.—Alcohol is not the only member of the hydrocarbon series which has been abused as an intoxicant. Ether, chloroform, chloral, paraldehyde and even turpentine and gasolin have their devotees. Their effects, in so far as they have been studied, correspond closely to those of alcohol.

Treatment of Chronic Alcoholism.—This follows the same principles as with other drug habits. The first essential is the complete withdrawal of the drug. This may be facilitated by scopolamine (see under "Morphine Habit"). A distaste may be created by the addition of some nauseant (apomorphine), but the effect of this deception is usually not lasting. Suggestion may be very useful. The local action of the alcohol may be replaced by capsicum or ginger, the stimulation by beef-tea; the depression may be met by caffeine, the insomnia by bromide. The prospects of cure are better than with morphine or cocaine; but the patients will often relapse.

Delirium Tremens.—This peculiar manifestation occurs in drunkards when their forces are unusually weakened—by extraordinary excess, or by the suppression of their usual allowance of alcohol; by absence of food; exposure; overexertion; trauma; hemorrhage; operations; psychic shock; or in any serious illness, especially in pneumonia. Premonitory symptoms of restlessness, tremor, insomnia, and anorexia last usually a couple of days. They pass into excessive tremor, persistent insomnia, violent and talkative delirium and terrifying specific hallucinations of sight (often small animals), touch, and sometimes hearing. It usually runs its course in a few days, ending in prolonged sleep. Acute amblyopia has been reported (Kaiser, 1912). The treatment aims to support the strength of the patient by allaying the gastritis and giving light but nourishing food. The insomnia, restlessness and excitement should be treated on their first appearance, by moderate doses of sedatives and hypnotics; such as bromide (1 Gm. every one to four hours); chloral at night (not over 1 Gm.,

since large doses have caused death); barbital (1 Gm.); paraldehyde (3 Gm.); morphine; or scopolamine (0.5 mg.).

Petechial hemorrhages in the gastric mucosa are very common lesions in necropsies of delirium tremens patients. They exist without any evidence of acute inflammation, and must be due to a direct toxic action on the vessels (E. F. Hirsch, 1916).

The pulmonary capillaries may contain fat emboli, as in other convulsive conditions (MacCallum).

PECULIARITIES OF ALCOHOLIC BEVERAGES

Common experience teaches that the effects of the various alcoholic beverages differ in minor details. These differences are due to the concentration of the alcohol, extractive matter, and to the presence of esters and higher alcohols. However, the scientific data are scanty and unsatisfactory.

Beer owes its *hypnotic qualities* somewhat to the lupulin of the hops as well as to the alcohol. The *diuretic action* of *gin* is largely due to the essential oils contained in it. *Absinthe* produces hallucinations and finally epilepsy. The Mexican drink, "*pulque*," produced by the fermentation of the juice of the maguey plant, produces an alcoholic intoxication in which the thought and language are low, the patient is boisterous and quarrelsome, and, it is said, generally unhappy.

The **stronger spirits** contain, besides alcohol, substances which may pharmacologically be divided into two groups: the "oethanolic ethers" that give the bouquet (flavor), which add to the stimulation and have no other marked action; and those that have a deleterious effect. The latter—which are commonly called impurities—are largely destroyed by age. The most abundant is amyl alcohol (fusel oil).

The action of these "impurities" as far as studied is, upon the whole, similar to that of alcohol itself, but more toxic. However, the whole subject is in dispute. (The literature is abstracted by R. Foerster, 1910.)

Carelessly fermented and distilled un-aged spirits, the so-called "*moonshine*" liquors, are generally believed to be more toxic than properly prepared whisky. MacNider, 1924, found that they cause extensive albuminuria, which is not produced by pure alcohol in corresponding doses. This may be due to the irritant acetaldehyde, which is the most definite impurity of "moonshine" liquors. They may contain as much as 0.1 per cent., twenty-five times as much as legitimate whisky (Doran & Beyer, 1923). It is not known whether the aldehyde influences the toxicity, otherwise than through its irritation.

Friedenwald, 1911, found that, with intravenous injections into rabbits, the toxicity of alcoholic liquors, wines and beers was higher than would correspond to their alcohol content. The small value of these results is illustrated by the fact that they would place the toxicity of pure 10 per cent. alcohol considerably above that of 36 per cent.

Furfural, which was formerly believed to modify the intoxication, does not appear to do so. Larger doses are convulsant (Laborde, 1888; McGuigan, 1923). It is used as a paint and varnish remover (Gardner, 1923).

Artificial liquors are made by the admixture of ethers and essential oils to alcohol. Their action is not uniform, but it is generally believed to be more irritating locally, and more injurious to the brain.

PREPARATIONS

* *Alcohol*, U.S.P.; *Spiritus Rectificatus* (Sp. Rectif.), B. P. (Ethanol).—Not less than 92.3 per cent. by weight, 94.9 per cent. by volume, U.S.P.; 90 per cent. by volume, B.P., of C_2H_5OH . Colorless, volatile liquid, of characteristic odor and burning taste. Freely miscible with water, ether, chloroform, etc.

Dilution.—Since a condensation occurs on mixing alcohol and water, the percentage of the resulting product can not be deduced by a simple ratio.

Tables for making the commonly needed percentages by the dilution from the official alcohols are given in the U.S.P. and B.P.

Alcohol Dehydratum (Alcohol Dehyd.), U.S.P.; *Alcohol Absolutum* (Alcohol Absol. B.P. (Dehydrated or Absolute Alcohol or Ethanol).—Not less than 99 per cent. by weight of C_2H_5OH . Very hygroscopic.

Alcohol Dilutum (Alcohol Dil.), U.S.P.—A mixture of equal volumes of official alcohol and water, containing 41 to 42 per cent. by weight or from 48.5 to 49.5 per cent. by volume of C_2H_5OH .

Denatured Alcohol.—Alcohol for industrial use is mixed with various nauseant, irritant and toxic substances, to render it unfit for drinking and so secure exemption from the internal revenue tax. The Journal of the American Medical Association, 1920 (74:343) describes the usual formulas.

The use of wood alcohol for denaturing industrial alcohol is to be deprecated, since prolonged exposure to vapors from alcohol containing only 4 per cent. of methyl alcohol has given toxic eye symptoms (J. M. Robinson, 1918). The drinking of spirits containing only one per cent. of wood alcohol is said to result in visual disorders, generally after three or four months, or with large doses (Eleonskaia, 1916).

Spiritus Frumenti (Sp. Frum.), U.S.P.; Whisky.—An alcoholic liquid obtained by the distillation of the fermented mash of malted cereal grains, and containing between 47 and 53 volume-per cent. of alcohol. It must be aged in wood at least four years.

Spiritus Vini Vitis (Sp. Vin. Vit.), U.S.P.; Brandy (Spir. Vini Gallici, Cognac).—Distilled from grape-wine containing 48 to 54 volume-per cent. of alcohol, aged in wood for at least four years.

Other distilled spirits have about the same alcohol concentration: *Holland Gin*, distilled over juniper berries; Common Gin, often containing turpentine; *Rum* from molasses; *Arrack* from rice, etc.

Wines.—These are made by fermenting the expressed juice (must) of the grape. If this contains the skins of dark grapes, the wine will be red; if made from light grapes, or from the juice of dark grapes without skins, it is "white," *i.e.*, an amber color.

A wine which contains much alcohol (15 to 20 per cent.) is "generous"; one poor in alcohol, "light"; one containing much sugar, "sweet"; poor in sugar, "dry." If it contains CO_2 it is sparkling"; if tannin, "rough" or "astringent"; if acid tartrates, "acidulous". The last two ingredients may interfere with indigestion if the wine is habitually used.

The most important wines are:

	Alcohol	
	Per Cent. Weight	Per Cent. Volume
<i>Sherry</i> (Vinum Xericum): Dark amber, dry, little acidity (<i>Madeira</i> , Marsala, Tokay, Malaga, are similar but more sweet).....	15 to 19	18 to 23
<i>Port</i> (Vinum Portense): Deep purple, rather sweet and rough		
<i>Claret</i> (Bordeaux): Red, dry, with some degree of acidity and astringency.....	8 to 14	10 to 17
<i>Champagne</i> : Pale amber, sweet, sparkling.....	8 to 10	10 to 13
<i>Hock and Moselle</i> : Pale amber, dry, slightly acid.....	12	15
<i>Catawba</i> : Amber, dry, rather acid (or sweet).....	10 to 12	13 to 15

Unfermented Grape Juice (*i.e.*, must, preserved by heat or an antiseptic) can scarcely be considered a medicinal agent.

Other Fermented Liquors:

From Apple: *Cider*,
From Pear: *Perry*,
From other fruits, } 5 to 10 per cent. of alcohol (by weight).

Malt Liquors.—These contain alcohol, CO_2 , sugar, and usually hops. The color varies from pale amber to dark brown, the difference being due mainly to charring of the malt. Lager beer is made by slow fermentation at a low temperature; porter, ale, and stout by rapid fermentation at a higher heat.

Their alcoholic strength is as follows:

Ale, Porter, Stout, and Export Beer..... 3 to 6 per cent.
Lager Beer 2 to 3 per cent. } by weight.

By fermenting milk, a pleasant alcoholic liquid, "*Kumiss*," can be obtained, which contains to 3 per cent. of alcohol.

HIGHER ALCOHOLS

In acute intoxication, the toxicity of the alcohols increases with the size of the molecule as shown in the following table:

	Boiling-point	Relative toxicity (Baer)	Acute lethal dose, cats (Macht, 1920)	Toxicity for isolated rabbit heart (Kuno, 1913)
Methyl, CH_3OH	65.0	1.0	1.0	1.0
Ethyl, $\text{C}_2\text{H}_5\text{OH}$	78.5	1.25	1.2	1.3
Propyl, $\text{C}_3\text{H}_7\text{OH}$	98.0	2.5	2.95	4.4
Butyl, $\text{C}_4\text{H}_9\text{OH}$	107.0	3.8	19.7	10.0
Amyl, $\text{C}_5\text{H}_{11}\text{OH}$	131.0	5.0	39	39.0

This (*Richardson's law*, 1869) applies also to the individual tissues: sensory and motor nerves, ciliated epithelium, muscle, ova, heart (Kuno, 1913). The toxicity of the alcohols for rabbits has also been studied by Munch and Schwartze, 1922; for paramcium by Bills, 1923.

It is quite conceivable that the late actions may differ more markedly from those of ethyl alcohol; as they do *f.i.*, in the case of ethyl alcohol.

ISO-AMYL ALCOHOL

The main constituent of "fusel-oil"; is more violent than ethyl alcohol in its acute and subacute actions (Salant, 1909) and the after-effects are more pronounced; but its admixture up to 1 per cent. produces very little difference in acute alcoholic intoxication (Baer, 1898).

PROPYL ALCOHOL

The actions have been studied especially by Macht, 1921, and Grant, 1923.

METHYL ALCOHOL

General Statement.—The extensive use of this substance (*Wood Alcohol*, Columbian Spirits) in the arts (as a combustible, solvent for shellac, etc.) and as an adulterant of alcoholic beverages and medicines has given rise to numerous cases of poisoning. The acute symptoms resemble ordinary alcoholic intoxication. The main differences are in the stronger local irritation and in the more protracted and more serious after-effects, the coma lasting several days and often terminating in death. A very important feature is the frequent occurrence of incurable blindness from retrobulbar neuritis and retinitis. This may occur after taking 10 c.c., but the individual susceptibility varies greatly. The effects are produced by the purest samples, and are therefore due chiefly to the methyl alcohol itself, although they may be exaggerated by the impurities (acetone, etc.) which are usually present. Methyl alcohol should never be applied to the body, externally or internally. Its presence in foods and drugs is properly prohibited by law. Protection against the inhalation of its vapors should be enforced in the trades. The **treatment** of poisoning by methyl alcohol includes evacuation, stimulants, heat, alkalies (Worth Hale, 1924), and morphine to allay suffering.

Etiology.—The practical seriousness of methyl alcohol poisoning is illustrated by the fact that Buller and Wood found 153 cases of blindness and 122 deaths recorded up to 1904, although the existence of the danger had only been recently recognized. A wholesale poisoning occurred among the inmates of a Berlin municipal lodging house (Stadelmann and Magnus Levy, 1912; Review of series of papers, Year Book, Am. Pharm. Assoc., 1912, 1: 364-367; Baskerville, 1913, has abstracted the cases in the literature). About 81 million gallons are produced annually, and 2 million people are engaged in trades where it is employed (Wilbert, 1915). Adulterated cologne and bay rum, etc., have often proved toxic when used externally. The vapor of methyl alcohol (varnish) is dangerous if ventilation is insufficient (recent Bibliography, J.A.M.A., 1913, 60: 1237).

The inhalation is also highly toxic to animals, the effects agreeing with those in man (Tyson and Shoenberg, 1914). Considerable absorption occurs when the air contains 0.2 per cent. (A. Loewy and Heide, 1914).

General Symptoms.—These begin with *gastro-intestinal disturbance*, abdominal pain, general weakness, nausea, vomiting, vertigo, headache. The symptoms of ordinary *alcoholic intoxication* supervene, with delirium, restlessness, unconsciousness, collapse and coma. The pupils are usually dilated and irresponsive; nystagmus may be present. *Dyspnea* and cyanosis are marked. The temperature is subnormal. *Death* is very much more frequent than with ethyl alcohol. It occurs in coma, from respiratory paralysis, in a few hours to three days. The *fatal dose* is probably from 100 to 250 c.c. The *postmortem lesions* show irritation of the stomach, duodenum, kidneys, and bladder. Continued use leads to fatty degeneration of the liver.

Late Symptoms.—Sometimes the symptoms are deferred for several days and then prove rapidly fatal. Delirium may set in after the acute symptoms have subsided. *Cystitis* is a frequent sequel. The most important sequel, however, is the:

Optic Injury.—The symptoms are bilateral and consist in scotoma, dimness or total blindness; the pupils are dilated and insensitive to light. The loss of vision may start in a few hours, or be delayed several days; it generally becomes complete; subsequently there is some improvement, which in most cases, however, finally relapses into total blindness (Buller and Wood, 1904; other reports summarized by Woods, 1913). The anatomic changes consist chiefly in hyperemia and edema of the fundus and destructive inflammation of the optic nerve or retinal elements or both, followed by their atrophy (Tyson and Schoenberg, 1914). The effective dose varies greatly: 10 c.c. has caused blindness in some cases while 90 c.c. has failed to do so in others. Permanent impairment of vision occurs in something like half of all cases of poisoning (for other toxic amblyopias, see "Nicotine"). The pathologic changes in rabbits are described by Kasava, 1913.

The cause of the peculiarities of methyl alcohol poisoning has not been satisfactorily explained. In *animals*, the acute toxicity of methyl alcohol is about 10 per cent. less than that of ethyl alcohol (also for rotifers, Whitney, 1912), but the subacute toxicity is markedly greater. The symptoms develop more slowly, even on intravenous administration and are much more protracted: While the ethyl alcohol coma lasts only six to twenty-four hours, that of methyl alcohol lasts three to four days. This protracted action leads to cumulative effects: Pohl, 1893; Reid Hunt, 1902; Langaard, 1913; and Sollmann, 1921, found that the daily repetition of sublethal doses is more fatal with methyl than with ethyl alcohol. Birch Hirschfeld demonstrated a similar cumulative action on monkeys. "Tippling" has also been found especially dangerous in man.

Excretion and Fate.—The protracted and cumulative action is connected with the slow excretion. Voeltz and Dietrich, 1912, found after 2 c.c. per kilogram that during two days about 21 per cent. were excreted unchanged by the lungs, 3 per cent. by the urine, 39 per cent. had been burned, and 37 per cent. were still in the tissues. Asser, 1914, administered 25 c.c. to a dog, by mouth, and recovered 56 per cent. from the expired air, and 4 per cent. as formate from the urine. Nicloux and Placet, 1912, found it present in the blood and brain after five days. The brain, however, is not an important storage organ; the alcohol being more soluble in water than in fats (Pohl, 1919).

The concentration in the blood is about the same as in the urine (Chabanier and Ibarra-Loring, 1916).

The slow destruction would explain the cumulation; but there may be an additional factor: While ethyl alcohol is oxidized completely to CO_2 and H_2O , methyl alcohol is oxidized mainly to formic acid (Pohl, 1893; Authenried, 1919). This is excreted rapidly by the urine, but gives rise to acidosis (increased ammonia excretion, Krol, 1913), and this may be responsible for part of the symptoms.

v. Fellenberg, 1915, claims that methyl alcohol is readily formed from the pectin of fruit and vegetables, pectin yielding from 9 to 12 per cent. of methyl alcohol. He asserts that this is not harmful, being practically completely burned in the body; whereas if the methyl is mixed with ethyl alcohol, as in liquors, the combustion is incomplete, and harm results from relatively small doses. Confirmation should be awaited.

Impurities.—The best commercial wood spirit contains about 95 per cent. of methyl alcohol; the common varieties 75 to 90 per cent.; some samples only 35 to 40 per cent. The impurities consist of acetone, methyl acetate, allyl alcohol, aldehyde, empyreumatic products, etc. (Baskerville, 1913). It has been suggested that these are responsible for the peculiar toxicity (Mueller, 1910; Kobert, 1910). However, most investigators have found no essential difference between the ordinary and the purest obtainable articles (Hunt, 1902; Buller and Wood, 1904; Ahrends, 1910; Sollmann, 1921): nor do any of the impurities produce the characteristic effects (Baskerville, 1913).

ACETONE (DIMETHYL-KETONE)

Acetone, U.S.P., $\text{CH}_3\text{CO.CH}_3$, is used as a solvent for fats, resins, rubber, etc.; and for the preparation of oleoresins. It is a rather feeble narcotic, causing considerable dyspnea (Albertoni, 1884). Hypodermically (guinea pigs) it is much more toxic than methyl alcohol (Rhamey, 1912). It is excreted mainly by the lungs. The urinary excretion in fasting dogs is diminished by caffeine and cocaine (Cervello and Gergenti, 1914).

ALLYL ALCOHOL

This occurs in commercial methyl alcohol to the extent of about 0.2 to 0.5 per cent. It produces gastro-intestinal irritation, convulsions and coma, but is apparently much less toxic than methyl alcohol (Atkinson, 1924).

ETHER AND CHLOROFORM GROUP

Ether, chloroform and other volatile hydrocarbons are employed mainly for producing surgical anesthesia. They depress successively the psychic centers, then probably the basal ganglia and cerebellum; then the spinal reflexes, first the sensory, and then the motor functions of the cord, probably from below upward; and finally the medullary centers. The most highly evolved functions are affected first. Chloroform also has a direct depressant effect on the cardiac muscle and is generally more dangerous. Locally, they act as irritants.

Discovery of Surgical Anesthesia.—The use of narcotics for dulling the pain of operations dates back to antiquity; however, the discovery of the means to achieve complete and safe anesthesia is an accomplishment of the nineteenth century (1842 to 1847). The credit for this discovery must be divided between several investigators: Humphrey Davy for the definite suggestion; C. W. Long for the independent discovery but inadequate publication of ether anesthesia; Horace Wells for the successful use and publication of nitrous oxide; Jackson and Morton for the successful public demonstration of etherization; Flourens and Simpson for the introduction of chloroform.

The Egyptians probably employed narcotics. The Assyrians are said to have strangled the children before circumcision, producing anesthesia by the aid of CO_2 . This method was revived by Valverdi in Italy early in the seventeenth century. The Chinese used hashish. All kinds of narcotics were given during the middle ages, especially opium and drugs containing hyoscine (such as the legendary "mandrake," *Mandragora officinalis*). The recent "scopolamine-morphine-anesthesia" is an interesting reversion to this ancient method, which became obsolete when the vastly superior inhalation anesthesia was discovered.

Sir Humphrey Davy in 1799 announced the anesthetic properties of nitrous oxide (laughing gas) and suggested: "As nitrous oxide in its extensive operation, appears capable of destroying physical pain, it may probably be used with advantage during surgical operations in which no great effusion of blood takes place." The suggestion was not acted upon at the time.

Dr. Crawford W. Long, of Jefferson, Ga., administered ether as a surgical anesthetic in 1842, but neglected the adequate publication of his discovery.

Dr. Horace Wells, a dentist of Hartford, Conn, witnessed an exhibition of "laughing gas" in a public lecture by Colton in December, 1844. He noticed that one of the subjects was insensible to pain; acting on this hint, he had a tooth extracted under its influence on the next day. The operation was a complete success. He introduced the gas into general dental practice in Hartford, and gave the matter wide publicity, without reservation. The intoxicant action of ether being well known, he tried this with Dr. Marcy of New York, early in 1845, but thought it inferior to the gas.

There can be no question that Wells discovered anesthesia independently, and that he introduced it successfully into practice; and he seems to have been the first to realize fully the importance of the discovery. Unfortunately, an attempted public

demonstration in Boston in January, 1845, failed partly and was met with ridicule. The successful demonstration of ether by Morton threw nitrous oxide completely in the shade for many years. Wells was greatly disappointed, became insane and committed suicide (Truman Smith, 1858, "An Examination of the Question of Anesthesia"). The use of the gas was revived about 1863 by Colton (whose demonstration had started Wells), and by 1868 it was extensively used in dentistry. It has since been reintroduced into major surgery, and has thus vindicated the claims of Wells.

Chas. T. Jackson, a chemist of Boston, etherized himself into unconsciousness, in the winter of 1841 to 1842; and thereby conceived the idea of ether-anesthesia. He did not apply it further, but discussed it with various persons, among others with Morton.

Wm. T. G. Morton, a dentist of Boston, was a former friend of Wells and Jackson, and probably received inspiration from both. It is said that after hearing about Wells' discovery, Morton consulted Jackson about the manufacture of nitrous oxide, and Jackson suggested ether as more convenient. Morton seems to have started successful experiments with ether-anesthesia in September, 1846. In October, 1846, he gave a perfect demonstration at an operation by Dr. J. C. Warren, at Massachusetts General Hospital. The complete success of this operation achieved the introduction of anesthesia into surgery. Morton obtained a patent in November, 1846. This step, and the methods which he was said to have employed to obtain it, raised much opposition. His life was embittered by the controversies, and he died of apoplexy. Jackson, the third party to the unfortunate contention for priority, also became insane.

The use of anesthetics spread rapidly, and related substances were tried: *Chloroform* was used on animals by Flourens in 1847, and in the same year, on the independent suggestion of McWaldie by Simpson of Edinburgh, on man. Flourens in the same year also called attention to ethyl chloride. It was used surgically by Heyfelder in the next year, but then neglected till 1895.

The first fundamental scientific work on the action of anesthetics was published by Snow, 1858.

Ether was discovered by Valerius Cordus, 1540; chloroform independently by Liebig, Soubeiran and Guthrie, 1831.

Stages of Anesthesia.—The main actions of alcohol, ether, chloroform, chloral, and the numerous other hydrocarbon or lipolytic narcotics are qualitatively similar; but they show practically important differences in severity, rapidity, duration and sequels. The successive effects may be divided into "stages." Hewitt, *f.i.*, classifies these as (1) analgesia; (2) light anesthesia; (3) deep anesthesia; (4) bulbar paralysis. Since the effects pass without abrupt transition from one stage to the other, any classification is arbitrary. In the following, they will be divided merely into the pre-anesthetic, anesthetic and paralytic stages. In surgical practice, the normal course of anesthesia is generally "complicated" by asphyxial phenomena, traumatic reflexes, hemorrhage, etc.

Pre-anesthetic Stage.—This sets in with a comfortable *feeling of warmth*, spreading over the whole body; but soon associated with a distressing *sensation of suffocation*, especially if ether is used and the access of air is limited, as in the "closed" methods. The *local effects* make themselves felt by prickling and smarting of the nose, throat and conjunctiva, with hypersecretion of mucus, tears and saliva. The suffocation, as well as the direct effects of the anesthetics, result in more or less *excitement and struggling*, and sometimes convulsions, especially in hysterical patients. The *reflexes* are at first rather exaggerated, later somewhat depressed and less purposive. Tonic muscular *spasm*, general, or of the jaws, glottis or respiration may occur. The *sensation* becomes disturbed: the sensibility is impaired after the first few inhalations. Stimulation evokes responses, but without pain. This "*primary analgesia*," while the patient is still conscious, may be used for short operations, especially under chloroform and nitrous oxide.

The thoughts become *confused*, with hallucinations (noises, etc.), sensation of stiffness, and want of muscular control. The patient may lose

self-control and indulge in loud incoherent talking, laughing, singing, etc.; passing gradually into unintelligent muttering. These initial excitement symptoms vary greatly in duration and intensity in different patients. Alcoholics may exhibit violent delirium and even mania. *Vomiting* (probably central), retching, and coughing may occur. The *face* is flushed; the *pupils* at first dilated, then gradually constricted; the *pulse* rapid; the blood pressure increased; the *respiration* somewhat quickened and at times irregular, sometimes suspended if the vapor is too strong.

The Anesthetic Stage.—This is the stage which it is aimed to produce and maintain. It is characterized by complete paralysis of the brain and of the motor reflex centers of the cord, and usually some depression of the medullary centers. *Consciousness, sensation, and most reflexes are lost*—the *corneal reflex* being among the last. Consequently the *muscles are lax*. The smooth muscles are not usually affected, but there is sometimes a relaxation of the sphincters. The pulse is full and soft, the rate rather slow with chloroform, slightly faster than normal with ether; the *blood pressure* being lowered by chloroform, normal or rather raised by ether. The *respiration* is regular and deep, often softly snoring or stertorous; rather rapid with ether. The *temperature* falls in consequence of the diminished muscular activity and increased heat loss. The *pupils* are somewhat small and respond sluggishly to light. The *face* is pale with chloroform, often cyanotic with ether.

The medullary depression does not reach a dangerous degree if the administration is carefully done. But with *prolonged anesthesia* the pulse tends to become progressively weaker, the respiration more shallow, and the temperature lower—it may fall as much as 5°C. This is due to paralysis of the function of temperature-regulation.

The *paralytic stage* is characterized by progressive paralysis of the medulla. This stage must be carefully guarded against.

All *reflexes* disappear. The *respiration* becomes shallow, irregular, labored, and then ceases. The *skin* is cold and pale, and covered with the clammy sweat of the “agony.” The *pupils* are widely dilated. The *pulse* becomes slow and weak, and ceases normally after the respiration.

Recovery of Patient from Normal Anesthesia.—The rapidity of the recovery is inverse to the duration of the administration. The first change after the withdrawal is usually in the respiration, which becomes quieter and less stertorous. Then the lid reflex and deglutition movements reappear. The pupils generally grow smaller, but dilate easily. The breathing is disturbed by swallowing, coughing, retching and actual vomiting, usually just before consciousness returns. This is commonly succeeded by sleep, lasting several hours. Thirst and gastritis persist for some time.

Behavior of Rats after Awakening from Anesthesia.—The intelligence, tested by the maze, was not impaired after nitrous oxide or ether. Chloroform depressed it more profoundly, for a whole day after an administration of only 1 to 2 minutes; and sometimes permanently after prolonged administration (Macht and Mora, 1919.)

Individual Functions.—The proper administration of anesthetics requires a detailed knowledge of their effects on the important individual functions in the successive stages.

Respiration.—This is influenced, not only by the direct action of the anesthetic, but also by the patency of the respiratory channels; by local and distant reflexes; the state of the circulation, etc. In the early stages,

if local irritation is avoided, the respiration is generally somewhat deeper and quicker from stimulation of the respiratory center. Most commonly it is apt to be irregular, especially if the administration is started abruptly, on account of the struggling, choking sensation and local irritation. The latter may produce temporary expiratory stoppage by a trigeminal reflex (Kretschmer, 1870); but in man, this reflex is not usually so strong or lasting. The "choking" is especially pronounced with ether. Reflex closure of the larynx may produce asphyxia under chloroform (Bernard). With chloroform spasmodic arrest of respiration may also sometimes occur, especially in vigorous subjects, and is probably a common cause of the early deaths. This is less likely to occur if dilute vapors are employed.

As the patient passes into anesthesia, the breathing becomes regular and noisy; with ether, the depth and rate may at first be increased; with chloroform they are decreased, partly by the low blood pressure. The respiration is mainly diaphragmatic. The snoring and the louder "stertor" are generally produced by the vibration of the tongue against the pharyngeal wall. "Stridor" is laryngeal, due to paralysis or spasm of the vocal cords or obstruction of the glottis by mucus. As anesthesia deepens, increase of concentration usually makes the respiration temporarily deeper, quicker and more stertorous, and *vice versa*. Cheyne-Stokes respiration is not uncommon with chloroform, but exceptional with ether, because the CO_2 tension is high.

Reflex respiratory changes occur even during full anesthesia but are most marked if the anesthesia is light. The respiration is usually stimulated by the operative procedures, and these may provoke coughing, deglutition, retching, stertor, or spasmodic inspiratory or expiratory arrest. Operations during partial anesthesia are therefore dangerous.

Laryngeal Reflex.—When a fresh portion of ether is poured upon the cone, the irritation of the more concentrated vapor causes the patient, so long as he is partly conscious, to hold the breath momentarily. The disappearance of this reflex is a valuable index of surgical anesthesia (Briggs).

With the approach of the paralytic stage, the respiration becomes more stertorous (softly snoring with chloroform), irregular, dyspneic, and stops; paralysis of the respiratory center being the usual mode of death in deep anesthesia. Chloroform has a more pronounced paralytic action than ether; the paralysis may also be due to very low blood pressure.

Reflex Inhibition of Respiration.—Deep etherization depresses or abolishes all augmentory reflexes, but intensifies those that produce inhibition. For instance stimulation of the afferent vagus or superior laryngeal fibers causes only short arrest of the respiration in normal animals. As etherization deepens, the arrest becomes longer. With deep anesthesia, not much beyond the surgical limit, the arrest is so long that the resulting asphyxia kills the heart (F. C. Mann, 1918).

Factors in the Respiratory Effects.—The understanding of the several factors concerned in the respiratory effects is essential to the intelligent conduct of anesthesia. The factors are classified by Y. Henderson and Scarbrough, 1910, as follows:

1. *The Threshold of Excitability for Carbon Dioxide.*—This is *elevated* (i.e., the excitability is depressed) by morphine, chloroform, and deep etherization. It is *lowered* by light etherization; by the acidosis of deficient oxygenation; and by fear.

2. *The Carbon Dioxide Content of the Blood.*—This acts as a stimulant to respiration. It varies inversely as the respiratory ventilation.

3. *The Threshold of Excitability for Afferent Impulses.*—This is *raised* (i.e., respiration is depressed) by deficiency of carbon dioxide (acapnia); and by morphine, chloroform, and ether. It is *lowered* by fear.

4. The intensity of afferent impulses, especially pain and psychic impressions.
5. Inhibitory cerebral impulses, such as the fortitude of the patient.

The several anesthetics act differently on these factors: *Morphine* raises the threshold for carbon dioxide; it has less effect on the threshold for afferent impulses. It quiets excitement.

Chloroform raises the threshold more for afferent impulses than for carbon dioxide.

Ether may lower the carbon dioxide threshold, whilst the afferent threshold may be elevated. Hence, ether tends to increase respiration (Fonteyne, 1906), so much so that in dogs it may cause fatal *acapnia* (Henderson). Most ether fatalities occur in the pre-anesthetic stage, the respiration almost always failing before the heart (Cunningham and Anderson, 1908). This tendency may be neutralized by morphine. The *respiratory excitement* during the early stages of anesthesia has a similar tendency; it lowers the carbon dioxide content of the blood and thus tends to subsequent failure of respiration. Good surgical anesthesia obviates the development of *acapnia* by preventing pain-hyperpnea.

Excessively deep anesthesia paralyzes respiration by raising the threshold of the respiratory center, and by diminishing the production of CO_2 . The paralysis is essentially central, although a curare action on the phrenic nerves may play a minor part (Githens and Meltzer, 1914).

Anesthesia before pain prevents *acapnia* by lessening the afferent hyperpneic impulses. The induction of *anesthesia after pain* is more dangerous, because the lowered excitability during hyperpnea is apt to lead to *acapnia* (Henderson, 1910). The *acapnia* also damages the heart, so that it succumbs more easily to chloroform (Cathcart and Clark, 1913).

Stoppage of respiration is therefore most apt to occur with uneven anesthesia (Henderson, 1911).

Irritation of Respiratory Passages.—Both anesthetics, but especially ether, produce irritation, with reflex phenomena, increased flow of saliva and mucus, and sometimes inflammatory after-effects. The hypersecretion is especially marked with ether; chloroform produces only a slight increase during induction, and practical arrest during full anesthesia. *Emphysema*, *bronchitis* and advanced *tuberculosis* are therefore special contraindications to ether. The increased flow of saliva and the anesthesia of the larynx are apt to lead to *aspiration pneumonia* (Hoelscher, 1898). *Pneumonia* may also be due to direct irritation and to hemorrhagic emboli; it is not known which has the larger share. It is much more common with ether than with the other anesthetics. It has been attributed to *impurities*, especially aldehydes and peroxides (Bruns, 1895; Smith, 1913); but this has not been conclusively established. Excessive mucous secretion may also produce acute suffocation by "inundation." The tongue during anesthesia is apt to fall against and close the glottis. These accidents are largely obviated by proper position of the head.

Coughing, retching and vomiting sometimes occur immediately after starting the administration; or later, during imperfect full anesthesia, especially with ether, being partly due to the swallowing of mucus. Their occurrence indicates that the anesthesia should be deepened. The approach of vomiting is heralded by swallowing movements. If it can not be averted, the head should be turned to the side and the opposite shoulder raised.

Bronchial Muscle.—Excised tracheal muscle is relaxed by ether, constricted by chloroform, in vapor-concentrations such as occur in anesthesia (Trendelenburg, 1912). In intact animals, however, chloroform produces slight dilation (Dixon and Brodie). In excised lung (guinea pig), temporary dilation is produced by ether, chloroform and urethane (Baehr and Pick, 1913).

Blood-gases in Chloroform Anesthesia.—The gas exchange is decreased; in the excitement stage by hyperpneic *acapnia* and mechanical obstruction; in the anesthetic stage by depression of the center (Y. Henderson; Buckmaster and Gardner, 1911). The production of CO_2 during anesthesia is only one-half to two-thirds of the normal.

The CO_2 content of the blood was increased from 25 to 36 per cent., the oxygen content reduced from 13.6 to 8.1 per cent. (Gardner and Buckmaster, 1910). The blood is therefore darkened. Chloroform seems to diminish the oxygen capacity of the blood; for the diminution of oxygen occurs even with artificial respiration. Gangitano claims that this lasts for twenty-five days.

The gas-metabolism of the brain is depressed by 60 to 90 per cent., proportional to the depth of the narcosis. With ether, the CO_2 falls less than the oxygen; the reverse is true of morphine (Alexander and Cerna, 1913). In nerve fibers, direct exposure to low (stimulant) concentrations increases CO_2 production, while anesthetic concentrations depress it (Tashiro and Adams, 1914).

Ether in Circulation.—*In the early stages*, the pulse rate and blood pressure are increased by the reflexes, excitement and incipient asphyxia. *During anesthesia*, the effects are similar to those of alcohol, stimulant rather than depressant: the cutaneous and cerebral vessels are dilated (also with chloroform, Berezin, 1916), the intestinal constricted (Derouaux, 1909), the pulse rate is increased to 80 to 110, and the blood pressure

FIG. 21.—Anesthetics on circulation. A. Ether on blood pressure (dog). The animal is very lightly anesthetized at the beginning of the tracing. The ether is pushed at (a). There is practically no effect on the blood pressure, even after ten minutes (b). B. Chloroform on blood pressure (dog). The inhalation is begun at (a) and pushed. The pressure falls, without any material change in the heart (central vasomotor depression). The anesthetic is withdrawn at (b). The respiration is very shallow. Artificial respiration is started at (c) and stopped at (d). The original pressure is gradually recovered. C. Ethyl chloride on blood pressure (dog). The inhalation is continued from (a) to (b). The effects are very similar to those of chloroform.

(Fig. 21A) is practically unchanged, or somewhat above normal in man (Blauel, 1901). The face is reddened. The pressure in the pulmonary artery rises even if the carotid pressure remains unchanged (Wood, 1911). There is generally some venous congestion, especially with the "closed" methods (asphyxia). The threshold to vagus stimulation is raised (Jackson and Ewing, 1914).

These indifferent or favorable actions on the circulation persist through the stage of surgical anesthesia, even if this is prolonged for hours. (However, Muns, 1916, claims that after about an hour of continued ether anesthesia, there is seen a marked and progressive arterial dilation of central origin). *In the paralytic stage*, the vasomotor center is gradually depressed: the pressure falls very slowly, the face becomes pale, while the

heart remains practically perfect even when the respiration ceases. It can therefore usually be revived effectively by prompt artificial respiration. Fatty feeble hearts, however, may be affected more severely.

The vascular effects are central; the cardiac changes are mainly the indirect results of the vascular disturbance; the heart-muscle (Bock) and the vagus excitability remaining unchanged. Concentrations of ether which injure the heart directly can be reached only in perfusions.

Toxic Circulatory Effects and Concentration in Blood.—These have been investigated on cats by Schram et al., 1916. With normal cats, concentrations of 0.13 to 0.14 per cent. of ether in the blood lower the blood pressure considerably by action on the vasomotor and vagus centers; but the heart-muscle is not affected by this concentration. Even with the fatal concentration (0.17 per cent.), the heart is scarcely damaged, although the circulation is depressed before death.

If artificial respiration is performed, cardiac arrest occurs with 0.25 per cent. of ether in the blood. This also is not essentially due to direct injury of the heart muscle; for by dividing the vagi, the minimal fatal concentration becomes 0.31 per cent. If low blood pressure is excluded (by the Starling arrangement), it becomes 0.44 per cent.; and if the nutrition of the heart is maintained (by Langendorff perfusion), the concentration rises to 0.553 per cent. before the heart is arrested.

Asphyxial Effects on the Circulation.—Slight mechanical interference with the respiration rather improves the respiratory movements and the circulation by stimulating the medullary centers. Severer grades produce venous congestion, extensive bleeding from severed vessels, etc. Profound asphyxia leads to extreme cardiac dilation by paralysis of the vasomotor center and heart.

In light ether anesthesia, 12 to 16 per cent. of CO₂ in the air raises the blood pressure, but slows and weakens the heart. These actions are much less pronounced in deep anesthesia (Cathcart and Clark, 1913). The secretion of *cerebro-spinal fluid* is increased by the anesthetics and CO₂ (Dixon and Halliburton, 1913).

Vasomotor Center.—Anesthetic doses of ether produce no direct effect, or moderate stimulation. The stimulation is probably largely asphyxial, from respiratory depression (Pilcher and Sollmann, 1915).

Heart Rate and Blood-pressure.—In light anesthesia, as in normal individuals (Marey, 1860), the heart rate tends to vary inversely to the blood pressure; *i.e.* as the blood pressure falls, the heart rate quickens, a response involving the accelerator innervation. In deep ether anesthesia, however, and with anoxemia or profound anemia of the medulla, this coordination fails, so that the heart-rate decreases with further fall of pressure.

Anesthetics in "Shock."—In partial shock, ether depresses the circulation more profoundly; for instance, etherization to disappearance of the conjunctival reflex lowered the blood pressure of a "shocked" animal from 65 to 30 mm. The use of nitrous oxide-oxygen mixture (3:1) does not produce this depression. In any case, deep anesthesia, and rebreathing methods, should be avoided in shock (Cannon, 1919).

Lipolytic Narcotics on Capillaries.—The drugs of this group tend to paralyze the capillaries with concentrations not much greater than those existing in the blood in anesthesia (Krogh). This may be an important element in the greater tendency to shock that ether anesthesia is by surgeons believed to entail.

Effects of Chloroform on the Circulation.—These are much more serious than those of ether. Even in smooth anesthesia, the pressure falls markedly (Fig. 21B) by central vasomotor depression. Slight faults, especially early in the administration, may produce sudden permanent arrest of the heart. "A.C.E. Mixture" and Ethyl Chloride (Fig. 21C) act similarly.

In normal chloroform anesthesia, with carefully graduated administration, the pulse and blood pressure in the *pre-anesthetic stage* are somewhat irregular, but generally increased and the face flushed, similarly to ether. As anesthesia is reached, or shortly after, the blood pressure

declines progressively (Lenz, 1853; English Chloroform Commission; Blauel in man); in an hour it may have fallen to one-half, in two and one-half hours to one-third the normal level (Rosenfeld, 1896). This fall of pressure is primarily due to depression of the vasomotor center: The vessels are dilated, but constrict on stimulation of their nerves (Scheinesson, 1869). The depression of the center can be shown directly by the perfusion method (Sollmann and Pilcher, 1911). The dilation involves mainly the splanchnic area (oncometer, Embley, 1902; increase of blood flow, Pick, 1899). The skin becomes pale and cold. The cerebral vessels constrict, the pulse is soft and slow but regular, the heart beating efficiently when the vasomotor paralysis is complete (no response to asphyxia, Knoll, 1878). The respiration also remains regular and efficient. The vasomotor depression is not necessarily harmful to the patient, unless it be excessive or prolonged.

With *prolonged anesthesia*, or with the approach of the paralytic stage, the heart is injured more or less by the direct action of the chloroform, as well as by the low blood pressure and asphyxia. It is also very probable that degenerated heart-muscle is more subject to these injuries. Ordinarily, however, the vasomotor paralysis dominates the circulatory phenomena until death, the heart beating after the respiration has stopped (Hyderabad Commission, 1889 and 1890), although it may not be able to maintain a circulation.

With *faulty administration* the events are quite different. Excessive concentration of the chloroform vapor, particularly when the anesthesia is incomplete, stops the circulation before the respiration (Fig. 22). This is the usual mode of chloroform death (Lancet Commission, 1893).

If the heart is exposed, it may be contracting feebly, even after the respiration has stopped, so that literally the respiration stops first; but these feeble beats can not propel the blood, so that in fact, the circulation, usually fails before the respiration.

The cardiac arrest may be due, in individual cases, to direct or reflex vagus stimulation, to asphyxia, to fibrillation or to direct paralysis of the cardiac muscle; or generally perhaps to a combination of these factors. Reflex circulatory disturbances are most dangerous in incomplete anesthesia where the reflex response is active; and in very deep anesthesia, when the low blood pressure may make even slight reflex changes fatal.

Laryngeal-reflex Syncope.—Desoubry and Magne, 1914, confirmed that brusque chloroform inhalation produces complete arrest of heart and respiration in dogs and rabbits. However, if absorption of the chloroform is prevented, the arrest is temporary, and followed by rise of blood pressure from splanchnic constriction. In the usual fatal result therefore the toxic action of the absorbed chloroform plays an important part in preventing recovery from the reflex arrest.

Vasomotor Center.—The preliminary stimulation is partly due to a direct action of the chloroform, for it occurs when this is confined to the cerebral circulation (by perfusing this from the vessels of a second, chloroformed animal; Gaskell and Shore, 1893). In part, the rise of pressure is also reflex and asphyxial. The vasomotor center becomes depressed quite early; *f.i.*, the normal vascular compensation against the head down position is destroyed (L. Hill, 1897). It does not become completely paralyzed until much later (Gaskell and Shore; Embley and Martin).

In their perfusion experiments, Pilcher and Sollmann, 1915, confirmed that the vasomotor center is depressed directly during chloroform anesthesia. Indirect stimulation may, however, occur when asphyxia is induced by respiratory depression, or if the center becomes suddenly anemic by rapid fall of blood pressure or cardiac arrest. Under such conditions, the center may be violently stimulated, with or without preceding depression.

Chloroform abolishes the effect of pressor reflexes at higher levels of blood pressure than normal (Pilcher and Sollmann).

In an intermediate stage of chloroform anesthesia, stimulation of the vasomotor center lowers blood pressure, since chloroform disturbs the reciprocity of antagonistic nerves so that afferent stimuli produce only inhibitory effects; chloroform causing the inverse effects to strychnine. The chloroform vasodilation may therefore be due to the reversal of the normal pressor impulses of the center. Asphyxia, however, still causes vasoconstriction (Bayliss, 1908). When the vasomotor paralysis is complete, asphyxia does not raise the pressure.

The typical fall of blood pressure occurs with all methods of administration.

Direct Action on Vessels.—Perfusion of excised organs with chloroform solutions produces a constrictor effect in some organs, a dilator effect in others, especially the kidneys (Schaefer and Scharlieb, 1904; Embley and Martin, 1905; Filehne and Biber-

FIG. 22.—Accidents of anesthesia: A. Reflex stoppage of heart; blood pressure, dog. Ethyl chloride is inhaled at (a). The heart and respiration stop promptly (trigeminus-vagus reflex). They resume spontaneously after two minutes. B. Direct paralysis of the heart, preceded by asphyxial rise. Ethyl chloride inhalation, blood pressure, dog.

feld, 1906; Campbell, 1911). The required concentration, however (0.1 per cent.), is almost twice as great as that which kills the heart and paralyzes respiration (0.06 per cent.); so that this peripheral action can play no part in chloroform anesthesia (Sherrington and Sowton, 1904).

Early Stoppage of Heart.—Most fatalities with chloroform occur during the induction of the anesthesia, by sudden arrest of the heart. Experimentally, the heart will often resume if the vagi are promptly divided. In these cases the arrest is due to *stimulation of the vagus center*. This may be *reflex*, due to nasal, laryngeal, tracheal or pulmonary irritation by the chloroform vapor (Dastre; Morat; Brodie and Russell); but it may also occur when all reflex paths are eliminated, or on intravenous injection (Embley, 1902); thus indicating *direct stimulation of the center*. Its excitability is exaggerated by high concentrations of chloroform (about 2 per cent.), by morphine, and by asphyxia. Deep anesthesia dulls this vagus hyperexcitability, thus explaining why these accidents generally occur at the start. The administration of atropine would prevent this form of fatality completely.

There is, however, another factor; for a normal heart can not be stopped permanently by vagus stimulation, direct or reflex; with a chloroformed heart permanent arrest is easily produced (Embley; Desoubry and Magne, 1914). It follows therefore that the high concentration of chloroform vapor must have injured the heart. This increased sensitiveness of the heart may be fatal apart from the vagus: A. G. Levy, 1911, finds the cat's heart in early chloroform anesthesia very sensitive to high blood pressure (epinephrine), death in this case being not avoidable by vagotomy or atropine. This condition disappears in deeper anesthesia and was not seen with ether.

Socin, 1914, showed that chloroform also renders the excised heart less resistant to venous engorgement or increased arterial resistance; i.e., that it dilates more easily. Similarly, excitement may stop the heart of lightly chloralized cats (Sollmann, 1908). Embley, 1915, finds that early chloroform death with cats is frequently due to ventricular fibrillation. With dogs, this was never witnessed, except as a terminal result of low blood pressure.

Hering, 1916, also finds the tendency to early death, in dogs and cats, parallel to excitement. The arrest is generally due to ventricular fibrillation from excessive excitability of the heart.

Henderson, 1914, is inclined to attribute the early fatalities mainly to acapnia.

Vagus Response.—Chloroform decreases the intensity and duration of cardiac inhibition by vagus stimulation (E. Nobel, 1919).

Cause of Ventricular Fibrillation.—This is presumably due to a shortened refractory period of the cardiac muscle, described by Sasaki, 1921. Higher concentrations of chloroform, however, paralyze the muscle directly.

Direct Cardiac Depression by Chloroform.—This was demonstrated on the excised frogs' heart by Clemens, 1850; on the exposed mammalian heart by Snow, 1852.

The excised mammalian heart (Langendorff method; Sherrington and Sowton, 1903) shows strikingly the difference between chloroform and ether. The chloroform depression occurs very promptly (within two minutes) and with much lower concentrations than are required for the vessels. It consists in a lessened force of the contractions, the rate being but little altered. The auricles are less affected than the ventricles. The effect is proportional to the concentration of the chloroform, and independent of the absolute quantity and of the time of perfusion. The heart recovers at once when the chloroform is removed, unless the concentration was excessive (0.15 per cent.), in which case fibrillary contractions appear and recovery is impossible. Ether has much less action, and alcohol is practically harmless even when 2 per cent. is present.

Burridge, 1917, finds that alcohols, ether and chloroform may produce either depressant or favorable effects on perfused hearts.

The quantitative difference in the cardiac depressant action of these narcotics is illustrated by the results of Dieballa, 1894, on perfused frog's heart: If the fatal dose of chloroform be taken as one, that of ethyl bromide would be 12; of ether 48; of alcohol 192.

That the heart may be directly depressed by chloroform in the intact animal was shown by Scheinsson, 1868, who found that the blood pressure fell even if vasodilation was largely excluded by clamping the aorta. Bock employed the same principle more perfectly, with the same results. This method involves high concentrations of chloroform.

Ordinary concentrations also weaken the heart somewhat (lessened systolic amplitude and rapid dilation; MacWilliam, 1890; Embley, 1902); but this may possibly be the result of the fall of blood pressure. However, the concentration of chloroform in the blood which is required for anesthesia (0.035 per cent.) is not very far removed from that which paralyzes the heart (0.06 per cent.; Pohl, 1891); so that there is probably some direct cardiac depression even in "safe" anesthesia, and the margin of safety is quite small. Levy and Lewis, 1912, also found that low concentrations of chloroform produce marked cardiac irregularity (idiopathic ventricular contractions) in cats. Hecht and Nobel, 1913, observed disturbed conduction, sometimes to complete auriculo-ventricular dissociation. In some experiments this could be removed by vagotomy or atropine, but in others it could not, indicating an action on the bundle. In perfused hearts, and doubtless also in living animals, the depressant action of chloroform is greatly increased by CO₂, and therefore by asphyxia (Sherrington and Sowton, 1906).

The pressure in the pulmonary artery falls, through the cardiac and respiratory depression (Wiggers, 1911).

With frogs' hearts, the depressant effects of anesthetics can be antagonized by calcium (Burridge, 1912).

Actions on Blood.—These are not important in ordinary anesthesia. Ether and chloroform, like all fat-solvents, produce hemolysis when added to shed blood; and an insignificant degree of this action seems to occur during life; examination of the blood

shows a polycythemia, due to diminution of the plasma. The hemoglobin is, however, reduced. Some corpuscles are destroyed entirely, others lose only part of their hemoglobin. Since a diminution of hemoglobin to 50 per cent. is dangerous, it is never safe to use anesthetics on patients showing only 60 per cent. of hemoglobin (Da Costa and Kälteyer, 1901).

It is conceivable that this hemolysis explains partly the *anemia and icterus* which are sometimes seen; but these may also be caused by hepatic changes.

Coagulation Time of the Blood.—This is shortened by ether anesthesia. Chloroform and chloral have no effect if the coagulation time is normal; but lengthen it if abnormally short. Mendenhall, 1915, suggests that these changes are due to disturbed interaction of the liver and adrenal glands.

When added directly to blood, complex effects are produced on coagulation. Chloroform and ether render antithrombin ineffective. Ether also weakens the thrombin action; chloroform does not, nor does it convert prothrombin into thrombin. The quantities used were much higher than in anesthesia (Minot, 1915).

The *specific gravity* of the blood is somewhat increased during anesthesia and for several days after (Sherrington and Copeman). Buck, 1914, describes marked decrease of the globulins after about two hours of chloroform or ether anesthesia. The *viscosity* of the blood is slightly increased in deep, diminished in light anesthesia, but not to an important degree (Burton-Opitz, 1911). The *osmotic pressure* is a trifle increased by the molecular concentration of the dissolved anesthetic (Carlson and Luckhardt, 1908). The fat-content of the blood is increased by ether; chloroform has this effect only when the animal has been on a fat-rich diet (Bloor, 1914).

Disappearance of Fibrinogen.—Profound chloroform narcosis diminishes or abolishes the coagulability of the blood. This change is noticeable after thirty-five minutes of anesthesia. In extreme cases the fibrinogen may be completely absent. This effect is connected with the injury to the liver, similar to that of phosphorus, and is not produced by ether. The coagulability recovers with the repair of the hepatic lesions (M. Doyon, 1913; Whipple, 1915; E. W. Schultz et al., 1925).

The *cholesterin content* of the blood does not show any significant changes in surgical ether anesthesia (F. C. Mann, 1916).

Blood Catalase.—This decreases during the administration of ether, by direct destruction; and increases during recovery, through increased output of catalase by the liver (Burge, 1917).

Temperature.—This falls during anesthesia by ether and chloroform, partly through diminished heat production, partly through increased heat loss. The diminished production (Scheinesson) is reflected in decreased CO₂ formation, and is due to the decreased muscular movements and tone. The increased loss of heat is due to narcosis of temperature regulation, aided by exposure, and a little by the cooling action of the vapor. In the paralytic stage, the dissipation of heat is also diminished by failure of the circulation, but the diminished heat production predominates in the collapse. Unless the heat is applied artificially the body becomes practically poikilothermal, and its temperature may reach a very low level if the coma is of long duration.

Clinically, chloroform and ether cause about an equal fall of temperature.

In ordinary operations on man the fall is from 1 to 4°F., averaging about 2.5°F. (H. A. Hare, 1888); much more in prolonged operations on animals. It is not markedly increased by the ordinary dosage of morphine. It can be prevented by external heat (the room temperature should be above 26.5°C. = 80°F.) and by keeping the skin dry (S. G. Davis, 1909). Excessive heat must also be avoided, since temperature-regulation is disturbed in all directions. Etherized dogs can maintain a constant body temperature only if the environing temperatures is very near 31°C. (Barbour and Bourne, 1924.)

Precautions against loss of heat are especially important, since chilling favors the occurrence of shock and of postanesthetic pneumonia. Warming the vapor has been advocated (Gwathmey, 1908; Pembrey and Ship-

way, 1916); but the loss of heat from this source would be insignificant (Boothby, 1913).

Anesthesia and Operative Procedures on Rabbits' Temperature.—L. W. Moore, 1918, found that the normal temperature of rabbits ranges between 38.2 and 41.4°C., averaging 39.7°C.

Tying the animal to a board caused a fall of 1 to 2°C. in 1 or 2 hours, after which the temperature remained stationary, with a subsequent rise of 0.5° above normal.

Ether.—During the administration there was an average fall of 1.4°C. with a subsequent rise of 1° above normal.

Nitrous oxide caused similar, but smaller changes.

Operations (trephining) gave an average fall of 1.9°C., with subsequent rise of more than 1° above normal.

Cerebral Compression.—This produces hyperthermia identical with puncture-fever. It acts presumably by stimulating the vasomotor center (in common with other centers), thus diminishing heat dissipation by contraction of the surface vessels. Fatal compression paralyzes the vasomotor center, and the temperature then falls (Moore, 1919).

Reflexes.—The gradual abolition of all spinal reflexes produces complete muscular relaxation in the anesthetic stage—an important surgical advantage over nitrous oxide or cocaine anesthesia. The relaxation and reflexes are also valuable for judging the depth of the anesthesia, for the reflexes vary with remarkable uniformity according to the concentration of the anesthetic in the blood (van Leeuwen) and even according to the concentration in the air (Mann, 1918). There are, however, rare exceptions. No initial stimulation of reflex excitability is noticeable (van Leeuwen, 1913).

The reflexes disappear in a rather *definite order*; but this is not the same for chloroform and ether, indicating that their actions are not strictly alike (van Leeuwen, 1916). Among the last to disappear are the corneal, laryngeal, pharyngeal, rectal, vesical, peritoneal and genital. The patellar reflex persists very late. The movements of paralysis agitans cease during anesthesia as they do in sleep.

The Sensory Component Is Depressed before the Motor Component.—In the early stages sensation is blunted while motion is unimpaired or indeed increased. The psychical condition is similar to alcohol, but the facilitation of motor processes is early obscured by the sensory depression (Kraepelin, 1892). In the deeper stages, the sensory cells of the spinal cord are paralyzed before the motor cells: If chloroform is restricted to the upper half of the cord, so that this will not react to reflexes from the upper extremities, it will still respond to impulses from the unpoisoned sensory cells of the lower cord (Bernstein). The response to direct stimulation of the cord disappears first from the sensory posterior columns (Flourens, 1847). Eventually, however, the motor cells also become inexcitable.

Forbes and Miller, 1916, conclude (from the action-currents) that the efferent impulses are blocked before they reach the cerebral cortex.

The cerebral motor cortex is also depressed, but loses its excitability only in very deep anesthesia (Hitzig, 1873).

Ether as an Intoxicant.—The resemblance of the earlier effects of ether to those of alcohol has led to its use as an intoxicant. It is said that ether drinking is a common form of dissipation in Ireland. The effects are produced, and pass off, more promptly than with alcohol (Discussion and literature, J.A.M.A., 64; 168, 1915).

General Protoplasmic Poisons and Local Irritants.—The anesthetics, on direct application, narcotize all cells, of the lower organisms, as well as of the higher. This is preceded, at least in some cases, by evidences of stimulation. The concentration required for irritation is greater than is reached from systemic administration. At the place of application, however, the irritation is quite marked. Chloroform is more irritant than ether, with equal concentrations, and can be employed as a rubefacient and even vesicant.

The irritation is due largely to *coagulation of the protoplasm*. The cause of this differs in the various members. In the case of *alcohol* it rests upon withdrawal of water, and consequently all proteins are affected; *chloroform* has a more marked action upon globulins (especially myosin), and *ether* upon albumins (especially egg-albumen).

Peripheral Action on Nerves.—The direct excitability of the muscles and nerves is not materially altered when the central nervous system is completely anesthetized (J. Bernstein, 1870). Direct application of solutions or vapors of the volatile anesthetics to a nerve lowers its conductivity and excitability, changes the polarization (Waller, 1896; Alcock, 1906; Bethe, 1908), and abolishes the action-current (Forbes, McIntosh and Sefton, 1916). The sensory fibers succumb before the motor (Longet). The *conductivity of the nerve* is lowered, as well as its excitability; for if a nerve is exposed to ether vapor, stimulation at the proximal end ceases to be effectual much sooner than at the distal end; and with a long stretch of partly narcotized nerve, the response is the smaller, the farther from the muscle the stimulations are applied (Dendrinis, 1902). The excitability is recovered if the ether is washed off in time. With chloroform, recovery is more difficult. The concentrations required for these peripheral effects are greater than can exist in living animals; the motor and sensory nerves remaining excitable even in profound anesthesia; nor is the conductivity lowered during life (Forbes, McIntosh and Sefton, 1916).

Narcosis of a nerve diminishes its CO₂ production materially. Lower concentrations increase the CO₂ (Tashiro and Adams, 1914).

The undiluted anesthetics when *injected directly into a nerve* produce a circumscribed neuritis (caution in subcutaneous or intramuscular injections).

Special Senses.—The *odor and sweet taste* of chloroform and ether show a peripheral stimulation of these sense organs.

Curare Action.—Auer and Meltzer, 1914, found that deep ether anesthesia produces a moderate depression of the motor endings (confirmed by *van Leeuwen*, 1916). Chloroform does not have this effect (Githens and Meltzer, 1914).

Muscle.—All forms of muscle are depressed. Chloroform further causes a specific *rigor* of the muscle when applied directly or injected into an artery (Kussmaul, 1858; Cl. Bernard). It also coagulates the extracted muscle proteins (Fuerth, 1896).

Ureter.—The contractions are depressed by chloroform in living animals, even by doses which do not affect the respiration or circulation (Lucas, 1906 and 1907). The inhalation of chloroform therefore relieves the ureteral spasm of *renal colic*. Ether stimulates the contractions.

Ciliary movement (as in the frog's pharynx) is arrested.

The narcotic effect on *infusoria* were observed by Cl. Bernard, 1876.

Phagocytosis.—This is stimulated by small concentrations, arrested by higher (H. J. Hamburger, 1911). The stimulation is perhaps due to asphyxia, since cyanide or carbon dioxide produce the same effect (Hamburger, 1915).

During surgical ether anesthesia, a *leucocytosis* sets in slowly, usually after one to four hours. It concerns mainly the polymorphous, but the other forms are also increased. It appears to be due to stimulation of the bone-marrow. The phagocytic activity is not decreased, even after four to six hours of anesthesia (F. C. Mann, 1916).

In plants the narcotics abolish protoplasmic movements; cause plasmolysis; suppress the gross movements of the Sensitive Plant (*Mimosa pudica*), etc. Exposure to chloroform and especially to ether vapor hastens blooming (Keeble, 1906).

The assimilation of oxygen is abolished by fairly low concentrations of chloroform; whereas CO₂ production is stimulated even by considerably higher concentrations. Excessive concentrations, however, paralyze this also (A. A. Irving, 1911).

Dry seeds resist high concentrations of anesthetics, because the dry envelopes of the seeds are impermeable. If these are removed or punctured, anesthetics become injurious (B. Schmid, 1901).

Ferments.—Pepsin, rennin, trypsin, diastase, invertase, catalase and other organic ferments, as well as metallic catalysts, are restrained by anesthetics in the same general order of efficiency as living cells.

Vermifuge.—Chloroform has been employed for the expulsion of tapeworms; but the effective doses are too irritant and toxic to make its use advisable. It has been revived by Alessandrini, 1915, against hookworm and other parasites. He gives 3 to 4 Gm. in olive oil or castor oil. Hall and Foster, 1917, found it highly efficacious in animals. They are dubious about exceeding 2 to 3 Gm. dosage, and would not repeat this for some weeks, for fear of liver degeneration. Darling, Barker and Hacker, 1918, did not find it very effective.

Action on Fishes.—This is described by Clayberg, 1917, and utilized for bioassays.

Antiseptic Action.—Chloroform is fairly antiseptic (Strassmann, 1888; Salkowski, 1891), and may be used as a preservative.

Ether has come into some prominence as a surgical antiseptic. It is applied on compresses; and for flushing the peritoneum after perforation (Souligoux, 1913). Saliba, 1916, reports it as satisfactory and generally without untoward after-effects or complications. He injects the liquid ether before closing the sutures, about 100 c.c. for adults; 30 c.c. for children above one year. Fatalities have, however, been reported (for instance, Merck's Reports, 28: 204).

Use on Open Wounds.—Distaso and Bowen, 1917, recommend daily irrigation with 2 liters of 2 per cent. ether claiming that this promotes healing, especially by new formation of vessels.

Cutaneous Irritation.—The evaporation of the volatile anesthetics cools the skin. Local anesthesia by freezing may thus be produced (see "Ethyl Chloride"). With ether and especially chloroform, the cooling is succeeded by a burning sensation and rubefaction. If evaporation is prevented, this may proceed to vesication. Chloroform is therefore used as an active counterirritant (*linimentum chloroformi*, U.S.P.: Chloroform 30, Soap Liniment 70; B.P.: Chloroform 50, Camphor Liniment 50). The irritant action on mucous membranes is even more violent.

Hypodermic Injection of Ether.—This is employed (1 to 2 c.c.) as a rapid stimulant in collapse. Like other similar irritants, it tends to produce a slight and transient rise of blood pressure; but it fails in the severer grades of hemorrhage and shock, and in anesthesia (Lieb and Herrick, 1917). The *respiration* of normal rabbits is stimulated by the hypodermic injection of chloroform or ether; but these have little effects on deeply morphinized animals (Hanzlik, 1923).

Gastro-intestinal Tract.—The inhalation of the anesthetics generally results in *nausea* and often in *vomiting*, sometimes during the induction, and especially when the patient awakens. The mechanism is mainly central, but the local irritation and the swallowing of mucus may contribute.

By their peripheral action on the muscle and on the peripheral innervation, ether, and to a still greater extent chloroform, relax the tone and arrest the movements of the entire digestive tract from the stomach to the rectum, during the duration of the surgical anesthesia. The stomach relaxes so that the division between fundus and pylorus largely disappears. Acute gastric dilation is an occasional serious complication. Asphyxia does not overcome the depression.

When the administration is discontinued, and if the anesthesia was not too profound or too prolonged, the digestive tract recovers promptly, and may pass into a period of stimulation, increased colon tone being especially notable.

After deep narcosis, especially after chloroform, complete paresis of the stomach and intestines may persist for two hours, and incomplete paresis for twenty hours. The paresis that commonly follows laparotomies, however, is only partly attributable to the anesthetic, and mainly to the operative procedures (Cannon, 1911).

The above observations have been made with the fluoroscope (Cannon, 1911; Baron and Barsony, 1914; Kuehlewein, 1921); or on permanent fistulae of the stomach, small intestines and colon (G. H. Miller and Plant, 1924).

Other lipolytic narcotics produce similar depression. With *nitrous oxide*, on the other hand, the asphyxial stimulation predominates. During the administration, peristalsis is increased and irregular. After the discontinuance of the administration, marked inhibition follows; but this largely passes off within an hour (Miller and Plant).

The oral administration of ether and especially chloroform causes considerable gastric irritation. In milder degree this produces a carminative and anodyne effect, which is useful in colic and dyspepsia (Spiritus Aetheris, 5 c.c., 15; Spiritus Chloroformi, 2 c.c., $\frac{1}{2}$ 3; Aqua Chloroformi, 15 c.c., 45). Spiritus Aetheris is also employed as a reflex "diffusible stimulant."

If ether is taken into the stomach, it is rapidly volatilized and larger quantities distend the organs, sometimes so much as to interfere with respiration; it may even produce rupture of the organ. It also causes considerable local irritation, and consequently a temporary leucocytosis.

Reflex Stimulation of Pancreatic Secretion.—The duodenal injection of 2 c.c. of ether, through the Einhorn catheter, has been used clinically for this purpose (G. Katsch and v. Friedrich, 1922).

Pupils.—These furnish valuable information of the efficiency of the reflexes and asphyxia; and therefore of the depth and course of the anesthesia. In the *excitement stage*, they are dilated with the light reaction moderately decreased. This dilation cedes with the approach of *anesthesia*. In man there is then actual constriction; the light-reaction is diminished or abolished; the eyes are turned inward and upward as in sleep. The constriction persists throughout the anesthetic stage and into recovery. With ether, the diameter averages $3\frac{1}{2}$ to $4\frac{1}{2}$ mm.; with chloroform, 2 to 3 mm. If the anesthesia deepens they usually dilate; with lighter anesthesia they become smaller. However, their behavior is easily modified by reflexes, respiratory embarrassment, etc.; and should be occasionally ascertained by intentionally changing the depth of anesthesia. *Constricted pupils* usually mean that the anesthesia is light. *Dilation* may either mean deep anesthesia, asphyxia, or reflexes with light anesthesia. If the corneal reflex is present, dilation should lead to more rapid administration; in the absence of reflexes, to lighter administration. *Sudden and extreme dilation* generally signifies dangerous asphyxia. Morphine and atropine interfere with these reactions.

The effect of anesthesia is identical with that of sleep and is due to the abolition of the cerebral impulses which normally inhibit the constrictor tone of the oculomotor center. Asphyxia, on the other hand, increases this inhibition (Braunstein, 1894).

The Pupillary Reactions of Animals.—These are somewhat different: all show the dilation in the excitement and asphyxial stages, and the abolition of the light-reflex during anesthesia; but the anesthetic miosis is witnessed only occasionally in dogs, never in cats or rabbits. In these animals the pupils assume a median position. The frog's pupil is not affected by anesthesia (Nakazawa, 1910).

The Corneal and Conjunctival Reflex.—These disappear very late, as in all modes of death. Cl. Bernard found that the conjunctival reflex disappears before the corneal in ether anesthesia and in asphyxia; whilst the corneal reflex disappears first in death by cold or strychnine.

Absorption and Excretion.—Chloroform and ether, like most other chemically indifferent vapors and gases, are absorbed almost instantly from the lungs, and excreted rapidly and almost quantitatively by the same channel. A small part is excreted by the urine. Absorption from the stomach and rectum is also very prompt, and may be utilized for anesthesia.

Retention.—The percentage of the anesthetic in the expired air is at first much less than in the inspired. It begins to rise after two minutes, but remains considerably below the inspired even after ten minutes (Brodie and Widdows, 1906). This shows an actual retention of the

anesthetic, which is reflected by the percentage in the blood (Buckmaster and Gardner, 1907).

Harcourt, 1906, states that at the end of half an hour of anesthesia, about one-third of the administered chloroform has remained in the body; after this time but little further retention occurs.

The excretion of volatile anesthetics through the lungs is a merely physical process, analogous to their evaporation from aqueous solutions. It depends more upon their solubility and affinity for water than on their boiling point (Cushny, 1910).

Ultimate Fate.—*Ether* is not oxidized in the body; 79 to 92 per cent. can be recovered from the expired air, and practically all the remainder from the other excretions (Haggard, 1924).

A small amount of *chloroform* is decomposed in the tissues, with the production of chloride (excreted by the urine; Zeller, 1883), and carbon monoxide. The quantity of the latter is too small to produce any effects. This decomposition occurs also in shed blood (Nicloux, 1910).

Concentration of Anesthetic in Inspired Air.—The anesthetics exist in the blood and tissues mainly, if not solely in physical solution: they are therefore absorbed and excreted by the alveolar blood in proportion to their concentration in the alveolar air, until the whole system of air-blood-tissues is in equilibrium. The absorption into the blood and tissues is not instantaneous, so that a given concentration in the blood can be reached the more rapidly, the more concentrated the anesthetic vapor, and the more effective the respiration (Haggard, 1924). With fairly uniform administration, however, the exchange is sufficiently rapid, so that the quantity of anesthetic in the tissues at any given moment depends essentially on the concentration (partial pressure) of the anesthetic vapor in the inspired air (P. Bert). The action is determined by this concentration, and only in a minor degree by the absolute dose of the anesthetic. A knowledge of the concentrations is therefore important.

The effective concentrations for the respired air have been determined experimentally, mainly on animals; but they agree for all mammals; and according to available data, also for man (Bert, 1884; Dreser, 1893).

With *ether*, light operative anesthesia can be maintained with about 6 per cent. (volume) of ether vapor (18.5 mg. per 100 c.c. of air); deep narcosis (abolition of reflexes) requires 10.5 per cent. volume. The fatal concentration is 11 per cent. In surgical operations on man, T. K. Kruse, 1924, found the ether concentration under the mask to average 7 per cent. after 10 minutes of anesthesia. Boothby, 1916, finds the "anesthetic tension" (the partial pressure of ether vapor which maintains anesthesia indefinitely, after it has been established) as 47 mm., equivalent to about 6.7 volume per cent.

For *chloroform*, the corresponding concentrations are, for light anesthesia, 1.35 volume per cent. (6.8 mg. in 100 c.c. of air); deep narcosis, 1.65 per cent.; fatal, 2 per cent. (Kochmann, 1914). The *anesthetic zone* between the minimal anesthetic and the fatal dose is much wider for ether (viz., 5 per cent.) than for chloroform (0.65 per cent.). This is one reason for the greater safety of ether. Another difference is that the deep anesthesia can be maintained almost indefinitely with ether, whilst chloroform kills within one or two hours (Rosenfeld, 1896). The *time factor* therefore plays a part especially with chloroform (also on account of the postanesthetic degenerations). On the other hand, the concentration may

rise momentarily above the fatal limit, since the absorption, although rapid, is not instantaneous.

The above figures are those of Kochmann and his pupils. The older experiments generally gave lower numbers, probably due to analytical errors. Thus, Spenser, 1894, stated the effective volume per cent. of ether as 3.5 per cent.; fatal, 6 per cent.; for chloroform, Rosenfeld, 1896, named 1 per cent. as anesthetic, 1.65 per cent. as fatal. The various results are collated by Ritschel and Stange, 1893.

Concentration of Chloroform in Practical Anesthesia.—For inducing anesthesia, 1 per cent. chloroform vapor is insufficient: 2 per cent. is generally effective; less than this must be used in pathologic conditions, but requires a longer time to establish narcosis. Even 3 per cent. may be necessary in exceptional cases. The maximum limit of safety is placed at 2 per cent. by Waller; at 1 to 1.5 per cent. by Embley. Therefore, as soon as anesthesia is reached, the concentration must be gradually reduced to 1 per cent., and after half an hour even lower (Alcock, 1909; Levy, 1910).

Even perfectly adjusted mixtures are not absolutely safe. In practice the inconveniences of exact vapor mixtures are generally held to outweigh their advantages. However, the above figures are fairly approximated in the ordinary methods of administration. *The air under the ordinary mask* has been found to contain generally from 1 to 2 per cent. of chloroform, and with rapid application, up to 4 per cent.

The Equilibrium between Air, Blood and Tissues.—This depends on their relative solution affinity for the anesthetic. The exchange is very rapid at first, but slows as equilibrium is approached. Consequently, although a uniform concentration of anesthetic is inhaled the concentration of the blood continues to increase for over eight hours; and when the anesthetic is discontinued, the excretion extends over the same period (Nicloux).

The equilibrium between blood and tissues is probably established more promptly; for the concentration in the venous and arterial blood soon becomes equal. The anesthesia depends upon the concentration in the brain; and this on the concentration in the blood multiplied by their partition coefficient. The ether-solubility in hashed brain is to that in blood as 0.92 to 1.31. The other tissues play the role of a buffer (Haggard).

Concentration of Anesthetics in Blood and Tissues.—This has been investigated especially by Nicloux, 1906, to 1908; Tissot; Mansion and Tissot, 1906; Sicard, 1906. According to these, the *arterial blood* contains, with complete anesthesia of chloroform, 0.032 to 0.05 per cent. (0.014 to 0.028 according to Buckmaster and Gardner); of ether, 0.13 to 0.4 per cent. At death, the chloroform concentration averages 0.08 per cent. (0.06 per cent., Pohl; 0.04 per cent., Buckmaster and Gardner); ether, 0.16 to 0.17 per cent. The concentration in the venous blood is somewhat lower, since the anesthetic is given off to the tissues. This difference is of course especially large before equilibrium is reached. The left heart is therefore exposed to a higher concentration than the right especially if the anesthetic is "pushed" (Pohl, 1891).

Very similar figures for ether were obtained from the internal jugular vein of dogs by Haggard, 1924, who took special pains that equilibrium between expired and inspired air had been reached (the quantities can be expressed in mm. tension by multiplying by 17. *Concentration of the ether (Gm. per Liter) in dog's jugular blood* (Haggard))

0.18-0.25	Respiratory augmentation begins
0.39-0.46	Anesthesia
0.8-0.91	Respiration normal
1.15-1.25	Corneal reflex disappears
1.45-1.5	Respiration depressed
1.54-1.7	Respiration fails

After prolonged anesthesia, much lower concentrations suffice to maintain anesthesia, or to produce death (Haggard).

The dangerous concentrations of ether in the blood have been determined for cats by Schram, van Leeuwen and Made, 1916.

0.13 to 0.14 per cent., corresponding to deep anesthesia, cause marked fall of blood pressure by action of the vasomotor center and vagi.

0.17 per cent. is fatal unless artificial respiration is used.

With artificial respiration, 0.25 per cent. is fatal if the vagi are active; 0.31 per cent. if they were paralyzed.

0.44 per cent. is fatal to the isolated heart-lung preparation and 0.5 per cent. to the perfused heart. The perfused heart is but little damaged by 0.17 per cent., *i.e.*, the concentration that is fatal to intact cats.

During good anesthesia, the ether concentration in the *gases of the peritoneal cavity* reaches about 4 per cent. (Y. Henderson, 1918).

The concentration of ether in the urine approaches that in the arterial blood (Haggard, 1924).

The *cerebro-spinal fluid* also contains small quantities of chloroform when this is inhaled (Hald, 1921).

The distribution of the chloroform in the tissues is related to their content of lipid matter (Frison and Nicloux, 1907); especially of cholesterin and lecithin, in which chloroform is much more soluble than in water. Blood therefore absorbs considerably more chloroform than does salt solution; and the percentage is two and one-half to eight times greater in the red corpuscles than in the plasma (Pohl, 1891; Nicloux, 1906; Buckmaster and Gardner, 1907); twice as great in brain (0.057 per cent. at death) than in liver or muscle (0.026 per cent.). Adipose tissue is a curious exception, since it contains no more than muscle. Waller, 1904, states that only 15 per cent. of the chloroform when added to blood can be removed. With ether, which has a relatively smaller affinity for lipoids, the percentages in all the tissues are practically equal (Nicloux). It should be added that Guenter and Hoelscher, 1906, contradict these statements of the French observers, and claim that there is no difference in the percentage of chloroform in the blood, brain, liver and kidney; provided that the inhalation of a given concentration is kept uniform until equilibrium becomes established.

Elimination.—When the anesthetic is discontinued, the greater part *disappears very rapidly from the blood*. Within five minutes, the percentage of ether or chloroform has fallen to one-half. The final elimination is more gradual: With ether, there are traces in two hours but not in four hours. With chloroform, the concentration falls to only a seventh in three hours, and traces are present even in seven hours (Nicloux).

Ether on Urine Flow.—This is *diminished* during the anesthesia (*e.g.*, Hawk, 1911; Ginsberg, 1912; MacNider, 1913), presumably by the altered circulation and perhaps also by the irritation. Kemp, 1899, described contraction of the renal vessels with diminished kidney volume; but according to Buxton and Levy, this occurs only in overdosage, and then as a part of the general circulatory disturbance.

The oliguria is partly due to an increase of blood concentration which is a constant phenomena of ether-anesthesia. Consequently, the decrease of urine can be prevented by increasing the water-supply (Barbour and Bourne, 1924).

As soon as the anesthesia is terminated, the flow *increases*, the output being above normal for several days. The specific gravity is also increased. This diuresis is proportional to the duration of the anesthesia (W. H. Thompson; Hawk, 1908, 1911, dogs; Pringle, Maunsell and Pringle, human, 1905). In surgical patients, the urine output is often diminished by restriction of the water-intake (Epstein, Reiss and Branower, 1916).

Ether on Nitrogen Excretion.—This is diminished during the anesthesia (Pringle, 1905); it is then increased for twenty-eight to forty-eight hours, depending but slightly on the duration of the anesthesia. The total increase may amount to 45 per cent.; but is generally smaller, and therefore much less than with chloroform (Hawk, 1908).

Amino-acid of Blood Serum.—In dogs, this is not materially influenced by ether anesthesia. However, there is a slight decrease after 15 minutes, especially if the amino-acids had been raised by meat-digestion (E. L. Ross, 1916).

Anesthetics on Gaseous Metabolism.—In animals there is first a temporary fall; then a rise, with higher concentrations. In plants, anesthetics produce a rise, followed by fall (Osterhout, 1918).

Ether Glycosuria.—Ether anesthesia sometimes causes temporary hyperglycemia and glycosuria (animals, Hawk, 1904; Shaffer, 1914; human, Roehrich, 1905). They occur also on intravenous injection (King, Moyle and Haupt, 1913). They are due to increased hepatic glycogenolysis, for they do not occur if the liver is excluded from the circulation (King and co-workers, 1912); and are more intensive in well-fed dogs than in fasting (Hawk, 1911). They occur after division of the splanchnics (King, *etc.*, 1911), but only to a slight degree (Keon and Ross, 1919). Atropine reduces the hyperglycemia considerably (Ross, 1919).

Ether and nitrous oxide also increase the glycosuria and D ÷ N ratio in phlorhizine diabetes, the extra sugar being derived from glycogen, probably through tissue-asphyxia (Sansum and Woodyatt, 1915).

Hawk, 1911, attributes the ether glycosuria to dyspnea. Grube, 1911, believed that the cooling was a factor; but Ross and Hawk, 1914, find that the glycosuria is not due to fall of temperature. Ross and McGuigan, 1915, claim a direct action of the ether, and that asphyxia and excitement are not essential.

Diastatic Activity of the Blood.—This is increased parallel to the rise of blood sugar (Killian, 1917).

Renal Irritation.—Postanesthetic albuminuria occurs in about one-fourth of ether anesthetics, and about one-third of chloroform (Wunderlich). Tube casts are also common. With previously sound kidneys, the renal irritation usually disappears in a short time. In patients with chronic nephritis there may be fatal suppression of urine; but patients with some albuminuria are often etherized without bad effects. Chloroform is apparently somewhat more injurious than ether, but the difference is not very marked.

Relation of Renal Injury to Age and to the Lipoid Material of the Kidneys.—The renal epithelium of old animals shows greater histologic and functional injury after chloroform or ether, even though the kidney function appeared normal before the anesthesia. This is paralleled by increase of the stainable lipid of the epithelium, which is normally more abundant in old animals, and which is further increased by anesthesia, especially in the old. Chloroform is distinctly more deleterious than ether (MacNider, 1921). Foulerton, 1921, attributes the lipid to infiltration from lipemia, due to hepatic injury.

Acetonuria is frequent after ether or chloroform anesthesia (E. Becker, 1895; Beesly, 1906; Marshall and Rowntree, 1916; ethyl chloride, Telford, 1906; even after local cocaine, Gundrum). With ether, it is not much influenced by the duration of the anesthesia; fasting may be a factor (Chalfant, 1912). It is more common with the close than with the open methods of administration. Children are more susceptible. Bicarbonate has been advised as prophylactic.

J. J. Short, 1920, however, found the acetone substances in the blood and urine practically unchanged in patients who had been under ether for $\frac{3}{4}$ hours; with more prolonged administration, there was a slight increase; but not enough to account for the decrease of blood-bicarbonate.

Acidosis.—Inhalation anesthesia, whether by ether, chloroform or nitrous oxide, tends to reduce the reserve alkali (bicarbonate) of the blood (Menton and Crile, 1915). The reduction is greatest with chloroform (Morris, 1917).

With clinical ether anesthesia, compensated acidosis occurs in 30 to 85 per cent. of routine operations; uncompensated acidosis in 15 to 20 per cent. The average reduction in plasma-bicarbonate is equivalent to 5–15 c.c. of CO_2 per 100 c.c. (Reimann, 1919). The acetone substances of the blood are increased, accounting for at least 60 per cent. of the bicarbonate decrease, and perhaps for all (Reimann and Bloom, 1918).

Killian, 1917, claims that the oral administration of sodium bicarbonate, 20 grams per day, corrects not only the diminished alkali reserve, but also the hyperglycemia. It would be especially indicated if the CO_2 capacity of the plasma before operation is less than 58 c.c. (Reimann and Bloom).

With normal dogs under ether anesthesia, W. S. Carter, 1920, found but little change in the alkali reserve during the first hour; thereafter it fell gradually, but never to a dangerous degree. The fall is not due to hyperpnea, for it occurs also under uniform artificial respiration. It is prevented by inhaling air with $3\frac{1}{2}$ per cent. of CO_2 ; 3 per cent. is ineffective.

McNider, 1921, found the alkali depletion much more marked with old than with young animals; it was also greater with disturbed kidney function. Intravenous injection of sodium carbonate conferred some protection, normal saline injection was ineffective (MacNider, 1918).

Phenolphthalein Output.—The "functional capacity" of the kidney, as measured by this test, is generally somewhat decreased by ether anesthesia. The effect is the greater, the longer the anesthesia. The output is lowest soon after the operation, returning to normal in twenty-four to forty-eight hours. Exceptionally, there may be no decrease, but even an increase; or the decrease may be very large. It has no relation to albuminuria. All shock and collapse conditions lower the phthalein output (R. H.

Miller and Cabot, 1915; Epstein, Reiss and Branower, 1916). Whipple and Sped, 1915, also found the phthalein output lowered after ether, paraldehyde, chloral, chloroform or alcohol anesthesia. They observed that Eck's fistula produced lowered output, as also phosphorus, and therefore attribute the effect to disturbance of liver function.

Anesthetics in Experimental Nephritis.—In dogs rendered polyuric and glycosuric by tubular uranium nephritis, MacNider, 1913, found chloroform anesthesia much more damaging than ether. In full-grown animals, chloroform promptly arrested the urine flow, so that it would not respond to diuretics; it made the histologic lesions much more marked. The damage was much less in young animals. Ether produced but little effect even in adults. (Young puppies are remarkably tolerant also to the other dangers of chloroform; Whipple, 1912.)

Chloroform on Urine Flow.—In man this diminishes steadily during anesthesia (Bovee, 1909). Animals also usually show this decrease, due to the low blood pressure with diminished kidney volume (Thomson and Kemp, 1899). Thompson, 1906, often observed increased diuresis in the early stages, and invariably after recovery.

Chloroform on Nitrogen Metabolism.—Chloroform anesthesia *increases* the total nitrogen excretion (especially in carnivorous animals), and the ammonia, allantoin, diamino-acids, polypeptids, creatinine and organic sulphur. It *decreases* the excretion of urea and of monoamino-acids (Strassmann, 1889; Salkowski, 1889; Noel Paton, 1894; Vidal, 1897; Rostoki, 1901; Howland and Richards, 1909; Lindsay, 1911). The increase persists for some days and may amount to 300 per cent. These changes indicate an *increased destruction but incomplete oxidation of the proteins*. They are similar to those of phosphorus poisoning, and probably depend on the hepatic lesions.

The chloride excretion is increased during and after the anesthesia.

Chloroform Glycosuria.—This is quite common in ordinary anesthesia. The disturbance is probably analogous to ether hyperglycemia (E. L. Scott, 1914) but more profound. There is some dispute as to whether other reducing substances besides dextrose are present (Hawk, 1911). Chloroform diminishes the tolerance to galactose and levulose (Marshall and Rowntree, 1915).

Ether Hyperglycemia.—This does not depend on epinephrine, for it can readily be induced after excision of the adrenals (G.N. Stewart and Rogoff, 1920).

Epinephrine Store.—This is decreased by etherization; not by trauma (Stewart and Rogoff, 1920).

Delayed Chloroform Poisoning (Postanesthetic Toxemia).—The prolonged administration of chloroform may be followed by fatty degeneration of the liver, heart, kidneys; leading to profound toxemia, vomiting, prostration, icterus, and coma, which is often fatal. These results are very exceptional with ether. Postanesthetic toxemia is especially common with children; and in patients with acetonuria, diabetes, hepatic disorders (Hildebrandt, 1913), cyclic vomiting, rickets or wasting diseases.

Symptoms.—The importance of late chloroform poisoning seems to have been first recognized by Bevan and Favill, 1905; although cases had been reported previously. The symptoms start after ten to one hundred and fifty, generally twenty-four to forty-eight hours; the intervening time being indistinguishable from the normal course. They consist in profuse, sometimes incessant vomiting, first bilious, then blood-stained; excitement and delirium, alternating with apathy and prostration; dilated pupils; rapid pulse; icterus; unconsciousness deepening into coma. Death occurs in four to five days (Herb, 1911).

The blood generally shows retention of non-protein nitrogen, urea and amino acids, similar to phosphorus poisoning, though less intensive (E. K. Marshall and Rowntree, 1915).

The *functional activity of the liver, f.i.* the oxidation of phenol, is impaired in chloroform poisoning (Pelkan and Whipple, 1922). Comparative studies on the liver functionation after surgical anesthesia by chloroform, ether, nitrous oxide and procaine were reported by Widal, Albrami and Hutwiel, 1921.

Anatomic Lesions in the Liver.—These consist in extensive vacuolization, fatty degeneration, swelling and necrosis of the cells, especially about the central veins (Nothnagel 1866; Ungar and Junker; Wells, 1906; Howland and Richards, 1909; Whipple and Sperry, 1909; Herb, 1911). The fatty changes are perhaps due to infiltration and not to degeneration (Foulerton, 1921; see also under Phosphorus). The icterus, the disappearance of fibrinogen from the blood; the diminution of liver lipase with increase of plasma, kidney and muscle lipase (Quinan, 1915); the delay of the biliary excretion of

phenoltetrachlorophthalein (Whipple and pupils, 1913); the changes in metabolism; and the occasional occurrence of leucin and tyrosin, must be referred largely to the hepatic lesions, and are analogous to acute yellow atrophy and to phosphorus poisoning. H. G. Wells suggests that they are due to checking of the synthetic processes, whilst the autolytic activity is unimpaired (Quinan). (Large doses of other anesthetics (urethane, Sollmann) cause similar degeneration.) In animals which recover, the liver changes tend to return to normal, even when there has been extensive necrosis (Whipple and Sperry, 1909). Mosiman and Whipple, 1912, found that puppies and feti are less subject to the hepatic necrosis; and that pigeons, frogs and terrapin seem to be immune.

Influence of Experimental Conditions on Chloroform Hepatitis.—W. C. Davis and Whipple, 1919, found that a practically uniform degree of hepatitis can be induced by 1½ hours of light chloroform anesthesia in dogs that had fasted three days. This served as the standard:

Diet.—Starvation renders dogs much more susceptible. More or less marked protection is conferred by feeding with sugar or carbohydrates; skim milk or casein; brain substance. Meat is but slightly protective; fat not at all.

These observations suggest that patients who are to take chloroform should receive liberal quantities of carbohydrates and milk.

The protective action of sugar was also asserted by Graham, 1917, and has been confirmed by Simonds, 1919.

Hepatitis and Diet on Metabolism.—Chloroform hepatitis is accompanied by increased nitrogen excretion, which is greatest in fasting animals; and by the rapid disappearance of hepatic glycogen. Both effects are prevented by feeding sugar, but not by fat. Davis, Hall and Whipple, 1919, suggest that the sugar acts by conserving protein cleavage products.

Influence of Drugs.—Davis and Whipple, 1915 obtained no protection from alkalies. Epinephrine and quinine appeared somewhat protective, the epinephrine, however, only after a day. The addition of other liver-poisons did not markedly modify the effects of the chloroform.

Histologic Changes in Other Organs.—These are also important. Fatty and degenerative changes are seen in the epithelium of the straight and convoluted tubules of the kidneys (Howland and Richards; Apperly, 1912); in the pancreas (Whipple and Sperry); in the suprarenal cortex and other glands of internal secretion (Scaglione, 1915). Involvement of the heart-muscle sometimes dominates the symptoms. Degeneration of the cardiac ganglia has been described (Strassmann, 1898). Small hemorrhagic foci exist in the gastro-intestinal tract, mesentery, pleura and pericardium (Herb). These histologic lesions can be produced, especially in young dogs, by chloroform anesthesia lasting two hours (Whipple and Sperry, 1909; Whipple and Hurwitz, 1911). Repeated chloroform anesthesia, with rabbits, produces degenerative changes also in the central nerve cells and those of Auerbach and Meissner plexus. So do many other poisons, but not ether (Lissauer, 1914).

Cragin and Hull, 1911, point out the similarity of the late chloroform phenomena to *eclampsia*, and suggest that chloroform would be much more injurious than ether in this condition.

McCrudden, 1912, finds that chloroform is more apt to produce fatty changes of the rabbit's heart after *nephrectomy*. Ether does not do this.

Relation to Acidosis.—Lesions resembling delayed chloroform poisoning occur in many intoxications, among others in acidosis. Graham, 1915, assumes a causative relation. He points out that the oxidation of chloroform and other analogous halogen compounds may lead to the production of HCl, and believes that this would produce acidosis, and thus the degenerative changes. It has never been shown, however, that such oxidation actually takes place in the body, especially to a degree that would overcome the very efficient defense mechanisms neutralizing acidity. It is also difficult to explain away the observations of similar degenerations after chloral, urethane, ether, phosphorus, etc., which certainly are not oxidized to acids.

Davis and Whipple, 1919, failed to confirm some of Graham's data, and point out the possibility of technical errors.

Treatment of Anesthetic Acidosis.—W. H. Morris, 1917, finds that the depletion of reserve alkali is largely prevented by the preliminary administration of sodium bicarbonate (15 to 30 Gm. in the 36 hours preceding the anesthetic—sufficient to make the urine alkaline).

Experimental Hepatic Cirrhosis.—This occurs after repeated administrations of chloroform (Mertens, 1896; Herter and Williams, 1905). It is favored by the presence of bacterial infections and may then proceed to acute yellow atrophy (Opie, 1910).

Intravenous injection of ether (large doses in rabbits) causes destruction of liver tissue, with extensive thrombus formation (prevented by leech extract). The mechan-

ism is evidently altogether different from ordinary chloroform degeneration (L. Loeb, 1906; Loeb and Meyers, 1910).

Repeated Anesthesia on Growth.—Schapiro, 1906, found marked retardation in young cats anesthetized every morning and evening for forty-eight days. When this was discontinued the animals caught up, at least partly with the controls. The effect therefore has no practical importance.

Other After-effects of Anesthetics.—These are mainly due to the irritant action, and may therefore occur with either anesthetic. They may be recapitulated as:

Gastric Irritation, Nausea and Vomiting.—Almost universal; vary with duration of anesthesia; less with open methods.

Tympanites.—Especially after abdominal operations; the anesthetics are only contributory.

Renal Irritation.—About equally frequent with either anesthetic.

Aspiration Pneumonia.—More frequent after ether.

CHOICE OF THE ANESTHETIC

This is determined by the particular conditions of the patient and of the operation. Safety should be the first consideration; but the depth and duration of anesthesia, the comfort of the patient, and the convenience of the operator are also important. The principal anesthetics which deserve consideration are: general anesthesia by ether, chloroform, nitrous oxide, ethylene, or ethyl chloride; with or without morphine and scopolamine; spinal anesthesia; and local anesthesia.

For short operations, local anesthesia by procaine or similar drugs should be preferred. Where these are not practicable, nitrous oxide or ethyl chloride are used. Nitrous oxide is the safer. It is practically devoid of danger in short anesthesia.

For longer operations, the advantages of general anesthesia outweigh the disadvantages, as compared with spinal anesthesia. *Chloroform* is far more dangerous than ether, ethylene or nitrous oxide, although with practical experience the acute dangers may be greatly reduced. The chief immediate risks are in the induction period. The danger of post-anesthetic toxemia makes its employment in prolonged operations almost inexcusable.

Ether, ethylene and nitrous oxide are practically equally safe in ordinary cases. *Ether* has several advantages: it is easily administered; it gives more complete relaxation, less asphyxia, and less rise of blood pressure; so that the condition of the respiration and circulation are more nearly normal. Its administration is simple and does not require as much experience; ether being perhaps the safest anesthetic for long operations. The disagreeable features of its administration can be practically avoided by skillful administration. The advantages of nitrous oxide and ethylene appear especially in the cases in which ether is specifically contraindicated.

Contraindications to Ether.—The irritant action contraindicates its use (and also that of chloroform) in *renal disease*, and in *acute respiratory disease* (colds, bronchitis). In these, nitrous oxide is preferred, although ether is often employed without damage. Chronic respiratory disease is not a contraindication, unless there is actual dyspnea (emphysema).

Children are especially subject to ether irritation, resulting in respiratory embarrassment and choking. Ether favors bleeding, especially in parts in contact with the vapor; it is therefore not popular for operations

of the mouth and larynx. In *brain tumor or atheroma*, ether and especially nitrous oxide may produce apoplexy; local or spinal anesthesia should be preferred. *Advanced heart disease* makes all anesthetics more dangerous. In this respect, ether and nitrous oxide are about equal; both should be preferred to chloroform. The danger is proportional to the functional condition, rather than to the valvular lesion: With fair compensation, ether can be used safely; indeed, the circulation may be rather improved during the anesthesia. In advanced fatty degeneration, it is better to employ local or spinal anesthesia. In *hot climates*, above 93°F., ether is vaporized so rapidly that its use by the ordinary methods is difficult.

Nitrous Oxide.—This is the safest anesthetic for short operations. If the anesthesia lasts longer than an hour, it becomes somewhat more dangerous than ether even in the hands of experts; and much more dangerous if experience is limited (Bevan, 1915). It is more pleasant to take; it causes no irritation, and but little excitement or gastric disturbance. It has little or no influence on immunity. There are practically no after-effects. According to Crile, it lessens the tendency to shock. It is especially preferred for short operations, and for excitable and neurotic patients. Old individuals are good subjects.

Disadvantages.—On the other hand, the muscular relaxation is less complete; it causes more or less asphyxia and abnormal rise of blood pressure; it is expensive; and it requires special apparatus and special experience for its successful administration. It is not appropriate for children under three years, since their thorax is too feeble to withstand the asphyxia. Obese or anemic patients are also unsuited to all anesthetic methods which interfere with respiration.

Ethylene.—This is in most respects intermediate between ether and nitrous oxide. It is discussed in a separate section.

Advantages of Chloroform.—Its continuance in practice is due to its convenience for patient and operator: Its action is much more rapid than that of ether; it induces the most profound anesthesia and relaxation; it does not have the disagreeable taste, causes less suffocation, less excitement, and less postoperative nausea and vomiting. These disagreeable features of ether can be largely avoided by proper administration (preliminary gas, and open-drop method). At their worst, they are not enough to offset the dangers of chloroform. These should only be risked in emergencies; when prompt anesthesia is imperative; in brain surgery, atheroma and aneurism, where the lowered blood pressure is advantageous; and possibly on the battlefield to increase speed and lessen bulk. It has no advantage over ether in renal disease, and but little in respiratory diseases.

Specific contraindications to chloroform are: advanced heart disease, Graves' disease, hemorrhage, prolonged operations, and the conditions which favor acidosis.

Chloroform in Obstetrics.—It is quite generally believed that the use of chloroform in childbirth is relatively safe (J. Hill, 1916). This is explained partly by the lesser apprehension of the patients, and partly by the light degree of anesthesia or rather analgesia, which ordinarily suffices. For deep anesthesia, it is doubtless quite as dangerous as for other patients, and presents the added disadvantage of delaying labor and thus favoring postpartum hemorrhage. The analgesic dosage does not cause serious delay. The anesthetics pass into the fetal circulation (Jung, 1914); and prolonged anesthesia is probably as injurious to the child as to the mother.

Chloroform Analgesia.—A light chloroform anesthesia is used to dull the excitability of the central nervous system, in *pain* or *insomnia*; and to *check convulsions*, as those of strychnine, tetanus, or eclampsia. It is especially useful in the onset of these conditions: when the convulsions are fully developed it must be used cautiously, to avoid asphyxia.

For the production of the light anesthesia, chloroform is preferred to ether, since it can be more easily regulated, and its effects are more lasting.

A very deep degree of anesthesia is employed in *reducing dislocations*, to relax the tone of the opposing muscles.

Ether is probably safer.

Fixed Dose Self-inhalation Chloroform Analgesia.—A single dose of 5 c.c. of chloroform, poured on cotton and inhaled from the hand, produces a very effective analgesia, with slight confusion, but without unconsciousness, nausea or dangerous effects. The action is complete in five minutes and lasts about 20 minutes. The method has been used successfully for painful dressings and short operations (Sollmann, 1918; Sykes, 1919).

Ether Analgesia by Oral Administration.—This has been employed for similar purposes. The action is more lasting, but not always as efficient. The dose consists of an ounce of a 50 per cent. solution of ether in liquid petrolatum, sandwiched between two drinks of port wine. The petrolatum is intended to act as an automatic regulator for the evaporation and absorption of the ether vapor (Gwathmey and Karsner, 1917).

A similar suggestion has been made for ethyl chloride (Baskerville and Hirsch, 1921).

Statistics of Anesthetic Mortality.—No reliable statistics of sufficient extent can be available until the reporting of all anesthetics, good and bad, is compulsory. Even then, the ratio of "bad risks" will be indefinite. The existing statistics therefore give only a rough idea of the relative danger; but since they agree fairly well, they are worth considering. Modern American statistics are given by Gwathmey, 1912. According to the various compilations, the acute mortality for *chloroform* is given as 1:1,000, 1:2,075, 2,500, 3,000, 3,000, 3,500, 3,700, 5,900; a fair estimate would seem to be 1:3,500. This does not take account of the delayed deaths. For *ether*, the figures run 1:5,100, 14,000, 14,600, 16,500, 16,800, 23,200; the average would be perhaps 1:16,000. For *A.C.E. mixture*, the ratio is 1:3,370; for *ethyl bromide*, 1:5,400; for *ethyl chloride*, 1:3,000, 7,000; for *nitrous oxide* in short operations (dentistry), less than 1:5,000,000.

Anesthetic Mixtures.—The attempts to blend the actions of anesthetics by mixing them have been unsuccessful, mainly because the ingredients do not volatilize with equal rapidity (Snow). The composition of the inspired anesthetic is therefore absolutely uncertain. As a rule, the concentration of the chloroform increases during the administration. The administration is further complicated by the different sequence of the disappearance of the reflexes with chloroform and ether (van Leeuwen, 1916). These mixtures are therefore at least as dangerous as chloroform, and should be condemned (Kochmann, 1903).

The principal mixtures of this type are the *English A.C.E. mixture*, introduced by Harley (A₁; C₂; E₃);¹ *Billroth mixture* (A₁; C₃; E₁); *C. E. mixture of Hewitt* (C₂; E₃); *Schleich mixture* (benzin 1 : C₃ : E₁₀). Other mixtures containing ethyl chloride or bromide, etc., have also found advocates. The alcohol and benzin of these mixtures were intended mainly to raise or lower the boiling-point, but benzin is not indifferent. The statement of Schaefer and Scharlieb, that the addition of 10 per cent. of alcohol to chloroform practically prevents the fall of blood pressure, needs confirmation. However, there seems to be some combination between ether and chloroform; for on mixing equal volumes (25 c.c.) the temperature is said to rise 14°C. (Marcelet, 1912).

Synergism of Ether and Chloroform.—Analysis of the concentration of the anesthetics in the blood show that mixtures of the vapors do not exhibit a potentiated effect, but a rather imperfect summation of action. Earlier work with imperfect methods gave contradictory results: Honigmann, 1899, and Kionka and Kroenig, 1905, apparently obtained considerable potentiation; while Madelung, 1910, and Buerger, 1910, found only simple summation and Damkoehler, 1913, obtained different results for different depths of anesthesia.

Combination with Aliphatic Hypnotics.—This gives rather complex results, Barten, 1913; ordinary hypnotic doses, combined with inhalation, rabbits; with *ether*, chloral and barbital do not materially lower the vapor concentration required for light anesthe-

¹ The proportions of all the mixtures are by volume. A, stands for alcohol; C, for chloroform; E, for ether.

sia; but reduce that for deep anesthesia by 30 per cent., and paraldehyde even by 50 per cent. The zone of safety is normal. With *chloroform*, chloral and barbitol also reduce the deep-anesthesia concentration, but still more the fatal concentration; so that the danger is greater. Paraldehyde acts as with ether, so that its use would be advantageous.

Mansfield and Hamburger, 1915, believe that ether actually potentiates with chloral or morphine, by favoring their distribution into the nervous system.

Ether-magnesium Anesthesia.—The combined use of these anesthetics was proposed by Meltzer, 1913, for laboratory animals. Le Heux, 1919, showed that there is only simple summation between magnesium salts and ether, chloral and urethane, at least as to the reflexes of decerebrated cats.

Gwathmey et al., 1924, introduced a more complex *combination for obstetric analgesia*. They administer 0.1 Gm. of morphine hypodermically; one to three hypodermic injections of 2 c.c. of 50 per cent. magnesium sulphate; and a colon injection of ether 75 c.c., quinine hydrobromide 0.6 Gm., and olive oil, q.s. 120 c.c. Their paper should be consulted for the details.

Sequence Anesthesia.—A more rational method of combining the advantages of anesthetics is to employ them in sequence; particularly to induce anesthesia by the pleasant and promptly acting nitrous oxide oxygen inhalation, and to continue it with ether. This probably presents the nearest approach to an ideal anesthesia.

Chloroform was formerly used for the preliminary anesthetic, but presents considerable danger. Ethyl chloride may be employed successfully. Nitrous oxide without oxygen is not so satisfactory, because the ether must be pushed rapidly, to avoid asphyxia or return of consciousness, and the concentrated vapor is apt to cause sudden laryngeal spasm (Cunningham and Anderson, 1908). Hewitt endorses the sequence of C. E. mixture (to two to six minutes), with the gradual addition of ether, by the open method. Changing from full ether anesthesia to chloroform is especially dangerous (Hewitt).

Morphine, Scopolamine or Atropine Preliminary to Anesthesia.—One or several of these drugs are often injected hypodermically, half an hour before starting the operation. They diminish the anxiety of the patient and avoid some of the dangers of anesthesia. The doses as given below may be combined.

Morphine (10 to 15 mg., $\frac{1}{6}$ to $\frac{1}{4}$ gr.) is most effective in decreasing apprehension, excitement and struggling. Labbé and Guyon, 1872, were the first to use it clinically. It makes anesthesia prompter and smoother. It reduces materially the quantity of anesthetics, and thereby the gastric, pulmonary and toxic after-effects. The patient does not awaken so early. Since the morphine narcosis involves an entirely different mechanism, the side effects of both are probably relatively smaller. On the other hand, morphine depresses the excitability of the respiratory center, and the miosis interferes with the pupil danger signal; morphine is contraindicated in pulmonary disease, in semicomatose patients, or when the operation would involve bleeding into the air passages. On the whole, the marked advantages appear to outweigh the disadvantages, although many anesthesiologists condemn its routine use.

Morphine reduces the concentration of ether or chloroform vapor required for light anesthesia, but not that for deep anesthesia or death. The margin of safety is therefore widened considerably—60 per cent. for chloroform, 50 per cent. for ether (Stange, 1913; Kochmann, 1914). However, the respiration must be carefully watched with chloroform, for this also shows dangerous potentiation (Wolff, 1913; W. Straub, 1913).

Atropine (0.3 mg., $\frac{1}{200}$ gr.) stimulates respiration and is therefore often added as a corrective to the morphine. It also diminishes the reflex vagus stoppage of the heart by chloroform, and ether salivation and bronchorrhea,

thereby lessening the occurrence of ether pneumonia. The atropine mydriasis and tachycardia interfere with the use of the pupil and pulse as danger signals. The above dose should not be exceeded on account of occasional idiosyncrasies.

Scopolamine (0.5 mg., $\frac{1}{120}$ gr.) is often substituted for the atropine. It has the same peripheral actions on the pupil and glands, but greatly intensifies the narcotic effects of morphine. On the other hand, it disposes to pronounced vasodilation, so that the pressure falls as deeply in ether anesthesia as with chloroform (Mayor, 1908). Moreover it sometimes intensifies the respiratory depression of morphine to a very dangerous degree. This danger is so serious that its use is not advised. Bevan, 1915, who opposed it strongly, believed that it also increases the percentage of vomiting and of bladder paresis.

The combined action of morphine or scopolamine with the hydrocarbon narcotics is far more than simple addition (Knell, 1907; Hauckold, 1910; Lindemann, 1910; Hamerschmidt, 1910). Madelung, 1910, and Rappaport, 1911, find that one-half to two-thirds of the ordinary concentration of anesthetics suffices. Buerger, 1911, proposed a receptor theory in explanation; but this is not generally accepted. Fuehner, 1911, found that the lipolytic narcotics change the lipid solubility of morphine, and thus presumably favor its penetration and action.

Scopolamine alone does not reduce the concentration of chloroform or ether required for light anesthesia, but lessens somewhat that for deep anesthesia. Scopolamine and morphine together resemble morphine; except that they do not increase the zone of safety. The anesthesia is deeper, however; and this may be practically important (Ludewig, 1913; Jochmann, 1914).

Bromides.—These give practically only simple summation with morphine or the aliphatic narcotics (Klammer, 1913).

Strychnine (1 to 2 mg., $\frac{1}{60}$ to $\frac{1}{30}$ gr.) has been suggested when respiratory failure is feared (Fothergill). Its usefulness is doubtful.

Cocainization of the nasal mucosa has been employed to avoid the trigeminal vagus reflex.

Preparation of Patient for Anesthesia.—The patient usually receives a cathartic (castor oil) twenty-four or thirty-six hours before the operation, and an enema on the morning. An interval of at least five hours should have elapsed since the last meal, which should not have been too heavy. These precautions are to prevent the discharge of the contents of the alimentary canal during the anesthesia. He should be carefully examined for cardiac, renal and pulmonary disease. He should then be placed in such a position as to interfere to the smallest possible extent with respiration; the head preferably low and turned to the side. The clothing should be loosened and all foreign bodies—false teeth, etc. removed from the mouth.

To prevent the local action of the anesthetic on the face, it is well to anoint the mouth and nose with petrolatum. Care should be taken to have the patient close his eyes.

The Administration of Anesthetics.—Inhalation is superior to all other methods in the convenience of its application, and in the facility with which the depth of anesthesia can be regulated to suit the needs of the moment. It must be remembered that this depends solely on the concentration of the anesthetic vapor. This could be regulated either by using exactly dosed mixtures of anesthetic and air, or more simply, and on the whole more efficiently, by watching closely the condition of the patient. The response of the respiration, pupils and other reflexes to changes in the concentration of the vapor must be studied. The concentration can be increased either by pouring the anesthetic more rapidly; by

applying the mask closer to the face; or by limiting the supply of air. With either anesthetic the mask should at first be kept fairly away from the mouth, until some narcotic effect is obtained, to lessen the feeling of choking from the concentrated vapor. The patient should be encouraged to breathe quietly and regularly. Counting is a good expedient for this purpose. If the patient holds his breath, struggles or coughs during the induction of the anesthesia, the concentration should be temporarily reduced, not increased. Rapid and deep breathing lessens the concentration of the anesthetic by dilution and cooling. Slow and shallow breathing gives more concentrated vapor. Warming the anesthetic liquid also increases its evaporation and concentration (Snow).

Management during Recovery from Anesthesia.—The patient should not be left until he is fairly conscious, since vomiting, inspiration of mucus, etc., might cause asphyxia. No nourishment should be given for at least four hours. If vomiting is persistent, a tumbler of hot water, with a teaspoon of bicarbonate may be given. Recovery is usually more speedy and satisfactory if the patient is placed on his side.

Special apparatus for supplying measured concentrations can be constructed (Dreser, 1896; Geppert, 1899; Kionka, 1895 and 1899; Kochmann, 1913; Jackson, 1915, etc.), but they are complicated and cumbersome. (A simple form is that of A. V. Harcourt, *Suppl. Brit. Med. Jour.*, 1903, p. 143.) Another objection to standardized mixtures is the slowness with which they produce anesthesia. It is certain that much stronger mixtures may be borne for a short time, and are quite safe in starting the anesthetic.

Regulation of Anesthesia.—No mechanical device can replace the sense of responsibility, the constant watchfulness, and the quick reasoning of the experienced anesthetist. Anesthetization is not a physical experiment where the factors can all be foreseen, but the condition of the patient is apt to vary from moment to moment, and must be taken into account. The state of the respiration must be carefully watched: if the patient holds his breath, the mask must be held farther away, since the next respiration will be an especially deep one. When the respiration becomes slow and shallow, a sufficient amount has been taken, and the concentration may then be diminished. The aim is to give no more than is necessary to just keep the patient anesthetized. On the other hand, care must be taken to keep him thoroughly under the influence, for excitement, struggling, stoppage of respiration, shock and overdosage are much more common under partial or uneven anesthesia. Since the respiration and circulation react one upon the other, so that no change could occur in the latter without being noticed in the former, and since most accidents occur from stoppage of the respiration, it may be sufficient to watch this alone, as is advised by some. But as it is of the highest importance to discover beginning failure of the one or the other at the earliest possible moment, the anesthetist cannot be considered as doing his duty unless he carefully observes both. The argument that watching the circulation distracts the attention from the respiration should not hold: the anesthetist must learn to keep his attention fixed upon both.

Closed and Open Methods of Administration.—The anesthetics may be administered with (open) or without (closed) free access of air. In the closed methods, the patient rebreathes more or less from a permanent mixture of vapor through a fairly air-tight mask or cone. In the open methods, he breathes air freely through gauze (the usual chloroform mask), on which the anesthetic is poured. The closed methods are more rapid

and economize the anesthetic; but from other standpoints they are rather objectionable. The open methods avoid the asphyxial effects, and are therefore pleasanter, safer, and less subject to after-effects (mucorrhea, vomiting, etc.). The apparatus is also simpler and more easily sterilized. The open methods deserve preference, except for very short operations, or when rapid anesthesia is important. The closed method, however, is also capable of refinement. Henderson, 1915, advises a closed method with ether vapor, claiming that this is scarcely more unpleasant than nitrous oxide and produces less nausea, vomiting, gas pains, etc., than other methods. The skin should be kept pink, neither pale (acapnia) nor dusky (asphyxia).

Inhalation of Carbon Dioxide.—Y. Henderson and Haggard, 1918, advise post-anesthetic inhalation of air containing 1 to 8 per cent. tension of carbon dioxide, to counteract the general depression that otherwise persists for several hours after profound ether anesthesia. This expedient usually stimulates the respiration; and in this manner promotes the more rapid elimination of the ether. The blood pressure is restored more promptly, and the patient is said to be practically normal in half an hour. The frequency of nausea and vomiting also appears to be diminished; and the originators believe that gas pains and intestinal atony are prevented.

In the *induction of anesthesia*, the stimulation of respiration by five per cent. carbon dioxide hastens the attainment of equilibrium between the anesthetic vapor and the tissues, and therefore permits the use of lower concentrations. This should diminish local irritation (Haggard, 1924). It is perhaps too early to decide whether these concentrations of carbon dioxide are entirely harmless in themselves.

Administration of Ether by the "Cone" Method.—A special mask is used, which admits only a limited amount of air. About a tablespoonful is poured in the mask, and repeated as needed. The fact that the required concentration of ether is much greater than with chloroform, leads to the temptation not to admit sufficient air. This must be carefully guarded against, or asphyxial symptoms may result simply from a deficient supply of oxygen. Concentrations of ether above 7 per cent. irritate the mucosa so strongly that in imperfect anesthesia, they cause reflex coughing, closure of the glottis and suffocation (Dreser, 1893).

To obviate the asphyxia it has been advised to administer oxygen with the ether (Guy, Goodall and Reid, 1911); but this is superfluous, especially if the drop method is used.

Ether by the "Drop" ("Open" or "Perhalation" Method).—This avoids to a very great extent the irritation, suffocation and excitement of ordinary ether anesthesia. This advantage more than compensates for the disadvantages, the relative slowness, waste of ether, saturation of the room, and refrigeration of the inspired air. In this method, the ether is dropped rapidly (about 150 drops per minute) over the entire surface of an open (chloroform) inhaler, covered with some eight layers of gauze, and held an inch from the face. If the mask is closely applied, the vapor concentration may rise to 9.3 to 10.8 per cent.; never above 12 per cent. (The method was originated by L. H. Prince, 1895.)

Danger of Open Lights.—The vapor of ether being highly inflammable and explosive, this anesthetic should not be used with the actual cautery or by an open light. The flame may leap over considerable distance, especially if there are drafts. If the use of an open light is unavoidable, it should be placed *high* above the patient, since ether vapor is heavier than air.

Ethylene is even more explosive than ether, so that serious accidents have resulted from sparks of static electricity.

Chloroform is not explosive; but if used with an open light, it is partly oxidized into phosgene gas (COCl_2 , carbonyl chloride), chlorine and hydrochloric acid, which cause considerable irritation—cough, dyspnea, collapse (Langenbeck, 1888). Fatality to the spectators has been reported (see Gerlinger, 1902).

The decomposition of chloroform may be illustrated by the equations:

The inhalation of the burned chloroform vapor by rabbits produces dyspnea, pulmonary edema, and sometimes death (Stobwasser). The toxicity of phosgene was shown by R. Mueller, 1910.

Administration of Chloroform.—This is dropped on a few layers of gauze, supported by a frame, and held some little distance from the face. The rate should under no circumstances exceed 60 per minute, and usually should not be over 12. After the anesthetic stage has been induced 6 drops per minute will usually suffice. This is better than to remove the mask altogether and reapply it with a large dose when the patient shows signs of recovery.

Self-inhalation of Chloroform.—It may become necessary to keep patients lightly under the influence of an anesthetic when no skilled assistant is available, as in obstetric practice. Here a method suggested by Brunton is useful:

The inside of a tumbler is covered with blotting-paper. A few drops of chloroform are poured on, and this is given to the patient, with directions to hold it an inch from her mouth and inhale. This works automatically, for as the patient becomes narcotized she naturally allows her hand to drop, and so removes the tumbler; and as soon as she becomes conscious and sensitive to pain, she will replace it.

The quantity of anesthetic which is required for an ordinary operation is very variable. Some 40 c.c. of chloroform, or 150 c.c. of ether, by the ordinary method, or 250 c.c. by the drop method, are about the smallest quantities for an hour's anesthesia.

"One-minute Anesthesia."—Short operations can be done under the analgesia of the preanesthetic stage: A teaspoonful of ether is poured into the cone, and the patient directed to count and take deep inspirations. The operation is done as soon as the counting becomes irregular.

Other Methods of Administration.—The anesthetic may also be administered by other methods, but these demand special experience, and generally special apparatus, and therefore have a more limited field.

In operations about the face, the anesthetic may be inhaled through a *nasal catheter*; in operations on the thorax, it may be administered by tracheal insufflation.

Intratracheal Insufflation.—The insufflation of air passed over the anesthetic has been elaborated experimentally by Githens and Meltzer, 1913. It eliminates respiratory paralysis as a fatal factor. Ether is especially safe: Excessive doses first stop the spontaneous respiration, but this is immaterial since the insufflation constitutes an efficient artificial respiration. The blood pressure declines very slowly, and recovery is possible during an hour after the respiration is arrested, by simply stopping the ether. With *chloroform*, the respiration and circulation fail together, so that there is no reliable danger sign, and the zone of safety is much narrower.

Unskillful insufflation presents various dangers (George, 1917).

Intrapharyngeal Insufflation.—In this, the ether is driven by bellows through a nasal catheter; usually after anesthesia has been induced by the open method. It is about as simple and safe as the open method (Bevan, 1915).

Rectal insufflation of the warmed ether vapor is especially useful in operations about the head; it also avoids excitement, struggling, and gastric disturbance. It acts promptly (within six to fifteen minutes) and can be maintained indefinitely. However, it is uncomfortable; the dosage is more difficult; it is apt to be followed by severe, sometimes fatal, irritation of the colon, with gas distention, colicky pains and bloody diarrhea (Cunningham, 1920; Morel, 1910; Bevan, 1915). The fatality is fairly high.

Rectal Ether-oil Anesthesia.—Operative anesthesia may be produced by the rectal injection of a mixture of equal parts of ether and oil. However, several fatalities have occurred, presumably because the dosage has not been satisfactorily worked out.

Intravenous administration of saline solutions of the anesthetics (ether, 5 per cent., Burckhardt, 1910; 7.5 per cent., Rood, 1911; chloroform, 0.6 per cent., Giani, 1910), produce anesthesia; but *a priori*, one would consider the method both unsatisfactory and dangerous; and this seems to agree with the practical experience (Tyrode, 1910).

Solubility of Ether in Normal Saline.—This varies with the temperature as follows (Bennett, 1912):

°C.	Gm. of ether per 100 c.c. Saline	°C.	Gm. of ether per 100 c.c. Saline
0.....	13	20.....	6.9
5.....	11.2	25.....	6.0
10.....	9.5	30.....	5.3
15.....	8.1		

Intramuscular injection of undiluted ether has also been tried. The method is uncertain, painful and dangerous (see J.A.M.A., 1912, vol. 59, p. 288, Guibe, 1912).

Gastric administration of an alcoholic solution of chloroform is used in animal experimentation, but is too uncertain and dangerous for man.

Induction of Anesthesia during Sleep.—This question is of some medico-legal importance. Cases are reported (Brouardel, *Les Asphyxies*, p. 199), but it must be difficult, and consequently rare. False accusations of criminal assault are often based on the mental confusion of the patient while in the induction stage.

Causes of Death under Anesthesia.—These must be thoroughly understood in order that accidents may be avoided. They may therefore be recapitulated. They differ according to the anesthetic, the stage of anesthesia, the character of the operations, diseases of the patient, and other conditions. On this account the clinical accidents are rather different from the usual laboratory experiments.

Death Not Always Due to Anesthetic.—It is incorrect to attribute every death upon the operating table to the effects of the anesthetic; for patients died upon the table when anesthetics were yet unknown.

One such case was of considerable importance in the history of anesthesia. When Simpson was about to try chloroform on a patient for the first time, the orderly who was carrying the bottle fell and spilled the chloroform. No other being obtainable Simpson proceeded to the operation, which was for hernia, without anesthesia. The patient died with the first cut. Had the chloroform been given in this case and the same accident had happened, its introduction into practice might have suffered a long delay. Other similar cases are not unknown: A patient was to be operated and demanded chloroform. His condition, however, was so low that the surgeon feared to grant his wish, and to calm him held a cloth *without* chloroform before his face. Scarcely had the patient made four inhalations—of air—when he was dead. In preanesthetic days, the French surgeon Desault drew his fingernail over the perineum of a patient to mark the line of incision, when the patient suddenly gave a cry and was dead. And many similar cases of sudden death from the violent mental impression might be mentioned, besides deaths undoubtedly due to traumatic shock. Even at the present day patients often exhibit "psychic shock" when operated under local anesthesia, so that it is a general practice to precede this by morphine (Strassmann, 1898).

It is true that the public nowadays has largely lost the great fear for operations and that anesthetics lessen the danger of traumatic shock. But neither is excluded, and there is no doubt that many deaths attributed to anesthetics have their cause elsewhere.

State of Patient.—Healthy, vigorous patients are not the safest risks in anesthesia, but rather the relatively feeble and phlegmatic: These are less subject to excitement, struggling and muscular obstruction of respiration, and they require less anesthetic. Nervous, apprehensive patients and alcoholic subjects are always difficult to anesthetize. "*Status lymphaticus*" and *Graves' disease* predispose to acute circulatory failure from trivial causes, fright, excitement, etc. *Respiratory catarrh* tends to obstruction of respiration by mucus, especially if ether is used. Acute pulmonary diseases dispose to asphyxia; advanced heart disease to circulatory failure.

Death during the Induction of Anesthesia.—This is common with chloroform, rarer with ether. In a series of twenty chloroform deaths in which the time was noted, a third occurred within five minutes, and a half between six and fifteen minutes after the start of the administration (quoted from Brouardel, "Les Asphyxies," 1896).

The usual sequence of events is sudden suspension of the respiration from acapnia or muscular spasm; the asphyxia leads to cardiac dilation, vagus stimulation, and finally asphyxial failure of the heart. The failure is especially rapid with *chloroform*, because this adds the direct cardiac action of the drug. In light chloroform narcosis, the cardiac muscle is hyperexcitable; and any excitement is apt to induce ventricular fibrillation and death (G. Levy, 1913; this excitability disappears in deep anesthesia). The respiration may resume temporarily after the heart has stopped, but the heart itself can not usually be revived. Failure of the circulation therefore commonly precedes the final arrest of respiration and is the real cause of death.

In the case of ether, similar fatalities are rarer, but may occur early or somewhat later—in either case due to faulty administration during incomplete anesthesia. The error may have been committed an hour before actual death: In light ether anesthesia, the excitability of the respiratory center is increased. If this state is prolonged by excessively slow, incomplete or intermittent anesthesia (*f.i.*, in throat operations), acapnia results. When the anesthesia deepens and the center becomes depressed, the acapnia (deficiency of CO₂) leads to arrest of respiration and injury to the heart (Henderson, 1911).

Stoppage of respiration by *ether* is less dangerous, because the more vigorous heart generally beats until the respiration has resumed. Experimentally, the heart may also be stopped reflexly by vagus stimulation, but clinically this seems to be exceptional. In any case, the phenomena occur with little warning. The *danger signs* are sudden dilation of the pupils, pallor, and change of facial expression.

Too high concentration of the vapor is the immediate cause of these actions. Fright, excitement, struggling, irregular respiration and idiosyncrasy are contributing factors. Crying in children is especially dangerous. These accidents are avoided by beginning the administration with very dilute vapor, and increasing the concentration gradually. Morphine helps to prevent acapnia and fear. Atropine eliminates the vagus reflex.

Death in deep anesthesia is usually due to paralysis of respiration, generally with more or less involvement of the circulation. With *ether*, the circulation is usually fairly good when the respiration stops. The arrest may be due to exaggerated response to inhibitory reflexes, especially from the vagus or superior laryngeal (Mann).

With *chloroform*, there is a progressive fall of blood pressure, then failure of the respiration, and finally cessation of the heart; but the pulse is generally imperceptible before the respiration stops. These late accidents are caused by maintaining the concentration of the vapor too high; and since the paralytic phenomena develop gradually, with ample warning, these deaths are generally due to inexperience of the anesthetist. The *danger signals* are: increasingly shallow or irregular respiration; very, slow or very rapid pulse; cyanosis; dilation of pupil. These accidents may be avoided by carefully watching for these signs, by maintaining the anes-

thesia evenly, and no deeper than complete muscular relaxation and absence of the sensitive reflexes.

The **autopsy** in acute chloroform or ether deaths shows nothing beyond the ordinary phenomena of death by asphyxia—heart distended, veins congested, etc.

Poisoning by Swallowing Chloroform.—This usually produces immediate vomiting and sometimes defecation, followed by narcosis (Schoenhof, 1914). The acutely *fatal dose* is not known; an ounce or more would be dangerous. Recovery may be succeeded by fatal gastritis or icterus and the other phenomena of late chloroform poisoning. The treatment would be as for inhalation. Gastric lavage with oil has been advised (Wirth, 1909).

Treatment of Accidents.—The *tongue* may fall back and interfere with respiration, as denoted by noisy breathing. If this occurs, "place the index finger of each hand upon the corresponding cornua of the hyoid bone, while the middle fingers rest upon the angle of the jaw, and then press forward and upward, the same force serving to extend the head upon the neck; if this fails to open the glottis, by means of a tenaculum, thrust far back into the base of the tongue, draw it forward" (H. C. Wood).

If the mucus accumulates, it should be removed with a cloth (Mayor suggests the dental saliva siphon).

Serious Accidents.—These should be treated with the first warning of danger: The anesthetic should be stopped at once. The head of the patient should be lowered to give the medullary centers and heart the full benefit of any remaining circulation. A few rhythmic compressions of the epigastrium may be tried, but if these do not succeed quickly, *artificial respiration* by any of the methods should be begun at once. This prevents asphyxia and eliminates the poison. The cardiac region should also be compressed strongly at the rate of 40 times per minute, since this aids the action of the heart and supplies a mechanical stimulus. A liter of saline solution and 1 c.c. of 1:1,000 solution of epinephrine may be at the same time injected into the cardiac end of an artery. The combination of these measures may succeed, when the heart has actually stopped beating (Crile and Dolley). The chances of success are proportional to the promptness with which they are applied. Gunn and Martin, 1915, recommend the combination of intrapericardial injection of epinephrine with cardiac massage. This may be successful even when the heart is arrested and either measure alone would fail.

Of *drugs*, strychnine, or caffeine, by virtue of the stimulation of the respiratory and vasomotor centers, are useful if given in time—*i.e.*, while they may still be absorbed. Digitalis is too slow in its action. Oxygen is of uncertain advantage. *Reflex stimulation* by the inhalation of ammonia is sometimes remarkably effective; as is sciatic stimulation. *Hypodermic injections of ether* which have been used in man, might be supposed to act in the same manner. But clinical observers condemn their use, and experiments on animals show that the stimulus is too weak to produce much effect. On the other hand, it would tend to deepen the narcosis. The administration of brandy or nitroglycerin is similarly useless, though not quite as harmful. *Faradization* of the phrenic nerve or of the heart has also been advocated, but appears to be prompted more by the desires to do something than by any rational view of the object to be accomplished. Stimulation of the phrenic, to be sure, causes contraction of the diaphragm and inspiration, and if done intermittently, would take the place of artificial respiration. But it possesses no advantage over the latter, and besides the fact that the time required to adjust the apparatus might be much better utilized, there is apt to be stimulation of the vagus—a most undesirable feature.

With regard to faradization of the heart, there is no more effectual way known of killing this organ than electric stimulation (by the production of delirium cordis), and

the only reason why more harm has not been done by this senseless procedure is that the electricity, as it is ordinarily applied, does not penetrate through the chest walls.

Epinephrine in Light Chloroform Narcosis.—While epinephrine may be very valuable in deep narcosis, it is apt to cause dangerous arrhythmia in light chloroform anesthesia. This may be prevented by atropine, or section of the vagi; but if the arrhythmia has already started, atropine only adds to the danger (Nobel and Rothberger, 1914).

Idiosyncrasy.—This doubtless occurs, in analogy to alcohol; however, the actual concentration of ether required to induce and maintain anesthesia is about the same, whether the patient is refractory or otherwise (Boothby, 1914). The greatest practical differences in the reaction of patients consist in the manner of "taking" the anesthetic. They are therefore most conspicuous in the induction of anesthesia, which is peculiarly difficult in alcoholic patients. (Boothby, 1913, attributes their resistance to deep breathing, blowing the ether off the mask.) Morephinists are said to be relatively insusceptible. Patients with Graves' disease may react badly. A patient may tolerate one anesthetic better than another.

After the anesthesia is established, there is but little evidence of "peculiar" reactions, except such as may be foreseen in heart disease. Fatal accidents should therefore not be lightly ascribed to idiosyncrasy. The postanesthetic toxemias, however, are undoubtedly influenced by the individuality of the patient.

Mansfeld (1905) claims that **starved animals** are much more susceptible to chloral, paraldehyde and morphine but not to alcohol, amylene hydrate, or urethane.

Impurities.—The impurities which may occur in ether and chloroform, mainly by decomposition, are rather unimportant. They contribute to the local irritation, but probably not to the dangerous effects. Anesthetic fatalities seem to be as frequent with the "pure" chloroform or ether as with that not specially treated. However, the patients, are entitled to the benefit of the doubt, and the purest obtainable undeteriorated samples should be employed. In case of accident, inquiry should be made whether other patients have reacted abnormally to the same lot of the anesthetic agent.

The impurities of ether are due to the presence of moisture, which leads to complex oxidations. Among the products are hydrogen peroxide and most commonly the irritant aldehyde. Bruns, 1895, concluded from clinical observation that the ether impurities are mainly responsible for the bronchitis (R. B. Smith, 1913). Henderson, 1914, considers poor ether as more excitant, disposing to apapnia. Ether also very generally contains some ethylene, which is probably unimportant. The presence of alcohol slows the rate of evaporation, and may be necessary when the ether is used in high altitudes or at a high temperature.

The impurities of chloroform are also due to oxidation, accelerated by light and acids. The products vary with the conditions. The most constant are the irritant phosgene (carbonyl chloride) and hydrochloric acid.

Modified Ether.—Claims have been made, on the basis of rather far-fetched theories that pure ether is not truly anesthetic, and that it requires the addition of 2 per cent. of ethylene and $\frac{1}{2}$ per cent. of carbon dioxide to produce ideal anesthesia (Cotton, 1917). These assertions are untenable; for pure ether devoid of these admixtures produces perfectly satisfactory and smooth anesthesia (Stehle and Bourne, 1922); and ethylene and carbon dioxide are practically ineffective in the concentrations stated.

Origin of Chloroform.—It has been claimed that the effects of chloroform differ somewhat according to whether it is prepared from acetone or alcohol. Wade showed that the acetone product is purer; the alcohol product contains a little ethyl chloride, which might increase the anesthetic effects (Regnault, 1909). Hewitt, however, could discover no difference in the immediate or after-effects. Hale, 1915, also could detect no constant difference in the fatal concentration for mice and fish, for chloroform samples of different age and origin.

Preservation.—The U.S.P. X directs that “*ether* to be used for anesthesia must be preserved in small well-closed containers, and is not to be used for this purpose if the container has been opened longer than twenty-four hours.” The subject of the preservation of ether was investigated by Baskerville, 1911, 1912. *Chloroform* should be preserved in *sealed, dark glass bottles* and should contain 1 per cent. of alcohol, which acts as a reducing substance.

RELATED ANESTHETICS

The production of narcosis is a universal action of all members of the aliphatic series which are fat-solvents, and which are absorbable into the tissues. Accordingly, a large number of the more volatile “lipophilic” hydrocarbons may be used to produce anesthesia; whilst the less volatile are employed as “hypnotics,” to produce sleep.

Ethyl Chloride.—This is the only one of the related anesthetics which is practically useful. On account of its great volatility, the anesthesia appears and disappears very promptly, and is therefore especially adapted for minor surgery. It has the same dangers of chloroform: Relatively small doses may cause sudden stoppage of the heart, though less frequently than chloroform. Larger doses paralyze the heart-muscle directly; and are even more dangerous than chloroform, because of the extreme suddenness and rather indefinite signals (E. D. Brown and Large, 1905; Embley, 1906; Maas, 1907; Wood, 1910; Seifert, Nebenwirk, 1915, p. 36).

Its main *advantages* consist in the rapidity with which anesthesia is induced; in the consequent absence of struggling, excitement, and unpleasant sensation; in the very prompt and complete recovery. Its administration is often followed by headache, nausea, vomiting, and sometimes collapse. The muscular relaxation and abolition of reflexes are incomplete, and a little experience is required to recognize the proper time for operating. It has occasionally failed in alcoholic patients.

It may be administered by spraying it on a chloroform mask. This method is so wasteful that a special mask is to be preferred, allowing its administration in gas form, and restricting the admission of air. It has also been used by pouring a small amount into a closed mask. These methods utilize a partial asphyxia; they consume from 5 to 10 c.c. for short operations (Large, 1906).

Administering ethyl chloride by his special closed-circulation apparatus, D. E. Jackson, 1916, finds its effects to be intermediate between nitrous oxid and ether.

The concentration of ethyl chloride in the blood and tissues during narcosis has been investigated by Camus and Nicloux, 1908; and E. Frey, 1912.

The main use of ethyl chloride is for *local anesthesia*, freezing the tissues by a fine spray of the liquid; the tube being held about 3 feet away. The impossibility of dissecting the frozen tissues restricts its use to simple incisions (opening boils); the analgesia is imperfect, and the thawing rather painful.

Ethyl Bromide and Ethyl Iodide.—These resemble ethyl chloride closely, differing only quantitatively, according to their volatility (Weber, 1906). The more common ethyl bromide is used for short anesthesia or rather analgesia. It must not be pushed to the disappearance of reflexes, since the respiration is paralyzed about the same time. The zone of safety is therefore very narrow. Pain is abolished before consciousness, and the operation must be made before consciousness is entirely gone. The proper time for operating is somewhat difficult to choose, and the drug is very dangerous in unskilled hands. With experience, the danger seems to be slight. The proper amount (for adults, 8 c.c.; for children not more than 1 c.c. per year) is poured on a folded towel or cone, and administered to the exclusion of air, until the proper degree of anesthesia is reached. It is then removed. It is only suitable for short operations (tonsillotomy, etc.). The administration requires twenty to forty seconds; the anesthesia lasts about two minutes. Recovery occurs at once.

After a bottle has been opened, the contents can not be used again, as they deteriorate rapidly. The drug must not be confused with *ethylene bromide* ($C_2H_4Br_2$), which is very poisonous.

Bromoform (CHBr_3) is not sufficiently volatile to be of use as an anesthetic. It is employed as an antispasmodic in whooping cough, but is of very doubtful value (0.2 c.c., 3 minims, dropped on sugar. Practically insoluble in water, soluble in alcohol).

Tetrachlorethane.—This was employed in the airplane industry as a solvent for cellulose acetate, but has been displaced largely by less dangerous solvents. Its inhalation produced hepatic degeneration, with symptoms analogous to phosphorus or chloroform poisoning (Alice Hamilton, 1917, bibliography).

Amyl Acetate is also a cellulose solvent. It causes local irritation, but is not so dangerous systemically (Hamilton, 1917).

Industrial poisoning in rubber factories is described by Hamilton, 1915.

Carbon Disulphide (CS_2).—This very volatile fluid has a toxicologic importance, from its extensive use in the arts, particularly in the rubber industry (Stadelmann, 1896; A. Hamilton, 1915).

Acute Poisoning is quite rare and produces effects similar to those of chloroform.

Chronic Poisoning is the more common. The symptoms may not appear for several weeks and then develop quite slowly so that several stages may be distinguished. The effects have a pathological basis in irritative changes throughout the body. The symptoms begin with disturbed sensation (headache, formication, vertigo, etc.) and gastro-intestinal catarrh. In the second stage there is irritability, excitement, hysterical manifestations, etc., and signs of marasmus. The third stage shows central paralytic or epileptic features, and peripheral neurites. Ataxia has been reported. The marasmus is pronounced. Degenerative *histologic changes* are found in blood (hemolysis, leucocytosis, anemia; no methemoglobin formation), nerve cells and dendrites, liver (vacuolization), kidneys, and lungs. Death does not occur until very late.

The fluid or vapor causes conjunctivitis and other local inflammatory changes in the eye. Continuous exposure, even to small quantities, may produce a toxic blindness, similar to that produced by tobacco (Haas and Heim, 1911).

PREPARATIONS

**Chloroformum* (Chlorof.), U.S.P., B.P.; Chloroform.—Contains at least 99 per cent. CHCl_3 ; and 0.6 to 1 per cent. of alcohol. Heavy colorless volatile liquid; boils at 60 to 61°C. Characteristic odor, sweet hot taste. Not inflammable. Slightly sol. in water (1:210); freely miscible with alc., eth. etc. *Dose*, 0.3 c.c., 5 minims, U.S.P.; 0.06 to 0.3 c.c., 1 to 5 minims, B.P. *Maximal dose*, 0.5 c.c., 8 minims.

Aq. Chlorof., U.S.P., B.P.—A saturated watery solution; 0.25 per cent., B.P. Used as hypnotic and flavor. *Dose* 15 c.c., 4 drachms U.S.P.

**Linimentum Chloroformi* (Lin. Chlorof.), U.S.P.—30 per cent. of Chloroform in soap liniment.

**Lin. Chlorof.*, B.P.—Equal parts of chloroform and camphor liniment.

Sp. Chlorof., U.S.P., B.P.—6 per cent., U.S.P.; 5 per cent., B.P. *Dose*, 2 c.c., 30 minims, U.S.P.; 0.3 to 1.2 c.c., 5 to 20 minims, repeated; single, 2 to 2.5 c.c., 30 to 40 minims, B.P.

(*Tr. Chlorof. et Morph. Co.*, B.P.—See Index.)

Bromoformum (Bromof.), CHBr_3 .—A heavy liquid, resembling chloroform. Slightly sol. in water; miscible with alc., chlorof., eth., and fixed or volatile oils. Slightly volatile, not inflammable. *Dose*, 0.2 c.c., 3 minims, (maximal, 0.5 c.c., 8 minims), on sugar or dissolved in alcohol and glycerin. Used in pertussis, but probably without value. Side actions, Seifert, Nebenwirk, 1915, p. 116.

Carbon Disulphidum, B.P., CS_2 .

**Æther*, U.S.P.; *Æther Pur.*, B.P.; Ether (Sulphuric Ether).—Contains 96 to 98 per cent. of ethyl oxide ($\text{C}_2\text{H}_5)_2\text{O}$. Light volatile liquid. Sp. gr., 0.713 to 0.716, U.S.P.; 0.720 B.P. Boils at 35°C. Characteristic odor. Highly inflammable; vapors explosive. Sol. in water (1:12) and in all proportions of alc. *Dose*, 1 c.c., 15 minims, U.S.P.; 1 to 2 c.c., 15 to 30 minims repeated; single, 3 to 4 c.c., 45 to 60 minims, B.P.

Æther for anesthesia is to be dispensed only in small, well-closed containers and is not to be used as an anesthetic after the original container has been opened twenty-four hours.

Spiritus Ætheris (Sp. *Æther*.), B.P. (Hoffmann's Drops).—33 per cent. in alcohol. *Dose*, 20 to 40 minims repeated; single, 4 to 6 c.c., 60 to 90 minims, B.P.

Sp. Ætheris Co., "Hoffmann's Anodyne," is an antiquated preparation of about the same strength and dose as the spiritus, containing additional ethereal products ("ethereal oil").

Æther Aceticus (Æth. Acet.), B.P., $\text{C}_2\text{H}_5\text{C}_2\text{H}_3\text{O}_2$.—*Dose*, 1 to 2 c.c., 15 to 30 minims, repeated; single, 3 to 4 c.c., 45 to 60 minims, B.P.

* *Æthylis Chloridum* (Æthyl Chlor.), U.S.P.; *Ethyl Chlor.*, B.P. (Monochlor-ethane), C_2H_5Cl . Colorless, extremely volatile liquid, of sharp, sweet taste, and peculiar odor. Inflammable. Boiling-point, 12 to 13°C. Sparingly sol. in water, readily in alc. or eth. Dispensed in special glass or metal tubes. Used for freezing and for general anesthesia.

Ethyl Bromide, C_2H_5Br .—General properties resemble the preceding. Boiling-point, 38 to 40°C. Should be protected from light and heat. Used for short general anesthesia.

ETHYLENE ANESTHESIA

Ethylene, $CH_2:CH_2$, is an unsaturated hydrocarbon of the olefin series. It occurs as a gas, and is employed to produce gas-anesthesia. Since its clinical introduction in 1923, mainly through Luckhardt and Carter, and Luckhardt and Lewis, the published reports have been almost uniformly favorable.

Historical.—As pointed out in an editorial of the Journal of the American Medical Association (80: 1383) and by Luckhardt and Lewis, 1923, the production of stupeficient phenomena by ethylene, and their resemblance to those of nitrous oxide, was recognized by the toxicologist L. Hermann in 1864. Some animal experiments were published by Nunneley in 1849; and the effects on animals were described about as they are known today by Eulenberg, 1876, and Luessem, 1885; but it was not tried for surgical anesthesia on man, doubtless because gas-oxygen anesthesia did not appear practical at that time. No further work on animals appeared for the next 33 years, when Malisoff and Egloff, 1919, (cited from Brown and Henderson), did some further toxicity experiments. Meanwhile, it had been found by Crocker and Knight, 1908, that ethylene vapor in the high dilution of 1:2,000,000 has a toxic effect on plants, which was further studied by E. M. Harvey, 1914. This great toxicity for plants led Luckhardt and Carter, 1923, to study its effects on animals; and its very low toxicity but rapid action on animals led them and their co-workers (Luckhardt and Lewis, 1923) to develop its successful clinical application; which, as Luckhardt points out, was a by-product of a strictly "academic" problem. Nearly at the same time and in ignorance of their work, W. E. Brown, 1923 (Brown and Henderson, 1924), also reinvestigated the effects of ethylene on animals and men, with more knowledge of the older work, and with a direct view to surgical anesthesia; but he did not proceed to the clinical application.

Actions.—Ethylene is an aliphatic narcotic with relatively low activity, but with very rapid action and recovery, due to its high volatility. Its effects may be conceived as analogous to a very rapid ether anesthesia; but because of their rapidity, the phenomena appear more similar to those of nitrous oxide. It acts more powerfully and more promptly than the latter. Full anesthesia, which requires 90 per cent. (volume) of ethylene and 10 per cent. of oxygen, is established in about half the time required for the ordinary nitrous oxide-oxygen induction; the anesthesia and relaxation are deeper, and adequate for major operations; and the recovery is more rapid; the patient being usually awake with clear mind, within 2 minutes after discontinuance of the anesthetic. The percentage of ethylene may be gradually reduced toward 80 per cent. in prolonged anesthetics. The rapid action and recovery demand constant attention on the part of the anesthetist.

Mechanism of Action.—As with the other aliphatic narcotics, this appears to be connected with a high partition coefficient $\left(\frac{\text{solubility in oil}}{\text{solubility in water}} \right)$, Luckhardt and Carter, 1924.

Effective Concentration.—Mammals are generally only slightly depressed by mixtures containing 80 to 85 per cent. of ethylene diluted with oxygen; with 90 per cent., the anesthesia becomes complete in 20 to 30 minutes, about half the time required for 90 per cent. nitrous oxide (Luckhardt and Carter 1923). Frogs are anesthetized by the 85 per cent. mixture in 20 minutes, whilst 85 per cent. illuminating gas produces no marked effects in 30 minutes (Luckhardt and Lewis 1924).

Special Phenomena.—The *induction* is not disagreeable to the patient. The gas has a rather unpleasant odor, but it is not noticed after a half-dozen inhalations, because of the mental confusion. Talking and excitement are relatively slight and often absent. Analgesia occurs before the full anesthesia, and may be established with 82 per cent. of the ethylene.

During established anesthesia, the respiration is practically normal; the excitability of the medullary centers is not lowered, they tend rather to be slightly stimulated by the lowered oxygen concentration, and hemorrhage is accordingly somewhat increased during the anesthesia; but the asphyxia is very slight and does not progress to cyanosis. The respiration is slow and regular, and the pulse scarcely changed. Sweating and salivation are slight or absent, and the temperature-fall is relatively slight. Renal efficiency (phthalein excretion and saline diuresis) is not impaired; and pulmonary irritation also appears to be absent. Post-anesthetic vomiting is only half as frequent as with ether (30 per cent. of the ethylene anesthetics as against 77 per cent. of ether anesthetics, in the series of Luckhardt and Lewis), and when it occurs, it is less severe and less persistent. Gas-pains, in the same series, occurred in only 4 per cent. of the ethylene, against 37 per cent. with ether; they are no more troublesome than after local anesthesia. In obstetric use, it does not materially reduce the uterine contractions, and permits prompt respiration to the delivered child (Heaney 1924).

Morphine.—This is not required even for deep anesthesia, but it facilitates the administration, and permits the use of somewhat lower concentrations (Luckhardt and Lewis, 1924).

Gastric and Intestinal Movements.—When ethylene is administered to animals to produce ordinary surgical anesthesia, the gastric movements are slightly depressed; but the movements of the small and large intestines are stimulated, in contrast, to other inhalation anesthetics. In deep anesthesia, these are also slightly depressed (Miller and Plant, 1925).

Respiration, Circulation and Temperature.—In animals, the C_2O production is depressed only in proportion to the muscular relaxation. The respiratory center is not depressed by anesthetic doses, the rate and depth being increased in proportion to any anoxemia. The *blood-pressure* rises about 10 mm., showing that the vasomotor center is not injured. The temperature falls but little (Bouckaert 1924).

Heart-muscle.—The excised frog or mammalian heart is not injured by saturating the perfusion fluid with ethylene (Bouckaert 1924).

Hydrogen-ion Concentration of the Blood.—Ethylene lowers the actual alkalinity of the arterial blood considerably less than ether or chloroform, and about the same as nitrous oxide. If anoxemia occurs, this causes a preliminary alkalosis (always with nitrous oxide; Leake, 1924).

Fatalities.—None had been reported clinically at this time (1925). If the concentration is pushed much beyond 90 per cent. in animals, death will occur mainly from anoxemia, *i.e.*, by respiratory failure. The circulation is not affected directly by the ethylene, so that resuscitation is relatively easy.

Impure ethylene, of peculiar odor, produced cyanosis, imperfect relaxation, and subsequent prolonged emesis (Luckhardt, 1924).

Advantages over Ether.—They are principally: the easier, more pleasant, more prompt, and safer induction; the diminution of emesis and gas-pains; the more rapid recovery; and the minimizing of renal and pulmonary irritation.

Advantages over Nitrous Oxide.—These consist in the practical absence of asphyxia, and therefore greater safety; the deeper anesthesia and more

complete relaxation; the lesser excitement and struggling; and the prompt recovery.

Disadvantages.—The principal drawback is the explosiveness of the ethylene-oxygen mixture, which demands the careful exclusion of electric sparks (static or other), open flames and cautery. The odor appears a negligible objection.

PREPARATIONS

Aethylenum pro Narcosi, N.N.R.—Ethylene for anesthesia, $\text{CH}_2\text{:CH}_2$. A colorless gas of slightly sweet, somewhat offensive, odor and taste. Somewhat lighter than air. B.P., 104°C . Inflammable and explosive. Soluble in about 4 volumes of water. Tests in N.N.R.

OTHER OLEFIN GASES

The introduction of ethylene-anesthesia gave an impetus to the study of other gases of the series C_nH_{2n} . The literature is cited by L. K. Riggs 1925. The experiments of the latter, on rats, show that the activity of the lower members increases in nearly geometric ratio; *i.e.*, the concentration of gas required to produce anesthesia, is for ethylene, 90 per cent. (volume); for propylene, 40 per cent.; for butylene, 20 per cent.; and for amylene 6 per cent. With butylene and amylene undesirable side-actions appear (exaggerated excitement stage; respiratory disturbances).

Propylene.—This gas ($\text{H}_3\text{C.HC:CH}_2$) may prove to be an advantageous gas anesthetic. It acts similarly to ethylene but is more powerful, so that 50 per cent. (volume) induces unconsciousness in 2 minutes, in man; and concentrations of 37 to 40 per cent. suffice for anesthesia. This would permit considerable economy in oxygen as well as in the anesthetic. Its administration is not unpleasant and recovery is rapid. In animals, toxic phenomena appear slowly with 65 per cent., rapidly above 70 per cent. (W. E. Brown, 1924; Halsey, Reynolds and Prout, 1926).

Methane.—W. E. Brown, 1924, found that this has a very narrow zone of safety; unconsciousness occurs with 87 per cent., (volume), and death with 90 per cent. Its effects are mainly asphyxial.

Dimethyl Ether.—W. E. Brown, 1924, found 65 per cent. (volume) to produce anesthesia; but it is unpleasant to take and the recovery is slow.

ACETYLENE

Anesthesia by the purified gas, C_2H_2 , has been employed successfully in the obstetric and gynecologic clinic of Gauss; but its use has not become popular, perhaps because its advantages do not appear to be sufficiently great to balance the disagreeable odor. Its introduction, like that of ethylene, resulted directly from experiments undertaken primarily for theoretical "academic" purposes.¹

Clinical Application.—Gauss, 1923 (C. H. Horowitz, 1923) used a gas mixture of 40 per cent. (volume) of acetylene and 60 per cent. of oxygen. This is flavored with oil of pine. The effects as described are similar to those of ethylene. It is necessary to employ a purified gas, as ordinary acetylene contains toxic impurities, such as H_2S (Wefers, 1917), which were largely responsible for the effects described by earlier observers (literature reviewed in Editorial of the Journal of the American Medical Association, 1923, 80 :1383; and by Wieland).

Mechanism of Action.—The use of acetylene developed from the studies of Wieland, 1922, which were designed to furnish an explanation of the action of nitrous oxide. Wieland believes that nitrous oxide and acetylene differ from ordinary narcotics in that they do not appear to anesthetize organisms and processes that do not require free oxygen (ascaris; the contraction-phase of muscle, etc.). He also finds that acetylene anesthesia greatly reduces the carbon-dioxide production in higher animals. From this he concludes that the mechanism of action of these two anesthetics differs from that of the lipolytic anesthetics (although they have a rather high solubility partition-coefficient); that they act by interfering in a puzzling manner with the use of oxygen; and that the nervous tissue is easily injured by this interference. They do not combine with hemoglobin, and do not interfere with the oxygen-capacity of the blood, so that there remain important gaps in the theory.

Anesthetic Action on Animals.—The susceptibility appears to vary rather widely: Wieland found the anesthetic concentration as 37 per cent. (volume) for mice; 47 to 65 per cent. for frogs, but 78 per cent. for rabbits. Charles N. Jordan 1923 required about 80 per cent. for dogs. Jordan emphasized the rapid recovery, and the absence of after-effects, even with a four-hour anesthesia.

Effects on Man.—In contrast to these concentrations reported for rabbits and dogs, B. M. Davidson, 1925, found that human subjects were rendered unconscious in 5 to 6 minutes by 33 per cent. to 35 per cent.; 30 per cent. were not sufficient. Repeated inhalations (three times within a week), decreased the susceptibility; whilst 33 per cent. acetylene abolished consciousness in 6 minutes at the first inhalation, it required 9 minutes at the second; and more than 33 minutes at the third. A similar diminution was produced in the rapidity and the degree of the minor disturbances of the psychic functions by lower concentrations, which she studied in some detail.

NITROUS OXIDE

General Statement.—Nitrous oxide, N_2O , nitrogen monoxide or protoxide, "laughing gas," was the first of the inhalation anesthetics. When inhaled undiluted, it produces very rapidly unconsciousness and anesthesia, partly by a direct narcotic action, and partly by exclusion of oxygen. The asphyxia limits its use to very short operations, such as the extraction of teeth. It has the advantages of prompt action and recovery, absence of irritation and of after-effects, and is practically devoid of danger. By the addition of oxygen, the asphyxial factor may be removed. The anesthesia also becomes slower and lighter; but by carefully adjusting the percentage of oxygen (5 to 10 per cent.), a satisfactory degree of surgical anesthesia can be maintained for long periods, without letting the asphyxia obtain dangerous proportions. Nitrous oxide is especially valuable in the "Gas-ether Sequence," by avoiding the unpleasant features of the induction of ether anesthesia.

Historical.—Nitrous oxide was first prepared by Priestly about 1776. The discovery of its anesthetic properties by Humphry Davy and by Wells is described under "Ether and Chloroform." Elsworth (Boston Med. and Surg. Jour., 37) in January, 1843, amputated a thigh under successful nitrous oxide anesthesia. Its administration with oxygen was introduced by E. Andrews of Chicago in 1868; and the use of such mixtures under pressure by Paul Bert, 1880. The technic of its use in surgical operations has been extensively elaborated in recent years.

Inhalation of Undiluted N_2O .—For short operations, as in dentistry, the gas is administered through a tight-fitting mask, so that all air is excluded. The symptoms run a very rapid course: the *preliminary effects* consist in a sweetish taste; numbness; exhilaration (laughter); confusion; deeper and quicker respiration; and fuller pulse. *Partial anesthesia*, with loss of consciousness, ensues in twenty to thirty seconds. The patient is subject to dreams and the anesthesia is imperfect. The reflexes are preserved and excitement may be present, especially if the patient is disturbed. The respiration is still regular, deep and quickened; the pulse full and rapid; the pupils enlarged; the face dusky, livid or pallid; the eyelids twitching and slightly separated. *Complete anesthesia* occurs in fifty to one hundred and twenty seconds, averaging fifty-six. Its onset is denoted by a change in the respiration, which becomes slightly irregular and noisy. The pulse is quickened by about 30 per cent. and is small. The blood pressure shows a large asphyxial rise (Kemp, 1897). The vasoconstriction diminishes the urine flow. The limbs are relaxed, but individual muscles exhibit clonic or epileptiform contractions. The pupils are almost invariably dilated. The face is cyanosed. Relaxation of the sphincters occurs rarely.

Operative Period.—As soon as this stage is reached, the gas is removed. The pulse at once becomes slower and fuller; the respiration also recovers rapidly; and the asphyxial symptoms disappear. The anesthesia lasts some twenty-two to thirty seconds after the gas is removed; and it is

during this period that the operation must be performed. The total time between the beginning of the administration and complete recovery is therefore a hundred to a hundred and fifty seconds. The duration of the after-anesthesia increases with the duration of the administration. This may be prolonged to several minutes by giving the patient an occasional breath of pure air (every fifth inhalation); or by admitting a little air into the mask. The admission of air, however, makes the anesthesia uneven and unsatisfactory.

After-effects are generally absent with short administrations. Sometimes the patients complain of giddiness, headache, lassitude and drowsiness. Nausea is exceptional.

Accidents.—With short administrations, these are very rare, because of the wide margin between the first danger sign (noisy and irregular respiration) and death. Only about seventeen deaths have been reported, making the fatality less than 1 in 5,000,000. In patients with grave cardiac lesions, the pulse may become feeble and the respiration shallow before anesthesia is established. If the administration is continued too long in healthy individuals, the asphyxial phenomena become emphasized, with violent inspiratory, then forced expiratory movements; then shallow and intermittent and finally arrested respiration, in two to four minutes (Haggard, 1910). The violence of ordinary asphyxial convulsions is mitigated by the narcosis. Cyanosis is intense. The heart continues to beat for some time, so that *restorative measures* are generally successful. They should consist in artificial respiration, preferably with oxygen.

Contraindications.—Nitrous oxide should not be used in cardiac lesions, valvular or myocardial; in elderly patients especially with advanced arteriosclerosis or high cerebral pressure; and in operations on the brain. It is often ineffective in hysterical, obese, muscular or alcoholic patients (S. G. Davis, 1909).

Mechanism of Action.— N_2O is very soluble in blood, which takes up 45 per cent. by volume (Bert). Davy believed that it acted like oxygen, producing hyperoxidation of the blood; but Frankland showed that it is not decomposed. It was then believed that it acted merely as an asphyxiant. The phenomena produced by the undiluted gas are in fact partly asphyxial. This factor can be removed by the addition of oxygen when it is seen that narcosis results from the N_2O itself. This may also be demonstrated on frogs, which preserve their reflexes for hours when placed in pure hydrogen; but lose them promptly in N_2O . Evidently the nitrous oxide has a direct action on the central nervous system; first stimulating the psychic areas, then depressing these to insensibility. The motor reflexes are also abolished. The medullary centers are not affected, and the circulation remains unchanged, in the absence of asphyxia. Nitrous oxide also has no action on other tissues and is therefore absolutely harmless. Dogs anesthetized continuously for three days with a mixture of N_2O and oxygen, recovered without any damage.

H. Wieland, 1922, however, has pointed out that there are essential differences between nitrous oxide and the true narcotics; he claims that frogs are not anesthetized by the mixture of N_2O and oxygen; and that N_2O does not narcotize excised tissues, for instance, muscle, heart, invertebrates etc., but acts as an indifferent gas; *i.e.* N_2O does not affect processes that do not involve oxidation. He therefore ascribes its effects to interference with oxidative processes in the central nervous system. Acetylene acts similarly. The partition coefficient of both is on the lipoid side: 1.80 for N_2O ; 1.39 for acetylene, contrasting with 4.5 for ether. Nitrous oxide probably does not combine with hemoglobin. On account of its feeble chemic affinities, the gas is practically free from side actions, and herein lies its chief value.

Catalase of Blood.—This is diminished by nitrous oxide, just as in other forms of anesthesia (Burge et al., 1918).

High Pressures of Nitrous Oxide.—These are fatal above 3 atmospheres, even when inhaled with adequate oxygen. The symptoms consist in narcosis, convulsions, and finally depressed respiration. The heart remains strong (Bock, 1913).

Nitrous Oxide with Air or Oxygen.—The respiratory disturbances, convulsive features and cyanosis produced by undiluted N_2O are purely asphyxial. If the gas is mixed with a sufficient proportion of oxygen (15 to 20 per cent.), these asphyxial phenomena are entirely absent, and the anesthesia can therefore be prolonged indefinitely. With smaller percentages of oxygen, the symptoms are intermediate.

The dilution of the gas with oxygen lowers its concentration in the blood to a corresponding degree, so that the narcotic action is not as prompt or deep. It is generally stated that a mixture of 80 per cent. of nitrous oxide and 20 per cent. of oxygen, inhaled at atmospheric pressure, produces only confusion and analgesia, with incomplete loss of consciousness.

However, Hewitt claims to produce deep anesthesia in this way within four minutes; and that the anesthesia becomes incomplete only if the concentration falls below 66 per cent. Paul Bert, 1880, obtained perfect results by a mixture of 85 parts N_2O and 15 parts O_2 , condensed by an excess-pressure of $\frac{1}{6}$ atmosphere.

D. E. Jackson, 1916, describes an apparatus that involves the continuous rebreathing of the nitrous oxide with removal of the CO_2 and renewal of the oxygen. This permits of prolonged anesthesia at a minimum cost. Under these conditions, the effects have considerable resemblance to morphine. Man appears sensitive to lower concentrations than are needed for dogs. Careful administration induces an apparently natural sleep.

These methods are not very feasible in practice; but a satisfactory anesthesia may be maintained sufficiently long for ordinary surgical operations by adding only enough oxygen to the gas to prevent the major manifestations of asphyxia.

Hewitt found that 6 per cent. of oxygen are required to prevent the convulsive features and noisy respiration; 11 per cent. to prevent lividity. Above 10 per cent., the reflexes and movements of the patient were more pronounced.

Jackson, 1917, confirms that the addition of more than 10 per cent. of oxygen greatly delays or even prevents the loss of consciousness.

Nitrous Oxide Oxygen Mixtures.—Clark quotes the following compilation from Connell:

Vol. %		Depth of anesthesia	Degree of		Utility
N_2O	O		Asphyx.	Relax.	
80	20	Subconscious analgesia.	None	None	Dentistry
86	14	Complete analgesia. . . .	None	None	Surface operations
89	11	Partial anesthesia.	Slight	Slight	Abdominal operations
94	6	Complete anesthesia. . . .	Dangerous	Partial	Dangerous

Morphine-scopolamine greatly increases the efficiency of nitrous oxide; so that with these alkaloids, a mixture of 80 per cent. and 20 per cent. oxygen even at atmospheric pressure induces an operative anesthesia (Kochmann, 1914).

Administration of the Mixed Gases.—This requires a special apparatus for adjusting the two gases in any proportion. This is connected with a close-fitting mask. It is advisable to warm the gas mixture before it is inhaled.

To hasten the anesthesia, the administration is begun with a mixture containing 2 per cent. of oxygen. This is gradually increased to 10 per cent., but varying for different patients.

Phenomena.—The primary symptoms are the same as with pure gas.

The respiration is at first stimulated, so that the patient feels that he can breathe with less effort (Jackson, 1917).

The *anesthetic stage* is usually reached in a few minutes. It is characterized by regular, calm, moderately snoring respiration; slightly dusky

face; and medium pupils. The pulse is moderately quickened; the blood pressure somewhat high; the blood rather venous. Convulsive phenomena are absent. The reflexes and muscular tone are greatly decreased, but not abolished as with ether; and the anesthesia is not so profound.

After-effects.—When the administration is stopped, the patient awakens fully within two or three minutes. Nausea is exceptional, but more common than after short inhalations.

Advantages.—These consist mainly in the greater comfort of the patient, the smaller danger, and the absence of irritant side effects. The gas would therefore be especially indicated in renal and acute pulmonary diseases; or when the patient dreads the other anesthetics. Crile, 1910, claims that it diminishes the danger of shock and infection.

Disadvantages.—The contraindications and limitations were discussed under the undiluted gas. Its application is further limited by the rather shallow anesthesia; incomplete relaxation; high blood pressure and venosity of the blood; the expense of the gas and apparatus; inconvenience; and the need for very specialized experience.

Fatalities from the surgical use of nitrous oxide are perhaps fairly numerous; but reliable statistics are not available (cf. J. F. Baldwin, 1923).

Influence of Impurities.—Warner, 1915, reported that ordinary nitrous oxide often produces severe symptoms, especially cyanosis, which does not occur with proper purification. The toxic effects are due partly to nitric oxide, but especially to unidentified basic impurities, perhaps hydroxylamine and hydrazine. The gas deprived of these (as is now generally done) can be given with less oxygen, without cyanosis.

Gas-ether Sequence.—This was suggested by Clover, 1876; but has also come into extensive use only recently. It seems to combine the chief advantages of the two anesthetics, and is perhaps the nearest approach to an ideal method.

Nitrous Oxide Analgesia in Obstetrics.—This has been advocated as much safer than scopolamine-morphine "twilight sleep." It does not weaken the uterine contractions and has no bad effects on mother or child (Webster; Lynch; Davis, 1915).

PREPARATIONS

**Nitrogenii Monoxidum* (Nitrogen. Monox.), U.S.P. (Nitrous Oxide), N_2O .—Colorless gas; possesses a slight characteristic odor; somewhat sweetish taste. It is marketed, compressed into a liquid, in steel cylinders. It returns to the gaseous state when the pressure is released.

ALIPHATIC HYPNOTICS

Sleep is one of the earlier phenomena of light narcosis, and may therefore be induced by small doses of any of the aliphatic narcotics. With many of these, however, the hypnotic stage is too brief, passes too easily into general anesthesia, or is complicated by undesirable side actions, stimulation, local irritation, etc.

Desirable Features.—The usefulness of a hypnotic depends upon the following qualities: Its action must be fairly prompt and lasting, so that the hypnotic effect will persist for some hours. Very volatile or easily decomposable substances are therefore excluded. A good somnifacient must produce the maximum hypnotic action, with the least depression of the medullary centers. It must not possess an odor or taste which would preclude its employment; and it must not irritate the stomach. Preparations

which are insoluble in water, but which are nevertheless absorbed, are valuable because they are nearly tasteless, and because their action is apt to be more lasting. A soluble compound which could be used hypodermically would be very useful, but the important aliphatic narcotics are either too irritant or insoluble.

Manner of Action.—Small doses of these drugs depress the sensory and intellectual processes, so that the perception of external stimuli is lowered (Kraepelin, 1892). The subject is thus put into condition favorable to natural sleep. This should be the aim in their therapeutic use. Larger doses produce an actual stupor; and eventually coma. The stronger hypnotics (chloral) also depress the motor functions. Of other functions, the blood pressure and pulse are somewhat lowered, as in natural sleep. The skin vessels are moderately dilated. The brain vessels are also dilated (Berezin, 1916). The chlorinated hypnotics (chloral) in large doses, have a direct depressant effect on the medullary centers, especially the respiration; and on the heart-muscle. All the members are hemolytic when added directly to blood (L. Herrmann).

The Essential Mechanism of Sleep.—Sleep is essentially a condition of unconsciousness to external surroundings. This might conceivably result from (1) deficient blood-supply of the brain; or (2) direct alterations of the psychical processes.

Cerebral anemia will indeed produce unconsciousness; but it is not an important element in sleep; for there is presumably little difference in the circulation of sleep and that of waking reverie; and in dreams and agitated sleep, the circulation must be faster than in restful waking. Any slowing of the circulation in sleep is more probably the result of the muscular and psychical relaxation.

The psychic mechanism of sleep appears more important. *Consciousness* consists in the continuous association and coupling of impressions and ideas. It is therefore an active process. *Unconsciousness* is simply the absence of such synthesis. This may be brought about by: (a) Direct depression of the nervous mechanism, for instance by anesthetics or by anemia or asphyxia; (b) by fatigue; and (c) by voluntary inattention or inhibition.

The suppression of the synthesis of ideas may be of all grades; from mental concentration, through reverie, trance, the hypnotic state and sleep to anesthetic narcosis and coma.

Respiratory Center.—Cushny and Lieb, 1915, studied the behavior of decerebrated rabbits under urethane. The other lipolytic hypnotics presumably act similarly. They found but little effect on ordinary respiration (in intact animals, the respiration would be diminished by the general narcosis). The respiratory response to reflexes was also normal; the response to oxygen deprivation or CO₂ was, however, lessened or even reversed.

Hypnotic Response of Decerebrated Rabbits.—Chloral and urethane have a much more intensive action than in normal animals. Further, while normal animals are awakened from chloral sleep by cocaine or caffeine, decerebrated animals are not awakened. Tetrahydronaphthylamine awakens either (Morita, 1915).

Efficiency of Respiratory Stimulants against Poisoning by Aliphatic Hypnotics.—With rabbits, more or less improvement was reported after hypodermic injections of ether or atropine, or intravenous injection of camphor. Caffeine, strychnine, epinephrine and aspidospermine were not helpful (Meissner, 1923).

Therapeutic Indications.—Hypnotics (soporifics, somnifacients) are used to procure sleep in insomnia, especially when more physiologic measures (removal of the cause, etc.) are not applicable; and to break incipient habits of insomnia, by promoting the confidence and equanimity of the patient. Their continued use generally leads to tolerance and drug-habits and should be avoided if possible. Full doses often produce acute poisoning. Doses only large enough to induce sleep indirectly by quieting the patient are rarely dangerous, and can be used temporarily without apprehension.

Limitations.—In the treatment of insomnia it must be remembered that the drugs of this class act purely symptomatically; that they tend to

lose their effect; that none of them are entirely free from objection, be it through the tendency to the formation of drug-habit, through an irritant effect, or through the danger of overdosage. They should not therefore be resorted to except in case of necessity. The dose at the beginning may be small for in many cases the action of the hypnotic itself need not be very lasting, since sleep once induced tends of itself to continue. The small dosage presents the opportunity of enlarging the dose when the patient becomes accustomed to it. When the hypnotics needs to be continued for a long time, it is well to change frequently to a hypnotic of another type, to return to the first later. This obviates to a great extent the irritant effects and also the habituation of the patient.

Distribution of Hypnotics in Brain.—This has been investigated by Gensler, 1914 and 1915; utilizing the bromine hypnotics, neuronal, bromural and adalin. During the narcotic sleep, the absolute quantity of bromine found in the brain (all in organic form) represents only about 1.4 per cent. of the absorbed hypnotics; but the percentage of bromine is about 1.8 times greater than that in the remainder of the tissues, including the blood. The percentage in excited conditions is about the same; so that the known resistance of excitement to hypnotics, as would be expected, is due to the altered physiologic state, and not to altered distribution. The distribution is also unaffected by injection of magnesium, although the physiologic effects are additive.

Blood Lipoids.—The influence of continued administration of aliphatic hypnotics was investigated by Waser, 1915.

Inflammation.—Chloral, urethane, and presumably the other aliphatic narcotics inhibit the migration of leucocytes from the inflamed frog's mesentery (Ikeda, 1916).

Combination of Hypnotics.—Urethane and opiates give only simple summation of action in animals (Le Heux, 1919). The older work, which claimed potentiation, appears open to criticism (van Leeuwen, 1919).

Comparison of Aliphatic Hypnotics.—*Chloral*, the oldest member of the group, is really a very good hypnotic. Its action is certain, prompt but sufficiently lasting, and easily graduated by the dosage. It is very readily soluble, and not cumulative. However, it has been largely displaced by the newer hypnotics, perhaps not quite deservedly. It has an unpleasant taste and is somewhat irritant to the stomach. It is not effective against pain. The large doses that were originally employed sometimes produce dangerous cardiac and respiratory depression. It is doubtful whether these effects need to be feared with doses of 1 Gm., but it is generally advised to be cautious in its employment in the presence of depression of the medullary centers, or of vascular, cardiac, renal, pulmonary or gastric disease.

Paraldehyde is milder than chloral, but acts very promptly. It does not affect the respiration or heart, but is unpleasant to take.

Barbital (veronal) is about as effective but not quite as prompt as chloral. It is less disagreeable to take, and is not as toxic; but full doses have caused severe and fatal poisoning, and therapeutic doses may produce cumulative effects.

Phenobarbital (luminal) is more active and more toxic than barbital; but small doses are merely calming and sedative, similar to bromides, so that it has found a special field in epilepsy and in thyroid disease.

Carbromal (adalin) and *bromural* act rather feebly, and like the bromides are suitable mainly for mild nervous insomnias.

Sulphonal and *trional* are fairly powerful, but act very slowly, and produce considerable after-depression; they also irritate the kidneys and cause dangerous cumulative effects.

Comparison with Other Groups.—*Morphine* is ordinarily less effective than chloral, but is superior when insomnia is due to pain. *Scopolamine*

is useful especially in psychic insomnia and insanity. *Apomorphine* is said to be superior in acute alcoholism. *Bromides* are the least objectionable, but are effective only in mild nervous cases, worry, etc.

Composition and Action.—Certain relations have been found to exist between the chemical structure and action, although the connection is probably not a direct one, as explained in the discussion of the narcosis theories. The ethyl group and the next higher homologs seem to be especially valuable in conferring hypnotic action; and these are the most effective in the presence of aldehyde or ketone radicals. Alcohol radicals weaken the action, so that glycerin, *e.g.*, is not narcotic. The compounds must resist oxidation sufficiently, in order that their action may be lasting.

Role of Chlorine.—The narcotic effect is greatly enhanced by the introduction of chlorine, as shown by the comparison of acetaldehyde and chloral; and by the methane derivatives, the efficiency of which increases for each additional chlorine atom from methane to carbon tetrachloride. This peculiar property of the chlorine compounds has not been explained. Binz, 1877, assumed the liberation of free chlorine; but there is good evidence that this can not occur (Fraenkel).

CHLORAL HYDRATE

General Statement.—This is the hydrate of *trichloraldehyde*, obtained by the action of chlorine on alcohol:

It was discovered by Liebig in 1832, and was introduced as a hypnotic by Liebreich in 1869. Morphine was the only active hypnotic known at that time. Acetaldehyde is also narcotic; the entrance of chlorine greatly increases its efficiency, but also introduces damaging effects on the respiration, heart and metabolism, similar to those of chloroform.

Fate.—Chloral is readily absorbed from all mucous membranes. In the body it is mainly reduced to trichlorethyl alcohol, $\text{CCl}_3.\text{CH}_2.\text{OH}$, which is also hypnotic but less powerful. This is excreted by the urine, in one and one-half to eighteen hours, in combination with glycuronic acid (V. Mering, 1881), as the non-toxic trichlorethyl-glycuronic acid (urochloralic or chloraluric acid). This reduces Fehling's solution, and thus gave rise to the erroneous belief that chloral causes glycosuria. It polarizes to the left, but does not ferment. A true hyperglycemia may occur in profound narcosis, analogous to chloroform (Jacobson, 1913).

A small part of the chloral is excreted unchanged, and at most minimal traces as inorganic chlorides and chloroform.

Liebreich's Theory.—Liebreich, 1869, was led to try chloral by the assumption that it would be converted into chloroform in the organism, as it is by alkalies in the test-tube:

The theory was disproved: The blood and expired air contain no chloroform, or at most insignificant traces (Nicloux, 1906); and the greater part of the chloral is excreted in the conjugated form. Liebreich also stated that a fraction is excreted as chloride; this is contradicted by Kast, 1887.

Hypnotic Action of Ordinary Doses (1 or 2 Gm. for Man).—These act very promptly, producing drowsiness in ten or fifteen minutes, and quiet,

sound sleep within an hour, mainly by diminishing attention to external stimuli. The sleep lasts at least several hours; but the patient can be easily and completely aroused, and awakens refreshed, generally without depressant after-effects. The sleep is therefore strictly physiological. Very exceptionally, chloral may produce excitement and even delirium.

Other Functions.—The respiration and pulse are somewhat slowed and the blood pressure and temperature slightly lowered, but little more than in ordinary sleep. In respiratory and especially in circulatory diseases, these depressant effects may be somewhat more pronounced, and may perhaps lead to some cyanosis with the larger doses. In fact, however, the fear of respiratory and cardiac depression is based essentially on faulty deductions from animal experiments. There is no good clinical evidence of cardiac depression; while the danger is greater in cardiac diseases, it has often been given without bad effects (Cushny, 1914). The experimental evidence also indicates that the depressant dose is considerably larger than the therapeutic dose (Gunn, 1913, 1914).

Effects of Full Doses.—In man, 2 or 3 Gm. of chloral produce very deep sleep; and as the dosage is increased, this passes into stupor and coma, with complete muscular relaxation. The other depressant effects become much more important.

The depression of the medulla makes itself felt by *slowing of the respiration and fall of blood pressure*. The vasomotor paralysis is so prominent that chloral is often used in the laboratory to secure paralysis of this center. The pulse is also slowed through direct depression of the cardiac muscle.

As in the case of chloroform, it is impossible to state to what extent the vasomotor and the cardiac paralysis respectively are concerned in the fall of blood pressure. A *dilatation of the cutaneous* vessels is quite a marked feature. Sometimes there are skin eruptions. Larger doses always cause a marked *fall of temperature* on account of this cutaneous vasodilatation, coupled with the diminished production of heat from muscular relaxation and probably lessened activity of the heat-regulating centers. The temperature regulation in deep chloral-coma resembles that of cold-blooded animals (Sollmann and Hatcher, 1908). In *fatal doses* death is ordinarily caused by paralysis of the respiratory center, although it may take place by paralysis of a weakened heart, just as in the case of chloroform.

Respiratory Effects.—Cushny, 1913, found the respiratory center depressed, in decerebrated rabbits. With ordinary doses, this depression was masked by the accumulation of CO_2 , so that the respiratory movements were almost normal; but with larger doses, the depression predominated, with diminution of rate and depth. Wieland, 1915, also found the CO_2 threshold raised.

Cardiac Effects.—These are similar to chloroform.

They consist in shortening of the refractory period and depressed contractility. With *stimulated ventricular strips*, the shortening of the refractory state leads to superposition of contractions and tetanus, and because of the depression, the tetanic contraction may be lower than the normal single twitch. The threshold of stimulation is not materially raised (Sasaki, 1921).

Applied to the exposed heart of frogs or turtles, chloral produces progressive slowing; diminished contractility; lessened systole; and diastolic standstill. The arrested heart at first responds easily to stimuli, but can not be started by atropine (Razewski, 1870; Harnack and Witkowski, 1879). Further details are described by W. H. Schultz, 1906. Similar depressant effects are seen in the mammalian heart (Bock, 1898; Gunn, 1915). The depressant concentration is at least 1:1,000; the fatal, 1:400. The oxygen consumption of the heart is decreased, but not as much as its activity (Rohde and Ogawa, 1912).

Sudden stoppage of the heart may occur from relatively small doses, in cats, under the influence of excitement (Sollmann, 1908). This resembles some of the human cases.

Vagus Phenomena.—In rabbits, doses too small to affect blood pressure or heart rate lessen the irritability of the heart-muscle, so as to delay markedly the resumption of the beat under continued vagus stimulation (O. Loewi, 1912). Similar phenomena occur in frogs. The *accelerator mechanism* is generally depressed by chloral (Fredericq, 1913).

Excised Intestines.—The movements are increased by 0.05 per cent., diminished by stronger concentrations. This may be preceded by stimulation. Later, there may be occasional slow but strong contractions (Sembdner, 1913).

Action on Metabolism.—This consists in an increased destruction of protein, the waste products being excreted in a less completely oxidized condition than is the case normally.

The *urine flow* is diminished during the narcosis (Ginsberg, 1912), as also the phenol-s.-phthalein output (Whipple and Speed, 1915). The uric acid excretion is somewhat increased (Abl, 1913).

The output of nitrogen and neutral sulphur is increased; but in *distinction to chloroform*, this is delayed for several days after administration (Harnack and Remertz, 1893); nor is the disturbance as great as with chloroform. Doses so large as to maintain anesthesia over twenty-four hours may not produce the characteristic effects of prolonged chloroform administration on the liver and kidneys, or only occasionally, and to a slight degree (Hopkins, 1912). Severe chloral coma, however, is followed by prolonged anorexia, marasmus and loss of weight (Sollmann and Hatcher, 1908). Lissauer, 1914, also found changes in the cardiac ganglia in rabbits (which are specially susceptible).

The Local Action of Chloral.—This is so pronounced as to allow of its use as a rubefacient. Its action on the stomach is consequently quite prominent, and it must be largely diluted with water before administration; else it may produce vomiting. In any case, large doses are apt to show after-effects, referable to a gastritis.

Acute Chloral Poisoning.—The lighter grades show the narcotic phenomena, together with gastric irritation and vomiting, sometimes followed by icterus and albuminuria, skin lesions, and ataxia. In severe cases (as by "knock-out drops") there is prompt collapse, or delirium; pulse scarcely perceptible; severe fall of temperature; cyanosis; dyspnea or very slow respiration. In fatal cases, death is rarely delayed beyond five hours and may be almost immediate. Fatal relapses, after apparent recovery, have been reported (Purdy, 1889). Large doses (as in the Stroganoff treatment of eclampsia) may kill the fetus *in utero* (Jung, 1914).

The *fatal dose* averages about 10 Gm., but varies greatly. Death has been reported after 1 to 3 Gm., and recovery after 10 to 28 Gm. (Lewin). Doses above 3 Gm. must be used cautiously. (The dosage for cats was studied by Sollmann and Hatcher, 1908.)

The *treatment* consists in gastric lavage; emetics would often be ineffective. The patient should be kept warm. Caffeine, strychnine and atropine are useful. The heart may be stimulated by hypodermic injections of camphor. Artificial respiration is given as needed.

Efficiency of Cerebral Stimulants.—These are of little avail against toxic doses. Light chloral sleep, however, is easily broken by caffeine, cocaine or tetrahydronaphthylamine; not by phenol, epinephrine or pituitary (Airila, 1913).

Chronic Chloral Poisoning.—Chloral habit is not induced as readily as that of morphine or alcohol; but it is not rare. It presents the symptoms and degenerations of chronic alcoholism, with more severe gastric and cutaneous manifestations. The tolerance is only moderately increased and sudden death is not infrequent. Chloral habit is treated in the same general manner as other drug-habits.

Addiction to "Bromidia," a chloral nostrum, is not uncommon (Blair, 1919).

Habituation of Animals to Hypnotics.—This occurs with chloral, amylen hydrate, paraldehyde and others of the fatty series, but not with urethane, bromural or sulphonal (Biberfeld, 1918). Chronic chloral poisoning has been studied in dogs by Wallace, 1912. Habituation to morphine does not confer tolerance for chloral (H. B. Myers, 1917).

Growth.—Chronic chloral poisoning arrests the growth of young rats, and these remain permanently stunted even after the chloral is discontinued (Sollmann, 1924).

Therapeutic Uses.—Chloral, as all the aliphatic hypnotics, is used especially in insomnia of psychic origin. In ordinary nervous insomnia it should be given in small doses of 0.3 to 1 Gm. (5 to 15 gr.), usefully combined with 1 Gm. of sodium bromide. Its taste is not easily disguised; it may be given in Syr. Aurantii. Larger doses are needed in mania and in delirium tremens. In the latter condition, the large doses have caused collapse. It is not very effective against febrile delirium or pain. The addition of morphine is said to secure a stronger effect than if either were used alone (Knell, 1907).

Chloral is one of the most useful sedatives against the *convulsions* of strychnine, tetanus (Dreyfus, 1914), eclampsia, etc. Fairly large doses are needed;* but it is safer to use moderate doses (2 to 3 Gm.) repeated at fairly long intervals (to five or six times per day), and supplemented by chloroform inhalation. Chloral may be given *by rectum*; and is thus rather more effective than by mouth. It cannot be used hypodermically, because of its irritant action.

Chloral is also used in *asthma* and *seasickness*, but the benefits are uncertain.

Locally, it is sometimes employed against neuralgia and pruritus, as an ointment (15 per cent.), or as *chloral camphoratum*, N.F. (the liquid resulting by triturating equal parts of chloral and camphor).

PREPARATIONS

**Chloralis Hydras*, U.S.P.; *Chloral Hydras*, B.P. (Chloral Hyd.); *Chloral Hydrate* (Hydrated Chloral); $\text{CCl}_3\text{COH.H}_2\text{O}$ —Colorless transparent crystals, of penetrating aromatic odor and bitterish caustic taste. Slowly volatilized when exposed to air. Very sol. in water (1:0.25); freely sol. in alc. (1:1.3) or eth. and oils, fixed or volatile. *Incompatible* with alkalis, carbonates, and compounds of Hg, I, or Pb. *Dose*, 0.5 Gm., 8 gr., U.S.P.; 0.3 to 1.2 Gm., 5 to 20 gr., B.P.; largely diluted. *Maximal dose*, 4 Gm., 60 gr. *Syr. Chloral*, B.P.—20 per cent. *Dose*, 2 to 8 c.c., $\frac{1}{2}$ to 2 drachms, B.P. One dram contains 11 gr. of chloral.

OTHER CHLORINATED HYPNOTICS

Many of these have been suggested as substitutes for chloral, but none are seriously superior. Several are compounds which owe their activity merely to the liberation of chloral. Since promptness of action is generally desirable, the slow and uncertain liberation is a disadvantage.

Butyl-chloral Hydras, B.P.; Croton-Chloral Hydrate, $\text{CH}_2\text{CHCl.CCl}_2\text{CH(OH)}_3$.—This was also introduced by Liebreich, 1871. Its action is more powerful but shorter than that of chloral (Mering, 1875). It has been used especially in facial neuralgia. Sol. in water (1:40); very sol. in alc. or glyc. *Dose*, 0.3 to 1.2 Gm., 5 to 20 gr., B.P.

Tri-halogen Tertiary Butyl Alcohols.—These are also hypnotics. Their properties are described by Aldrich, 1916.

Chlorbutanol, N.N.R.; Chloroform-acetone; Methaform; Chloretone, $\text{CCl}_3\text{C(OH).CH}_2\text{CH}_3$.—This is produced by the action of caustic alkalis on a mixture of chloroform and acetone. It acts similarly to chloral, and is probably rather more toxic (Impens,

* In traumatic tetanus, K. Alexander, 1914, advised a single daily dose of 10 Gm. in 250 c.c. of water by rectum; 5 Gm. were inadequate.

1901); 100 gr. have caused severe poisoning, but recovery occurred (for further details, Seifert, *Nebenwirk.*, 1915, p. 44). It is used mainly as a mild local anesthetic, antiseptic and preservative for hypodermic solutions. *Dose*, 0.3 to 1.5 Gm., 5 to 20 gr., as powder. Locally, as saturated watery solution, (0.6 per cent. at 20°C.). It is sol. in oils, and easily sol. in alc. and fat solvents (*Literature*, Rowe, 1917).

Chlorbutanol appears in the mother's milk after the continued administration of very large doses; but not after therapeutic doses (Blanner, 1919).

Chlorbutanol is used as an *anesthetic for laboratory animals*, as it allows of long operations without requiring any attention. The dogs are given the usual dose of morphine. As soon as vomiting has occurred, 0.2 Gm. of chlorbutanol per kilogram of animal, is administered by stomach-tube or peritoneally (Rowe, 1916). The chlorbutanol is previously dissolved in the smallest possible amount of alcohol. The anesthesia is complete in fifteen to twenty minutes, and lasts several hours. The blood pressure falls rapidly in rabbits, slowly in dogs. In unanesthetized dogs, it decreases the response of the respiratory center to carbon dioxide (Voegtlin and Wiggers, 1918).

Chlorbutanol is inadvisable when it is wished to have the animal recover.

Excised Intestines.—These are depressed by chlorbutanol. This may lead to false results in testing epinephrine or pituitary solutions that were preserved by this drug (G. B. Roth; E. L. Backman, 1922).

Chloroformamidum (Chloral Formam.), B.P. (*Chloralamid*), $\text{CCl}_3\text{CH}(\text{OH})\text{NH}\cdot\text{COH}$.—This was introduced by v. Mering, 1889, with the idea that the formamide (CHONH_2) would counteract the medullary depression of the chloral. This was not realized; it is merely a less active hypnotic, being probably slowly decomposed into chloral. Sol. in water, freely in alc. *Dose*, 1 to 3 Gm., 15 to 45 gr., B.P.

Chloralose.—This compound of chloral and glucose was introduced by Heffter, 1888 and 1893. It is often contaminated with the non-hypnotic but toxic parachloralose (Mosso, 1893).

Isopral, trichlorisopropyl alcohol, is over twice as active as chloral, and its action is more prompt. Impens, 1903, claimed, that it is safer than chloral; but Sollmann and Hatcher, 1908, have shown this claim is to be totally unjustified.

Clinically, it is also uncertain and dangerous (Kleinschmidt, 1914). The clinical side actions are described by Seifert, *Nebenwirk.*, 1915, p. 71.

PARALDEHYDE

General Statement.—This was introduced by Cervello, 1882. Its actions are similar to those of alcohol (Kraepelin, 1892); but the hypnotic effect is more powerful, and sets in very promptly, so that the patient may be asleep in ten to fifteen minutes. He should therefore be in bed before the drug is given. The sleep is normal; and with ordinary doses, without after-effects. The drug is less certain and less powerful than chloral; but therapeutic doses do not tend to depress the heart and respiration. It is not analgesic. Its principal disadvantages are the disagreeable pungent taste; fusel-oil odor of the breath, persisting over a day; irritation of the throat and stomach; dizziness and faintness (Seifert, *Nebenwirk.*, 1915, p. 64). Tolerance is generally acquired, and a habit is not infrequent. This presents the phenomena of chronic alcoholism, including delirium tremens (Fornaca and Querelli, 1912). Its acute toxicity is low, so that 100 Gm. produced only very prolonged sleep.

Indications and Administration.—Paraldehyde is used when chloral is contraindicated, particularly in delirium tremens (Theunisan, 1915); in the insane; in alternation with other hypnotics, etc. The ordinary dose is 3 c.c., 45 minims, raised in severe cases to 5 to 15 c.c. (1 to 43); or better, a teaspoonful every hour, until effective. It is best given in iced water, tea or claret.

Metabolism.—Hypnotic doses (in dogs) lower the blood-sugar, and have no effect on the nitrogen excretion. Anesthetic doses produce considerable hyperglycemia and glycosuria, and a considerable decrease of nitrogen excretion (Powell, 1914).

Other aldehydes of fatty acids are said to produce arterial disease in rabbits (Denny and Frothingham, 1914).

PREPARATIONS

* *Paraldehydum* (Paraldehyde.), U.S.P., B.P., $(\text{CH}_3\text{CHO})_3$.—A polymer of paraldehyde. Colorless transparent liquid, of strong characteristic odor and burning taste. Sol. in water (1:8), freely miscible with alc. *Dose*, 2 c.c., 30 minims, U.S.P., 2 to 8 c.c., $\frac{1}{2}$ to 2 drachms, B.P. *Maximal dose*, 5 Gm., 75 gr.

Amylene Hydrate (Harnack and Meyer, 1894).—Tertiary amyl alcohol, $(\text{CH}_3)_2\text{-C}_2\text{H}_5\text{OH}$. It ranks between chloral and paraldehyde. It was said to lessen the polydipsia and polyuria of *diabetes insipidus*. Colorless fluid; sol. in 8 parts of water, readily in alc. *Dose*, 1 to 2 Gm. (15 to 30 gr.), in glycerine.

SULPHONAL (SULPHONMETHANUM)

General Statement.—The ethyl-sulphones were introduced by Baumann and Kast, 1888. Sulphonal has the structure:

The hypnotic action is connected with the ethyl radicals, and is further enhanced by replacing the remaining methyl radicals with ethyl (*trional*, one replaced; *teironal*, both replaced).

Sulphonal is a rather powerful hypnotic, but a weak analgesic. Its absorption and therefore its effects are slow, sleep occurring only after one to five hours. Its administration must therefore be properly timed. The sleep lasts six to eight hours, and the effect persists somewhat during the next day, with vertigo, lassitude, drowsiness, and depression. This is due to the delayed excretion, which is even slower than the absorption; thus tending to cumulative effects and very dangerous poisoning, if the administration is continued over longer periods. Sulphonal is therefore unsuitable for prolonged use. In acute cases, or in alternation with other hypnotics, it has several advantages. Its taste is not unpleasant; it does not produce gastric irritation; ordinary doses do not affect respiration and circulation; and the fatal dose is generally much higher than the therapeutic. It does not induce tolerance, but may probably cause a habit.

Acute Poisoning.—The symptoms consist in prolonged and profound sleep, with gradual failure of the circulation and respiration. Death occurs usually after several days. It has been reported from 5 to 30 Gm. (Knaggs, 1890); while 100 Gm. have been survived (Neisser, 1891).

Chronic Poisoning.—This has been produced even by ordinary therapeutic doses, when continued for some weeks. The symptoms develop slowly and consist in nervous depression, gastro-intestinal disturbances, and urinary changes. The appearance of hematoporphyrin in the urine (dark cherry color) is particularly characteristic. Skin eruptions are sometimes seen. If the drug is stopped when the symptoms are light, recovery occurs, but is very slow. After the urine changes have set in, the prognosis is discouraging; death occurring after some weeks by general exhaustion. The autopsy is generally negative (Taylor and Sailer, 1900).

The principal symptoms of chronic poisoning are the following: *Nervous*: confusion, pareses, ataxia. *Digestive*: Almost continuous vomiting, abdominal pain, particularly, about umbilicus, with tympanites and obstinate diarrhea or constipation (A. W. Rogers, 1912). *Urine*: Hematoporphyrin, methemoglobin and red corpuscles, albumin, casts, high acidity. The literature of the side actions is given by Seifert, *Nebenwirk.*, 1915, p. 92; *Trional*, p. 94.

The occurrence of *hematoporphyrin* was described by Stokvis, 1889. It is rarely seen in acute poisoning, but is very frequent and fairly early in chronic poisoning. It can be produced in rabbits, but not in dogs (Neubauer, 1900). The hematoporphyrin is also found in the bile (Pfoertner, 1914).

Urticaria may be produced by local application to the scarified skin (Sollmann, 1917).

Excretion.—Sulphonal is excreted partly as ethyl-sulphonic acid, partly unchanged, by the urine and intestines.

Administration.—Sulphonal is used in nervous insomnia especially when chloral is contraindicated. The ordinary doses, 0.75 to 1 Gm., 10 to 15 gr., or in severe cases 2 Gm., are taken in hot milk at least four hours before bedtime. A smaller dose may be taken the second night. The administration should not be continued beyond a week, when as intermission must be made. It is generally advisable to prescribe cathartics, alkalies and plenty of water.

TRIONAL

Trional is more effective than sulphonal; and being more soluble, its absorption and action are more prompt, producing sleep in one-half to one hour. It has the same dangers as sulphonal, and the latter is more commonly used.

A case of chronic trional poisoning is described by v. Noorden, 1916.

TETRONAL

Tetronal is less soluble, and therefore too slow.

PREPARATIONS

* *Sulphonmethanum* (Sulphonmeth.), U.S.P. *Sulphonal*, B.P. (Diethylsulphonedimethyl-methane); $(\text{CH}_3)_2\text{C}(\text{SO}_2\text{C}_2\text{H}_5)_2$.—Colorless, odorless and nearly tasteless crystalline powder, slightly sol. in water (1:365); sol. in boiling water (1:15) and in alc. (1:60). *Dose*, 0.75 Gm., 12 gr., U.S.P., 0.6 to 2 Gm., 10 to 30 gr., B.P., as powder. *Maximal dose*, 2 Gm., 30 gr.

Sulphonethylmethanum (Sulphonethylmeth.), U.S.P.; *Methylsulphonal*, B.P. (Trional; Diethylsulphone-methylethyl-methane); $(\text{CH}_3)(\text{C}_2\text{H}_5)\text{C}(\text{SO}_2\text{C}_2\text{H}_5)_2$.—Colorless, odorless, crystalline scales; bitter taste. Slightly sol. in water (1:200); sol. in alc. *Dose*, 0.75 Gm., 12 gr., U.S.P.; 0.6 to 1.2 Gm., 10 to 20 gr., B.P., as powder. *Maximal dose*, 2 Gm., 30 gr.

HYPNOTIC UREA DERIVATIVES

These furnish a convenient means of exhibiting the alkyl groups, the efficiency being apparently enhanced by the urea combination. The three most important types of compounds are represented by Carbromal, Barbital and Urethane, as may be seen from the following formulas:

BARBITAL (VERONAL; DIETHYL-BARBITURIC ACID)

This was introduced by E. Fischer and Mering, 1903 and 1905. It has a number of advantages over the other hypnotics: It is even more powerful than chloral and somewhat more analgesic; it does not produce local irritation, and the taste is not so disagreeable. The margin between the ordinary therapeutic dose (0.5 Gm.) and the toxic dose (usually 8 to 10 Gm.) is somewhat wider; and the ordinary doses have little effect on the blood pressure and respiration. However, fatal collapse (by peripheral paralysis of the blood vessels) has occurred in several cases from relatively small doses (10 to 15 gr., 0.65 to 1 Gm., J.A.M.A., 53, 1833, 1909). On the other hand, recovery has resulted after 10 Gm. Small doses are somewhat diuretic (A. Hoffman, 1906). The action is rather slower than with chloral, more rapid than with sulphonal. After-depression is exceptional, but more common than with chloral. The usual dose, 0.5 Gm., 8 gr., induces a deep, dreamless sleep in one-half hour; or even more promptly if the soluble sodium salt is used. The patient generally awakens refreshed, but exceptionally suffers from lassitude, vertigo, headache, nausea, diarrhea and skin eruptions.

Barbital is excreted slowly, so that continued doses may produce serious cumulative effects similar to those of sulphonal, but rather more slowly. Nervous symptoms are especially prominent (Glaser, 1914). It must therefore be intermitted after a week. Habit occurs rather readily (Krep, 1905; A. Lambert, 1915), but tolerance is not easily acquired.

Indications.—Barbital is used in nervous insomnia, mania and delirium. It is also somewhat analgetic, depressing the sensory irritability to faradic stimulation, in man; Hale and Grabfield, 1923). It appears to be highly effective in delirium tremens, 0.5 Gm., three times daily (Dreyfus, 1914). It has also been employed against vomiting, sea-sickness, migraine and for combination anesthetics (Wolfram, 1906). It is taken dry or in hot liquids. If a more rapid action is desired, the soluble sodium salt may be given (Katzenstein, 1909); but its taste is more disagreeable. This is said to be improved by the addition of an equal amount of sodium phosphate (W. Straub).

Acute Barbital Poisoning.—This has been rather frequent; a number of cases are collected by Heffter and Loeb, 1906. They present the phenomena of coma, fall of blood pressure, feeble heart, vasodilation, marked fall of temperature even with moderate doses, increased reflexes, sometimes convulsions; slower and especially shallow respiration, asphyxia, but with pupils constricted (often with rhythmic changes; Roemer, 1919); renal irritation, diminished urine or anuria; exanthemata (circumscribed dermatitis reported by Zeisler, 1912). Rommel, 1912, describes epithelial necrosis of the kidneys in two fatal cases, without clinical signs of nephritis. P. Gautier, 1918, described four cases of poisoning from doses of 3.5 to 8 grams. One woman who had taken 5 grams, died after 4 days of coma. He believes that addicts are *less* resistant.

The literature of the clinical side actions is given by Seifert, *Nebenwirk.*, 1915, pp. 75 and 99.

Barbital Habit.—This is rather readily acquired. The patients develop confusion, a mild dementia, ataxia, debility, gastro-intestinal irritation, anemia and hematoporphyrin. (Krep, 1905; A. Lambert, 1915.) The tolerance is usually not increased by the habitual use.

Fate and Excretion.—Barbital is excreted almost exclusively by the urine, only traces appearing in the feces. When given by mouth, about 63 per cent. are eliminated

unchanged. This proportion is not altered on continued use, so that the remainder must be destroyed (A. Hoffman, 1906). The proportion excreted may rise to 90 per cent. with small doses hypodermically; and fall to one-half with large doses (Bachem, 1910). The excretion is very slow, requiring several days even after 0.5 Gm. This explains the cumulative effects.

Experimental Effects.—These have been investigated especially by Groeber, 1911; Roemer, 1912; and Jacoby, 1912.

Vasodilator Action.—Jacobj and Roemer, 1911, refer the toxic peculiarities of barbital to a direct action on the blood vessels, perhaps analogous to an arsenic effect. They therefore advise against its use when the circulation and respiration are depressed.

Blood Coagulation Time and Blood Sugar.—The coagulation time is shortened and the blood sugar lowered, in cats and pigeons. The two processes appear to go parallel (Ellis and Barlow, 1923).

Narcosis in Pigeons.—This is very persistent, lasting from two to twelve days in animals that eventually recover. (M. M. Ellis, 1923.)

Urticaria.—This is produced by the local application of barbital to the scarified skin (Sollmann, 1917).

Smooth Muscle.—Excised intestines, ureter and uterus are depressed by the barbital group. These drugs also antagonize the contractor action of epinephrine on the ureter and uterus (Gruber, 1921).

Barbital Derivatives.—These may be obtained in great variety by substituting the ethyl by other alkyl and aromatic groups, etc. These all share the narcotic qualities in the general order of the Meyer-Overton law (Tiffeneau, 1923; Tiffeneau and Torres, 1924). The toxicity naturally increases in the same ratio, and it has not been shown that they present any material advantage from this standpoint. However, phenobarbital appears to be especially adapted for securing the calming effect.

PHENOBARBITAL

This is considerably more powerful than barbital, and its use as hypnotic is rather dangerous (Taddei, 1923). It is used especially as a sedative in epilepsy, chorea, and exophthalmic goiter; the latter especially in concentration with operations.

Use in Epilepsy.—Phenobarbital (Luminal) is not curative, but decreases the number and severity of seizures (Hauptmann, 1912; M. Klotz, 1915) in the idiopathic and traumatic forms; not so much in the senile and syphilitic. Its field is therefore similar to that of bromide, with the advantage of less side-actions. The results are often better when the two drugs are combined (I. A. Darling, 1923).

Side-actions.—These are rather rare with the sedative dosage. They consist of rashes, resembling measles or scarlatina (H. Strauss, 1917; Luce and Feigl, 1918); inebriation; severe cholera-like diarrhea; hebetude; delirium (Darling).

Dosage.—The sedative dose, f.i. in epilepsy, is usually 0.1 Gm (1½ grs.) per day, for five days in the week; the effect endures through the other two days, and these obviate cumulation. Exceptionally two or three doses may be given during the day, for short periods. The dosage should never exceed 0.8 Gm. per day, and this should not be continued. Phenobarbital is almost insoluble in water and is usually administered as tablets. The sodium salt is soluble, and may be used hypodermically 12 c.c. of 20 per cent. = 0.4 Gm.).

Toxic Effects.—These are similar to those of barbital (Seifert, *Nebenwirkungen*, 1915, p. 73; J. Stein, 1920).

Excretion.—It has been reported that phenobarbital does not appear in the urine, even in poisoning (Wetselaar, 1922).

PREPARATIONS

* *Barbitalum* (Barbital.) U.S.P.; Barbitonum, B.P.; (Diethylbarbituric Acid, Veronal, Diethylmalonylurea); $\text{CO}(\text{HN.CO})_2\text{C}(\text{C}_2\text{H}_5)_2$.—White, crystalline powder; odorless; faintly bitter. Slightly sol. in water (1:130); sol. in boiling water (1:13) and alc. (1:14). *Dose*, 0.5 Gm., 8 grains, U.S.P.; 0.3 to 0.6 Gm., 5 to 10 grains, B.P.; in hot milk or hot lemonade. Maximum dose, 1 Gm., 15 grains.

Barbitalum Solubile (Barbital. Sol.), U.S.P., Soluble Barbital (Sodium Diethylbarbiturate, Veronal-Sodium; Medinal).— $\text{CO}(\text{NaN.CO})(\text{HN.CO})\text{C}(\text{C}_2\text{H}_5)_2$.—White powder; odorless; bitter taste. Soluble in water (1:5); sol. in boiling water (1:2.5). Melts 187° – 190°C . *Dose*, 0.5 Gm., 5 grains, U.S.P.

Dial (Diallyl-malonylurea) has no advantage over other ureid hypnotics (Castaldi, 1915).

Dipropyl-barbituric Acid, Proponal, was also introduced by Fischer and Mering, 1904 and 1905. It is more powerful than barbital, but more dangerous and less reliable.

* *Phenobarbitalum* (Phenobarb.) U.S.P.; Phenobarbital, (Phenylethyl barbituric acid; Luminal).— $\text{CO}(\text{NH.CO})_2\text{C}(\text{C}_2\text{H}_5)(\text{C}_6\text{H}_5)$.—White crystalline powder, odorless, stable in air. Very slightly sol. in water (1:1,000); easily soluble in dilute alkalies (as Sodium Phenobarbital). Freely soluble in alcohol; soluble in ether or chloroform. *Dose*, 0.03 Gm., $\frac{1}{2}$ grains, U.S.P.

URETHANES

These have been disappointing in man; the hypnotic action is feeble and patients soon become immune. The efficiency increases with the magnitude of the alkyl radicals (Binet). There is also a decided diuretic effect.

Urethane (Ethyl Carbamate).—This acts more satisfactorily on animals than on man; producing a rapid and profound narcosis, with little change in the circulation or respiration (Schmiedeberg, 1885). It is therefore employed as a laboratory anesthetic. The CO_2 threshold of the respiratory center is, however, somewhat raised (Wieland, 1915). It decreases the oxygen consumption (Winterstein, 1914). Large doses cause in rabbits a vacuolar degeneration of the hepatic epithelium (Sollmann).

It also lowers the phenol-s.-phthalein output (Whipple and Speed, 1915). Large doses produce *hyperglycemia*, independent of the quantity of liver-glycogen and epinephrine, and unaffected by pituitary. Bang, 1914, believes that it acts through pancreatic degeneration. It is excreted as urea. Side actions, Seifert, *Nebenwirk.*, 1915, p. 97.

Urticaria.—Application to the scarified skin produces a wheal (Sollmann, 1917), and dilation of the capillaries and arterioles (Carrier, 1922).

Urethane, $\text{CO}(\text{OC}_2\text{H}_5)\text{NH}_2$ forms colorless, odorless crystals of saline taste. It is very sol. in water (1:0.45) and in alc. (1:0.8). *Dose*, 1 to 4 Gm. 15 to 60 grs.

Hedonal, is twice as active as urethane (Dreser, 1899). It has the same general effects, its absorption is relatively slow and it is more toxic. Its dose is about double that of chloral. It has been used intravenously for anesthesia (Jeremisch; Page, 1912); a 0.75 per cent. solution in normal saline being injected at the rate of 100 c.c. per five minutes, reduced to 50 c.c. when anesthesia is attained. Its use is dangerous. Literature, Seifert, *Nebenwirk.*, 1915, p. 67.

Thio-ureas and Thiuramdisulphides.—These have a low but definite toxicity (Hanzlik and Irvine, 1921).

BROM-CARBAMIDES

These are rather feeble hypnotics and sedatives. Their therapeutic field is similar to that of bromides, except that they are not used in epilepsy. The principal representatives are Carbromal and Bromural.

Carbromal is administered in powder or tablets. The sedative dosage is 0.3 to 0.6 Gm., 5 to 10 grains, three or four times daily; the hypnotic dose is 0.6 to 1.3 Gm., 10 to 20 grains. It is used rather extensively against nervous insomnia. Poisoning by 15 Gm. was reported by Kirschberg, 1919.

Carbromalum (Carbrom.), U.S.P. Carbromal. (Brom-diethylacetyl carbamide, Adalin); $\text{C}(\text{C}_2\text{H}_5)_2\text{Br.CONH.CONH}_2$.—A white, crystalline, odorless powder. Very slightly sol. in water (1:3,000); sol. alc. (1:18); easily sol. in chloroform (1:3). *Dose*, 0.5 Gm., 8 grains., U.S.P.

Bromural is a prompt but very mild hypnotic, effective only in slight nervous insomnias. It is not analgesic, and is rendered ineffective by cough or delirium. Ordinary doses have no side effects (v.d. Eckhout, 1907; Sollmann and Hatcher, 1908; litera-

ture, Seifert, Nebenwirk., 1915, p. 48). In man, 0.3 to 0.9 Gm. are effective in five to twentyfive minutes, producing a natural sleep lasting three to five hours, without excitement (Krieger and v.d. Velden). It dissolves in hot water, but not in cold.

THE SYSTEMIC ACTIONS OF GASES

The respiration of oxygen is essential to life. A deficient supply of this gas leads to the phenomena of asphyxia. A number of gases (N_2 , H_2 , CH_4) act merely by excluding oxygen mechanically. This also forms an important element in the action of nitrous oxide, as ordinarily used. Carbon monoxide also acts by excluding oxygen, but it does so chemically. Other gases have specific, direct actions, especially on the central nervous system. Oxygen itself, when at a pressure of several atmospheres, is toxic. Carbonic acid and nitrous oxide produce their peculiar actions at lower pressures, but the air must contain considerable proportions. Sulphuretted and arseniuretted hydrogen are toxic in very high dilutions. The gaseous acids (sulphurous, nitrous, etc.), alkalies (ammonia) and halogens (bromine and chlorine) act mainly as local irritants. Compressed air acts mechanically.

The symptoms produced by most toxic gases resemble those of asphyxia and this whether the effect is produced by the absence of oxygen; or whether the gas has a specific toxicity. They are closely related to those of anesthetics. The irritant and the anesthetic gases are considered under these headings (see index).

The quantitative effect of gases depends on their partial pressure in the air, for this determines their concentration in the blood, and hence in the tissues. At ordinary barometric pressure, this is equal to the volume-percentage of the gas. But it is important to remember that the effect of the normal percentage of oxygen at half an atmosphere is the same as that of half the percentage at ordinary pressure; and conversely, that 1 per cent. of a gas at 3 atmospheres produces the same effect as 3 per cent. at 1 atmosphere.

Rapidity of Action.—The effects of gases appear very promptly after beginning the inhalation, and disappear as rapidly when the animal is made to respire pure air. This is due to the large surface and large quantity of blood exposed to them in the lungs; for the whole blood passes through the lungs every thirty seconds. As these factors are relatively greater in small mammals, these succumb and recover very much more rapidly than man, and may indeed be used as a test of the safety of suspected air. Whilst the recovery from the direct effects of gases is rapid, indirect after-effects may be very persistent.

CARBON DIOXIDE (CARBONIC ACID)

This acts as a weak acid, producing locally a rather mild irritation; and after absorption, strong medullary stimulation, and in higher concentrations narcosis. These actions play the principal role in ordinary asphyxia. Deficiency of CO_2 (acapnia) leads to corresponding depressant phenomena. The carbonic acid therefore acts as a hormone (Bayliss and Starling, 1906), which regulates the activities of various functions, especially of the respiration. In this way, the CO_2 tension of the blood and tissues is normally kept automatically at a practically constant level.

Local Actions.—CO₂ as gas or solution produces a prickling sensation and reddening of the skin and mucous membrane, followed by numbness and local anesthesia. The sensory irritation leads to reflex stimulations (Quincke, 1877). The cutaneous stimulation is utilized in the form of carbonated baths (Nauheim baths), especially in cardiac diseases. Frozen CO₂ (carbon dioxide snow) is employed as a superficial cauterizant. In the stomach, carbonated water ("soda water") hastens absorption, increases the secretion of acid gastric juice (Chiari, 1915), and acts as a carminative. It is useful against nausea, and valuable for disguising the taste of medicines. Experimentally, it produces marked augmentation of the gastric contractions and of the pyloric discharge. This is apparently due to parasympathetic stimulation, for it can be prevented by atropine (Carnot and Koskowski, 1922).

Effects of Inhaled CO₂.—If oxygen deficiency is excluded by inhaling gas mixtures containing 20 per cent. of oxygen, no effects occur until the concentration of 3 per cent., volume, of CO₂ is reached (Zuntz). With this concentration, there is some hyperpnea and discomfort: 8½ per cent. in man produces in a few minutes distinct dyspnea, rise of blood pressure and congestion, which become insupportable in fifteen or twenty minutes, but disappear promptly in fresh air. The symptoms increase to 15 per cent.; but even 20 per cent. is not dangerous in an hour to animals, and probably not to man. With 25 to 30 per cent., the stimulant phenomena pass into depression, with diminished respiration, fall of blood pressure, coma (generally without convulsions), loss of reflexes, anesthesia, and gradual death after some hours; the heart outlasting the respiration. With higher concentrations, the stimulation is still briefer. With pure CO₂, death may occur in a few minutes as a mixed effect of carbon dioxide and anoxemia.

Ordinary Asphyxia.—This involves the two factors of *deficiency of oxygen or excess carbon dioxide in the blood*. The phenomena in both cases are almost, though not quite, identical. When asphyxia results from breathing in a confined space, both causative factors are intermingled in the early symptoms, but the fatality is usually due to oxygen deprivation.

The *symptoms* of asphyxia vary somewhat according to the rapidity with which it is produced. *When it occurs rapidly*, three typical stages may be distinguished: During the *first stage*, the respirations (particularly the inspirations) are increased. In the *second stage*, the respirations are irregular and convulsive, the inspirations being shallow and weak, the expirations powerful and prolonged. Consciousness is lost. The skin, especially the face, becomes cyanotic. The *third stage* is characterized by collapse and convulsions. The respiratory centers are depressed. The respiratory movements are shallow and infrequent. The convulsive, vagus, vasomotor and pupillo-dilator centers are stimulated. The extremities and the muscles of the face and neck twitch convulsively, there are gasping movements; the body of the animal is rigid and arched backward. Urine and feces are expelled. The pulse is very slow and soft, at first strong then progressively weaker. The pupils are at first constricted, then widely dilated until death. The heart continues to beat weakly for several minutes after the respiration has stopped. Artificial respiration during this interval will generally result in recovery. *Death* occurs within six or eight minutes, if the trachea is tied.

The *autopsy* shows a very venous color of the blood. The veins of the upper part of the body, and the right heart, are greatly distended.

If the *asphyxia* is produced slowly, the first symptoms are cyanosis and dyspnea on exertion. The individual becomes stupefied, but so gradually that he may not be aware of his condition. The stupor passes into unconsciousness and this into collapse. The motor symptoms may be entirely absent.

Cyanotic Tint.—Asphyxia by excess of carbon dioxide produces a deep-blue cyanosis, with venous congestion. Oxygen deficiency causes a gray tint, without rise of venous pressure (Haldane, 1917). This difference in tint is evidently due to the quantity of venous blood in the skin.

Lundsgaard, 1919, has confirmed that cyanosis proper is due to "oxygen unsaturation" of the capillary blood, appearing when this reaches 6 to 14 per cent.

There is no strict parallel between the two, since the depth of the color of the skin and mucous membranes is determined by the quantity as well as by the color of the blood.

The unsaturation may occur through incomplete aeration in the lungs; or through slowed peripheral circulation; or through excessive oxygen consumption in the tissues.

Medullary Centers in Asphyxia.—The effects are alike whether they result from CO₂, acidosis, or oxygen deprivation. The stimulation occurs in the order of respiratory, then vasomotor and then vagus centers. It is followed by depression of these centers. The relative preponderance of stimulation and depression depend on the degree and suddenness of the asphyxia, and on the prevailing condition of the centers (Loevenhart, 1915).

According to perfusion experiments on mammalian medulla, carbonic acid appears to be somewhat more stimulating than other acids of equal H-ion concentration (Hooker et al., 1917), presumably because it penetrates the nerve-cells more rapidly.

Rôle of CO₂ in Impure Air.—The popular idea of this is greatly exaggerated. "Pure" air contains 0.03 per cent. of CO₂; in city streets it rarely rises above 0.04 or at most 0.15 per cent. In badly ventilated rooms it may reach 0.3 per cent., which is far below the effective concentration. Neither the presence of CO₂ nor the absence of oxygen explains the harmful effect of sojourn in ill-ventilated rooms; nor does the expired air contain any poisonous ingredients. It is supposed that the acute discomfort and the suffocating sensation experienced in these places is largely psychic, being produced by the heat, humidity, odors, noise, etc. Whether this accounts also for the severely detrimental effect on health and resistance, the increased tendency to tuberculosis, etc., which are associated with habitually deficient ventilation, is an open question. Winslow and Palmer, 1915, conclude that the air of unventilated rooms (with controlled temperature and humidity) contains substances which diminish the appetite for food, without producing discomfort or other detectable symptoms. It may be remarked that the continued or repeated exposure to gases—particularly those acting upon the blood, and indeed to any poison which alters the blood, such as acetanilid—does not generally cause tolerance, but increase of susceptibility.

CO₂ on Circulation.—Increase of carbon dioxide up to a certain point causes a marked rise of blood pressure mainly by stimulation of the vasomotor center; moderate increase of CO₂ tension perhaps also increases the output of the heart. The peripheral action on blood vessels results in their dilation. High concentrations paralyze the vasomotor center and heart.

Vasomotor Center. The violent stimulation has been shown by Sollmann and Pilcher, 1911, and by Mathison, 1911. The latter demonstrated that identical effects

are produced by other acids and by lack of oxygen; and that all these act probably by increasing the hydrogen-ion concentration of the blood. The spinal vasomotor centers are much less sensitive than the medullary (Mathison, 1910).

Direct Action on Vessels.—Perfused or excised vessels are dilated by physiologic concentrations of CO_2 (Bayliss, 1901; Cow, 1911; Hooker, 1912). This occurs with concentrations that stimulate the respiratory center. Very high concentrations may constrict (A. Fleisch; Adler, 1921; P. Heymann, 1921. Roncato and Oselladore, 1923). A similar dilation is also produced by other weak acids (Schwarz and Lemberger, 1911). Barcroft, 1914, considers this an important factor for the increase of the local circulation in active organs.

Pulmonary Circulation.—The pressure in the pulmonary arteries rises in asphyxia, even if the rise of the systemic blood pressure is prevented by destroying the medulla (Wood, Jr., 1911). The pulmonary circulation time is slowed (Langlois and Desbouis 1912), indicating pulmonary vasoconstriction.

Venous Pressure.—Increase of carbon dioxide causes a large rise of venous pressure, even when the arterial pressure is but little affected. Henderson and Harvey, 1918, interpret this as due to direct dilation of the capillaries and venules.

The increased venous return would increase the diastolic filling and thus the efficiency of the heart. Acapnia would have the opposite result.

Heart Rate.—This is ordinarily slowed by stimulation of the vagus center; but if the vagi are divided, it is quickened by stimulation of the accelerator center (Dastre and Morat, 1885).

Efficiency of the Heart.—In intact animals, the cardiac effects are greatly complicated by the other actions. Jerusalem and Starling, 1910, claim that increase of CO_2 in the coronary blood lessens the tonus both in systole and diastole. The coronary vessels are also dilated (Markwalder and Starling, 1913). With higher concentrations, the systolic tone is lowered more, so that the excursions are diminished; with moderate concentrations, the diastolic tone is more relaxed and the output increased. A certain concentration would therefore be necessary for the optimum efficiency of the heart; this is insufficient in acapnia. Itami, 1913, claims that the rise of blood pressure with 5 per cent. of CO_2 in the inspired air is chiefly due to increased output of the heart; and that above 8 per cent. the vasoconstriction becomes the more important. These results have been contradicted: Ketcham, King and Hooker, 1912, attribute the increased output to dilation of the pulmonary vessels, for they found that the isolated heart is depressed by all concentrations. In the limulus heart, CO_2 produces depression, acting much more powerfully on the ganglion cells than on the muscle (Newmann, 1906). Perfusion of the coronary vessels of a mammalian heart with CO_2 gas causes prompt fibrillation and arrest, whereas the heart continues to beat for a considerable time if the perfusion is made with oxygen, or even hydrogen (Magnus, 1902).

Blood Viscosity.—This is somewhat increased, but not to an important degree (Burton-Opitz, 1911).

Oxygen on CO_2 of Blood.—Oxygen (and carbon monoxide) tends to expel CO_2 from the blood; for when exposed to a given CO_2 tension, blood that has been deprived of oxygen takes up considerably more CO_2 than oxygenated blood (Christiansen, Douglas and Haldane, 1914).

Peristalsis.—In intact animals, this is stimulated by asphyxia. Excised intestine is started to rhythmic contraction if it was quiescent; but is relaxed if it was already rhythmically active (Hooker, 1912).

Oculomotor Center.—The pupils are ordinarily widely dilated by asphyxia, after primary constriction (Guthrie and Ryan, 1910). The mydriasis is not due to sympathetic stimulation, for it occurs after division of the cervical sympathetic (Braunstein, 1894). It must therefore be ascribed to inhibition of the oculomotor center. Peripherally, CO_2 acts as a miotic on frogs' pupil (Auer, 1909).

Protoplasm Consistency.—The fluidity is first increased by CO_2 , then decreased. Accordingly, the protrusion of *pseudopodia* is first favored, then arrested (M. H. Jacobs, 1922).

Respiration.—The CO_2 content of the blood is the chief regulating factor in ordinary respiration (Zuntz, 1897), the respiratory center being stimulated (mainly the rate) even by very slight increase of the CO_2 tension. The normal CO_2 percentage of the alveolar air is 5.6 per cent. A rise of 0.2 per cent. of CO_2 (1.0 mm.) in the alveolar air doubles the respiration, and a slight reduction (0.2 per cent.) of the CO_2 produces apnea. The sensitiveness to oxygen is very much less, the respiration

being unaffected by variations of the oxygen in the air between 13 and 100 per cent. (Haldane and Priestley, 1905; Fitzgerald and Haldane, 1905). The effective increase of CO_2 also produces a slight but measurable change in the hydrogen ion concentration of the blood (Campbell and coworkers, 1913). Other acids are similarly stimulant (Winterstein, 1911; Laqueur and Verzar, 1911) although not quite as much (Hooker et al., 1917). Loevenhart, 1913, refers the effects ultimately to interference with oxygenation. The response to CO_2 is used experimentally as a test of the excitability of the respiratory center (A. Loewy, 1890).

Bronchial Muscle (Excised).—This is constricted by moderate, relaxed by high concentrations (Trendelenburg, 1912).

Convulsants.—Strychnine convulsions may be suppressed by CO_2 inhalation (Winterstein, 1900; Ryan and Guthrie, 1908). On the other hand, moderate asphyxia increases the convulsant effect (Pilcher). Concentrations above 20 per cent. also heighten the susceptibility to acid fuchsin convulsions (Joseph, 1915).

Conversely, picrotoxin, lobeline and camphor appear to make animals more subject to CO_2 convulsions (Wieland and Mayer, 1922).

Temperature.— CO_2 dyspnea lowers the temperature in health, and especially in fever. It also reduces metabolism (v. Magyary-Kossa, 1910).

Asphyxial Glycosuria.—All forms of asphyxia—whether from CO_2 or deficiency of oxygen—lead to hyperglycemia and glycosuria. All asphyxiant drugs produce this effect, although there may be additional factors. The glycosuria does not occur if the liver is excluded, nor in poorly nourished animals (W. Auel, 1914). It seems therefore that the glycogenolysis is stimulated in the liver, but not in the muscles. This effect is probably due to the increased H-ion concentration of the blood, acting through the nervous centers, but requiring the cooperation of the adrenals, for it does not occur if these have been excised (Macleod, 1913).

Drugs Leading to the Appearance of Reducing Substances in the Urine.—The following may be enumerated as among the most important (review, S. Weber, 1904): CO , N_2O , H_2 , H_2S , HCN , amyl nitrite, nitrobenzol, nitroglycerin, chlorate, chloral, urethane, chloroform, acetone, strychnine, morphine, atropine, curare, phlorhizin, caffeine, and other methyl xanthins, H_2O_2 , many acids, Pb, As, Hg, Ur, Cr, cantharidin, P, epinephrine thyroid, saline.

Deficiency of CO_2 (Acapnia).—The carbon dioxide tension regulates the heart rate, vascular tone, peristalsis, mental condition, and a number of other functions. A decrease of this tension in the blood and tissues produces depressant effects.

Phenomena of Acapnia.—These have been emphasized especially by Y. Henderson 1908 to 1910. Even a slight reduction of the CO_2 causes marked increase of the heart rate and slowing of respiration. Further reduction produces tachycardia, venous stasis, arrest of peristalsis, failure of many reflexes, coma and stoppage of respiration. Extreme reduction causes an almost tetanic condition of the heart, abolishing its output, lowering blood pressure and resulting in death. In the lighter grades, recovery occurs promptly if the CO_2 tension is increased, as by breathing through a long tube.

Acapnia and Respiration.—The respiratory center is readily depressed by deficiency of CO_2 in the blood. This is the main factor in the apnea following hyperpnea, and one factor in Cheyne-Stokes respiration (Haldane, 1905 and 1909). Weil, 1906, *f.i.*, showed that the apnea is the shorter, the more CO_2 is in the air; and that it can be prolonged by fixing the CO_2 with NaOH . The increased oxygen content, to which it was formerly attributed, seems to be unessential although excessive oxygen concentration is also depressant (Loevenhart, 1913).

The direct depressant effect of CO_2 deficiency on the respiratory center was also demonstrated by Winterstein's (1911) perfusion experiments. The respiration was not restored by oxygen, but by carbonic or other acids, and is therefore an hydrogen-ion effect. In intact animals, a persistently low oxygen tension leads to the accumulation of lactic and other acids, and hence to stimulation of the respiration.

Acapnia and Shock.—Y. Henderson, 1908 and 1909, pointed out the analogies between the phenomena of acapnia and surgical shock. He believed that the latter may be explained by loss of CO_2 through hyperpnea, exposure of intestines, etc. This may be one of the factors but it is unlikely that it is the only one. Henderson's conten-

tions are contradicted by Janeway and Ewing, 1913. Henderson (1918) believes that acapnia is also an important factor in hemorrhagic shock.

Apnea.—This suspension of the respiratory movements is usually due to depression of the respiratory center by excessively low CO_2 content of the blood (acapnia); for instance, as a consequence of hypernea. Fredericq showed that apnea can be produced by the transfusion of the blood of an apneic animal.

However, acapnia is not essential; for excessive distention of the lungs may produce apnea even when the air contains 5 per cent. of CO_2 . This phenomenon does not occur if the vagi were divided (Githens and Meltzer, 1914). In fowls, CO_2 deficiency also stops the respiratory movements, but in this case the effect consists in tonic spasm of the respiratory muscles, and not in heightened threshold. The function of CO_2 would therefore consist in the maintenance of the respiratory rhythm (Meyer and Meltzer, 1915).

Normal CO_2 Percentages and Tensions.—These are approximately as follows:

CO_2	Per cent. (Volume)	Tension
Expired air	About 4	30 mm.
Alveolar air	4.6 to 6.2	
	Avg. 5.5	42 mm.
Arterial blood	36 to 40	30 to 42 mm.
Venous blood	45 to 50	30 to 50 mm.
Tissues	51 to 58	40 to 70 mm.

Therapeutic Use of Carbon-Dioxide and Oxygen Inhalation.—The stimulant actions of carbon dioxide on respiration and on the vasomotor centers may be utilized by the inhalation of oxygen containing five per cent. of CO_2 . A well fitting mask with appropriate valves is indispensable. This has been used especially in the treatment of carbon monoxide poisoning. The deeper and more rapid respiration raises the percentage of oxygen in the alveolar air, so that it may displace the CO more rapidly, which is also fanned out of the lung more effectively. The inhalation is also useful in anesthesia accidents, by stimulating the depressed respiration and by washing out the anesthetic. It has also been advised in poisoning by alcohol, methyl alcohol, and morphine (Y. Henderson, 1924). No detrimental effects have been demonstrated, even when the inhalation is continued for half an hour. However, it would seem advisable to use it only as necessary; for it may be assumed that it is not quite indifferent, especially as regard the heart.

Re-breathing in Shock.—W. T. Porter, 1917, suggested the increased respiration produced by carbon dioxide as a mechanical aid to the circulation in fat embolism, and in shock generally. He apparently obtained some good results; but the clinical results have not been good (Crile) and the injurious direct effects of asphyxia on the heart do not ordinarily justify this method.

CARBON MONOXIDE

Carbon monoxide (carbonic oxide, CO) has considerable toxicologic importance, through its occurrence in artificial illuminating gas, especially "water-gas" (not in "natural gas") and as a product of incomplete combustion, in stoves, motor-exhaust gas, and mine explosions. It is a colorless, odorless and non-irritant gas, so that there is no warning of its presence. Accidental as well as suicidal poisoning by it are very common. It forms a firm compound with hemoglobin, thereby preventing it from carrying oxygen, and thus produces asphyxia. This agrees with ordinary asphyxia, except that the skin and mucous membranes are usually not cyanotic but often bright red, due to the color of CO-hemoglobin.

Occurrence in Artificial Illuminating Gas.—Carbonic oxide constitutes 4 to 10 per cent. of ordinary coal-gas, and 30 to 40 per cent. of water gas (which is consequently more dangerous, Sedgwick, 1911). It is the principal toxic ingredient of these gases.

Coal-gas, however, is said by Vahlen (1903) to possess more than double the toxicity which would correspond to its CO. Y. Henderson and Haggard state that dogs exposed to illuminating gas die when 50 per cent. of their hemoglobin is saturated with CO, but that they survive considerably higher concentrations when exposed to pure CO.

A. H. Huebner, 1916, also believes that the CO does not account fully for the toxicity of coal gas. The difference is due to coal-tar products (which may be removed by passing the gas through oil). The disagreeable odor of gas is not due to the carbonic oxide (which is practically odorless), but to sulphur compounds. These are not toxic but serve as a useful warning of the escape of gas. This odor can be detected in air containing 0.01 to 00.2 per cent. of gas; *i.e.*, much below the danger limit. They are removed by filtration through soil; so that underground breaks in gas mains are especially dangerous.

Occurrence in Automobile Exhaust Gases.—These contains an average of six per cent. of CO. The engine of a small automobile when running in a small closed garage, would contaminate the air to a dangerous degree in about three minutes (U.S.P.H.S.).

Manner of Action.—Carbon monoxide acts only by displacing oxygen and has no direct action of any kind; for if an animal is made to breathe oxygen under 2 atmospheres pressure (which renders it independent of the

FIG. 23.—Spectroscopic bands of blood pigments.

hemoglobin) the addition of carbonic oxide in any amount produces no symptoms. However, Geppert, 1892, believed that there is a direct but insignificant action on the central nervous system; and Giacosa, 1905, even claimed that the blood changes do not play the principal role in CO-poisoning.

Action on Plants and Lower Organisms.—Carbon monoxide (or illuminating gas) slightly retards the growth of bacterial cultures, but is not germicidal. Infusoria and ciliated epithelia are also checked, but not killed. The germination of the seeds of higher plants is not affected. The gas kills plants when applied to the leaves, but not when applied to the roots (Heider, 1914).

Action on Hemoglobin.—Claude Bernard first showed that carbon monoxide does not act as an indifferent asphyxiant, but that it forms a very firm compound, carbonic oxide-hemoglobin, with the blood pigment. This is distinguished spectroscopically from hemoglobin, and it is not reduced by ammonium sulphide (Hoppe-Seyler, 1864 and 1865). (See Fig 23.) It has a cherry red color (Piorry, 1826), which is quite different from that of oxyhemoglobin, especially when it is diluted. This forms one of the best tests for its presence.

The affinity of hemoglobin for carbonic oxide is about 210 times as great as that of oxygen; even *very small proportions* therefore prevent the complete oxygenation of blood and produce *asphyxia*.

The Blood at Necropsy.—This preserves the scarlet color for a long time after death. It putrefies slowly, and the CO bands have been demonstrated six weeks after death; and even with survival, they have been present for 96 hours. In some parts of the body the blood may appear black, presumably when death occurred before the CO was uniformly distributed; but even the black blood gives the CO-hemoglobin spectrum. The cadaveric echymoses have a rose color (Brouardel, *Les Asphyxies*).

Fate.—The CO is excreted unchanged, and is not oxidized to CO₂. In fatal cases, a part persists for a long time (over a month) in the blood, and to a less extent in the muscles (Wachholz and Lemberger, 1905). It may penetrate postmortem into a cadaver, but so slowly that it can not be demonstrated in the internal organs (Stoll, 1909). Cl. Bernard observed that CO delays the postmortem degeneration of blood corpuscles, the serum separating very clear.

Toxic Concentrations in the Air.—The absorption of CO is proportional to its concentration in the air. Gruber, 1881, found that 0.024 per cent. is harmless even after several hours. The toxicity begins with about 0.05 per cent.; is severe with 0.07 per cent.; and dangerous with 0.16 per cent.; 0.2 to 0.4 per cent. is generally fatal. A man at rest would collapse within an hour when exposed to 0.2 per cent. (Burrell and Gauger, 1919). The toxicity increases with the time of exposure (Sayers et al., 1922) and also depends somewhat on the total quantity of gas available, if this is limited (Gréhant). Several persons in the same room may be affected in different degrees, due to air currents.

Toxic Concentrations in the Hemoglobin.—Dizziness and hyperpnea occur when about 20 per cent. of the hemoglobin is saturated; unconsciousness with 50 per cent.; death with 60 to 80 per cent. of saturation (Dreser, 1891; Balthazard and Nicloux, 1911). With 90 per cent. saturation, the heart stops very suddenly.

For men exposed to dilute concentrations (1 to 4: 10,000) for 1 to 5 hours, the degree of hemoglobin saturation lies between 14 and 27 per cent. with corresponding symptoms (Sayers et al., 1922).

Course.—The phenomena agree with those of ordinary asphyxia, except that cyanosis may be absent; the skin being pink or pale, and the lips bright red (*i.e.*, the color of CO-hemoglobin). This is of diagnostic importance. The effects are insidious, the person becoming unconscious often with no premonitory symptoms.

The clinical cases may be classified as acute, chronic and relapsing (McConnell and Spiller, 1912).

Symptoms of Acute Illuminating Gas Poisoning.—These may be divided into three stages (following McCombs, 1912): (1) till loss of consciousness; (2) from beginning of syncope to the onset of apnea; (3) coma with arrested respiration.

Onset.—The symptoms generally begin with a feeling of discomfort, throbbing blood vessels; dizziness, headache, weakness, and sometimes nausea and vomiting; sometimes pain in the extremities, and muscular twitching. The temperature is normal; the pulse full and bounding, the blood pressure elevated; feeling of constricted thorax; pupils widely dilated; gradual drowsiness, stupor and *unconsciousness*.

After this has set in, the respiration becomes accelerated and stertorous; the skin dusky; lips and extremities blue, or pale or pink; loss of reflexes and exceptionally sphincter control. Tetaniform convulsions may occur and be followed by marked muscular rigidity, especially in the jaws. However, the convulsions are produced only in very rapid poisoning, and are therefore rare clinically.

The pulse and respiration gradually weaken, ending in apnea, and finally arrest of the heart.

Death sometimes occurs acutely through aspiration of vomited matter during unconsciousness.

Recovery.—This is often very slow, but it may occur even when the coma has lasted two or three days. Convalescence is also often tardy, with pulmonary and nervous sequels.

Sequels: aspiration pneumonia, often fatal; palpitation, localized hyperemias, gastrointestinal disturbances, transient asphyxial glycosuria (review, S. Weber, 1904), cutaneous eruptions, localized edemas, gangrene (J. E. Briggs, 1919); paralysis of central and peripheral types, choreiform movements, persistent headache; mental changes, loss of memory, confusional insanities, etc.

Chronic Type.—Headache, nausea, vertigo, weakness, anemia, slowed intellect and failure of memory, and all the phenomena of the acute type more slowly developed. The memory for recent events is impaired much more than for those of older standing (S. Brown, 1906). The nervous phenomena have been referred to serous leptomeningitis (Zieler, 1897).

Relapsing Type.—The acute symptoms are followed by complete recovery, but after some weeks grave paralytic phenomena appear and are often fatal. These cases show softening of the lenticular nucleus, referred to fatty degeneration of the vessels, proceeding to calcification.

Induced Tolerance.—Guinea pigs can be accustomed to live for months in an atmosphere by which 25 per cent. of their hemoglobin is saturated with CO. This tolerance is attained by an increase of the corpuscles and hemoglobin, so that the oxygen capacity becomes almost normal.

Fetal Blood.—This may contain much less CO than that of the mother (Quinquaud and Gréhan); so that Caesarian section may be indicated to save a fetus near term.

Differences According to Source of CO.—The gases usually contain impurities which modify the effects. The coma is longer and more severe in illuminating gas poisoning, than with pure CO (Y. Henderson and Haggard, 1918, 1922). In automobile gas, the benzol vapors play a minor part.

Circulation and Respiration in Acute Poisoning.—Carbon monoxide produces a progressive fall of blood pressure, and marked slowing of the heart, apparently not affected by section of the vagi. The respiration is at first slow and shallow, then slower and deep (D. E. Jackson and Chance, 1925).

Lower Vertebrates and Isolated Organs.—Intact frogs lose their reflexes in pure CO after about 2 hours, about the same as in hydrogen. Tadpoles, and the isolated (Straub) heart are not injured materially by pure CO (Kochmann, 1920).

Treatment of CO and Illuminating Gas Poisoning.—This is usually successful if begun while the heart is beating. In the presence of a large excess of oxygen, the carbonic oxide hemoglobin is again decomposed, and the CO eliminated (not burned). The treatment therefore consists in artificial respiration, or better, the inhalation of oxygen containing 5 per cent. of CO₂. Bleeding with transfusion of healthy blood is very effective (Worm-Mueller; Crile and Lenhart, 1907). Patients should not be exposed to cold.

With respiration, natural or artificial, of ordinary air, the CO-hemoglobin is decomposed below the danger limit within an hour, the CO being practically eliminated in two or three hours. It is therefore superfluous to use oxygen or transfusion after an hour.

If the coma continues longer, this is due to persisting injury of the nerve-centers by the early asphyxia. Once this injury has occurred it would not be helped by oxygen. The existence of acidosis indicates alkalies; otherwise the late treatment would be expectant (Y. Henderson, 1916).

The *prognosis* varies with the duration of the exposure and of the coma. It is bad if the coma has lasted more than forty-eight hours, or if edema or cutaneous blebs have developed (G. I. Jones, 1909). Even in favorable cases, recovery is rather more slow than with most gases; but the acute effects have generally disappeared within three hours.

OXYGEN

The Inhalation of Pure Oxygen.—Oxygen constitutes about one-fifth (20.94 per cent.), by volume, of ordinary air. An increase of this proportion, and even the inhalation of undiluted oxygen, produces no noticeable effect under ordinary conditions. The rate of oxidation or the consumption of oxygen is not at all increased (Pflueger); indeed, the output of CO_2 is rather lessened. Evidently, the proportion of oxygen in air suffices for all ordinary needs (or, rather, it is greater than necessary); and additional oxygen acts merely as an indifferent gas—as so much nitrogen or hydrogen. In other conditions, however, namely when the supply of oxygen is deficient from any cause, its inhalation will remove the asphyxial symptoms with striking promptness and efficiency.

Condition of the Oxygen in the Blood.—The effects of most gases are strictly proportional to their partial pressure in the respired air. Oxygen departs from this rule, for there are practically no effects when its percentage is varied between 10 and 15 per cent. This is explained by the fact that only a small part of the oxygen is carried in physical solution in the blood plasma. By far the greater part is in loose chemic combination with hemoglobin, 1 molecule of hemoglobin combining with 1 molecule of O_2 (Butterfield, 1913). This combination is only slightly affected by the above changes of pressure. When respiring ordinary air without obstruction, the hemoglobin of the arterial blood is already four-fifths to nine-tenths saturated with oxygen; and the amount taken up can therefore be but little increased by raising the oxygen tension (Buckmaster and Gardner, 1913). The oxygen of the plasma, however, increases directly with the oxygen percentage of the alveolar air. While the amount thus carried is numerically small, it becomes important in conditions in which the hemoglobin can not perform its function properly, as in anemias or CO poisoning. The plasma oxygen may also play a part when the demands for oxygen are greater than can be supplied by the hemoglobin; as in very severe muscular exertion or in cardiac disease.

Ordinary arterial blood contains about 18.5 per cent. of oxygen in chemic combination with hemoglobin; and 0.6 per cent. dissolved in the plasma—a total of 19.1 per cent. Inhalation of undiluted oxygen increases the percentage in oxyhemoglobin only to 18.7 per cent.; the dissolved oxygen is increased in proportion to the partial pressure; *i.e.*, to 3 per cent., giving a total of 21.7 per cent., or an increase of 2.6 per cent. This is not really as small as it appears; for it seems that the oxyhemoglobin does not yield all its oxygen to the tissues (for instance, after death by asphyxia the blood still contains considerable oxygen). Haldane, 1917, considers that the increase of 2.6 per cent. really equals about 40 per cent. of the easily available oxygen of the blood.

Dissociation Curve of Oxyhemoglobin.—This follows the law of mass-action, showing that the reaction is chemic and not adsorptive. The curve is identical for pure solutions of hemoglobin, whatever their origin; but it is markedly affected by electrolytes, and therefore differs in the blood of different animals or even individuals. The action of electrolytes is explained by aggregation of the hemoglobin molecules. It is especially great with acids (H-ion concentration). Increased acidity diminishes the affinity, and therefore the effective concentration of oxygen. Thus 40 mm. of CO_2 cuts the efficiency of oxygen into half. The same laws hold for CO-hemoglobin (Barcroft, 1914).

Oxygen Exchange in the Body.—A. J. Clark quotes the following average figures:

	Oxygen pressure (mm. Hg.):	Volume of gas per 100 c.c.	Per cent. satu- ration of blood:
Alveolar air.....	106	14	—
Arterial blood.....	104	20	95
Venous blood.....	46	16	75
Tissues (approximate).....	20	—	—

Absorption of Oxygen in the Lungs.—There has been much discussion whether this follows purely physical laws. The question is even now not absolutely decided. According to Douglas and Haldane, 1910, the absorption is simply physical under ordinary conditions; but if so much CO is inhaled that the supply of oxygen to the tissues becomes inadequate, there is an active (secretory) absorption, so that the partial pressure of oxygen in the arterial blood becomes higher than in the alveolar air. This occurs also when the demand for oxygen is increased by muscular work. It is not known how this correlation is brought about.

Mechanism of Oxidations in Tissues.—The oxidations of metabolism are not accomplished by oxygen directly, for they can not be reproduced *in vitro* at ordinary temperature. There must be some activation of the oxygen. The most commonly accepted theories are modifications of that of M. Traube, *i.e.* the production of superoxides, which produce *in vitro* types of oxidation corresponding closely to those in the body. The *oxidases* are supposed to consist of organic peroxides and a catalyst (*peroxidase*). *Catalases*, which occur in many tissues, act only on hydrogen peroxide; their function is problematic (Bibliography, Kastle, Hyg. Lab., Bul., No. 59). The oxidizing ferments so far identified are apparently not connected with the energy-producing oxidations of the body (Batelli and Stern, 1912).

Catalase Content of Blood.—The catalase of the blood is contained almost entirely in the blood corpuscles. It therefore fluctuates simply with the corpuscle-plasma ratio of the blood (Becht, 1919, Stehle, 1919). It has no relation to the oxidative activity of the body, or to the activity of the liver, etc. (as was thought by Burge, 1918).

Poisons on Catalase.—Dilute solutions of most alkaloids increase the activity, but stronger solutions, especially of the alkaloidal salts, depress (Santesson, 1920; review, Morgulis, 1924).

Relation to Medullary Centers.—These are stimulated by moderate deficiency of oxygen; paralyzed by extreme deficiency. The respiratory center is the most sensitive, then the vasomotor, and least the vagus center. The intensity of the reaction is determined by the rapidity and degree of the change and by the state of the centers. Excessive oxygen is depressant. Loevenhart, 1913, attributes ordinary asphyxial stimulation to depression of the oxidative processes of the cells, by actual abstraction of oxygen, or by increase of hydrogen-ion concentration (acidosis, CO₂). Very similar phenomena are produced very promptly by cyanides, which are known to interfere with oxidation. The response occurs so promptly that there would scarcely be time for the accumulation of acid; so that deficiency of oxygen probably acts directly (Gasser and Loevenhart, 1914).

Two-phase Oxidation Theory.—Loevenhart, 1915, suggests that asphyxia may be explained by assuming two phases of oxidation: the "rest process," occurring during rest and recovery, and requiring external oxygen; and the "activity process," during activity, which consumes internal oxygen. Both processes would be constantly in operation; their relative intensity determining the state of activity of the cell. The addition of external oxygen would reinforce the "rest process" and thus cause depression; while oxygen deficiency would have the opposite effect.

Relation of Oxygen to Activity.—Every increase of activity, in any organ, appears to produce an increased consumption of oxygen. This outlasts by far the time of actual stimulation and visible response. The same is true of the production of heat. This corresponds to the "rest process," and is evidently concerned in the storage of potential energy.

Oxygen and Muscular Fatigue.—According to the views of Fletcher, Hopkins, Meyerhof and of A. V. Hill, muscular contraction is produced by the formation of lactic acid from glycogen, a non-oxidative process; and relaxation by the re-conversion of lactic acid into glycogen. This involves the oxidation of about a fifth of the lactic acid, and this furnishes the energy. The restoration occurs very quickly if plenty of oxygen is available; but considerable work may be done by the accumulation of an oxygen deficit, which must be replaced before the muscle is restored. Muscular exhaustion consists in this oxygen deficit. Because of the limitations of the heart, the replacement in man may require an hour to an hour and a half, after severe exertion (A. V. Hill).

Minor Effects of Oxygen Inhalation. *Metabolism.*—Lavoisier and Seguin, 1780, claimed that pure oxygen has no effect on metabolism. This has been confirmed by the modern investigators. However, the reputed benefits from the inhalation of oxygen in *fatty degeneration and some other obscure diseases* (if the reports are reliable) would point to some effect on metabolism, perhaps too small to be detected by the usual methods of observation.

Oxygen inhalation also produces some other slight effects: Cl. Bernard claimed that birds placed in pure oxygen are greatly excited; and that the urine of rabbits

becomes acid. Benedict and Higgins, 1911, observed some slowing of the *pulse*, without change in respiration. There are rather more marked effects after *exercise* (Cook and Pembrey, 1913). The efficiency of athletes is increased and forced respiration can be maintained longer (Hill and Flack, 1909 and 1910). Christiansen and co-workers, 1913, attribute this to the smaller solvent power of blood for CO_2 in the presence of excess of oxygen.

Oxygen under excessive pressures (above 1.7 atmospheres) produces pneumonia; pressures above 3 or 4 atmospheres, cause violent convulsions and ultimately death. These effects are not due to pressure as such, for they are not produced by compressed air until the partial pressure of oxygen reaches the above figures. A. Adams, 1912, and A. Schmidt and David, 1912, claimed that prolonged inhalation, even of 70 per cent. oxygen at ordinary pressure would produce fatal pneumonia. Bruening, 1912, refers these results to the dryness of their gas, since the same effects were produced with dry compressed air, and not if moist oxygen was inhaled.

However, Karsner, 1915, found that even when these precautions are taken, rabbits exposed forty-eight hours to 80 per cent. oxygen show congestive or inflammatory changes in the lungs. Exposure for twenty-four hours did not usually produce any damage. With 67 per cent. of oxygen, exposure for 11 days produced very slight pulmonary irritation, but not true inflammation. Exposure to 53 per cent. of oxygen for $3\frac{1}{2}$ days showed no change (Karsner and Ash, 1917). Barcroft, Hunt and Dufton, 1920, also found that the inhalation of 40 to 50 per cent. oxygen for 16 to 17 hours daily for five successive days was harmless and apparently useful in the treatment of gas poisoning.

Phagocytosis.—This has been studied *in vitro* by H. J. Hamburger, 1915. Deprivation of oxygen stimulates phagocytosis for a time; prolonged exposure is depressant. Increase of oxygen is also generally depressant. Hydrogen peroxide stimulates markedly. Potassium chlorate and ferricyanide produce no effect.

Inflammation.—Mustard conjunctivitis is checked by the intravenous injection of substances containing chemically active oxygen, such as iodosobenzoic acid. Conversely, inflammation is intensified by cyanides, which check oxidation (Amberg et al., 1917).

Oxygen in Asphyxial Conditions.—The results are especially striking in those forms of asphyxia, in which the access of oxygen to the blood is hindered, as by *vitiating air* (anesthesia, mines, wells, etc.); by *mechanical interference with respiration* (suffocation, drowning, croup, etc.); by *depressed respiration* (anesthesia, collapse); or by a diminished absorbing surface of the lung (*pneumonia*). In all these cases the blood is distinctly venous, *i.e.*, the hemoglobin is not saturated with oxygen; and the inhalation of the gas promotes the saturation (Haldane, 1917).

According to Haldane, 1918, oxygen inhalation is of considerable benefit in emphysema and gives temporary relief in asthma; but has little effect on the dyspnea of cardiac disease or of nephritis.

Pulmonary Edema from Irritant Gases.—The gas exchange in the lung is hindered by the alveolar and bronchial foam. The inhalation of oxygen converts this into an oxygen-foam, and relieves the cyanosis. It does not, however, help to remove the accumulation of carbon dioxide, so that the air-hunger persists (C. F. Hoover, 1918).

Oxygen against Shallow Respiration.—Haldane and Meakins, 1918, regard shallow respiration as an important element of gas-poisoning, since it diminishes the alveolar exchange, even if the minute volume of the respiration were increased. This could be compensated by increased oxygen inhalation.

In *anemia* (whether from hemorrhage or any other cause, such as chlorosis or leucemia) asphyxial conditions result, not from deficient supply of oxygen, but from a deficiency of hemoglobin. The inhalation of oxygen, in these cases, does not increase the quantity of oxygen carried by the hemoglobin, but that carried in solution by the plasma, as has been explained.

The inhalation of oxygen is also useful, in an analogous manner, in *advanced cardiac disease*, when the circulation is too slow to convey the required oxygen to the tissues.

Another factor may possibly come into play, for G. N. Stewart, 1911, found that oxygen inhalation, while it produces no effect on the blood flow of the hand in normal individuals, produced a marked increase in a cyanotic patient. Artificially perfused vessels (frogs) are constricted by oxygen (Hooker, 1911).

Administration.—Compressed oxygen is marketed in metal tanks. The gas should be passed through warm water and delivered through a funnel suspended over the face of the patient. The rate and duration of the administration is regulated by the symptoms.

The funnel method, however, is wasteful, and only enriches the air by 3 to 5 per cent. of oxygen. If higher concentrations are desired, a mask with valves must be used (Y. Henderson, 1916).

Subcutaneous Injection of Oxygen.—This was introduced by Derosé, 1912. McCrae, 1914, believes that it has a limited field as substitute for inhalation.

Y. Henderson, 1918, states that life may be maintained by intraperitoneal injection of oxygen.

Intravenous Injection of Oxygen.—This is described by Tunncliffe and Stebbing, 1916. It gives rapid relief to the cyanosis and dyspnea. In man, the gas can be injected into a vein at the rate of 600 to 1,200 c.c. per hour; usually beginning with the rate of 500. The heart must be watched, the injection being stopped if any irregularity appears.

PREPARATIONS

**Oxygenium* (Oxygen.), U.S.P.

OXYGEN DEFICIENCY

Asphyxia Through Lack of Oxygen.—This may result from a deficiency of oxygen in the air—by breathing rarefied air, or air diluted with indifferent gases (N, H, CH₄); by the presence of CO; by anemia; etc. Ordinary air may be diluted until it contains only about 15 per cent. of oxygen (or may be rarefied to the same degree), without producing any immediate effect (Bernstein, 1882). A candle will be extinguished when the oxygen has fallen to about 17.5 per cent., and is therefore a test for the safety of the air, as far as oxygen is concerned. At about 10 per cent. slight symptoms are noticeable, especially on exertion; but they are not alarming—dizziness, shortness of breath, deeper and more frequent respiration, quickened pulse, slight cyanosis. With 7 per cent., these symptoms become serious, and stupor sets in. With a slightly lesser percentage, unconsciousness occurs. With 2 to 3 per cent., death occurs within forty-five seconds (the effects of low tensions of oxygen are described by Haldane, 1908; the effects on respiration are reported by Schenk, 1908).

Blood Vessels.—These (including the coronaries) are dilated by anoxemia, on direct perfusion (Richards, 1914). Oxygen deficiency also lowers the tone of excised arteries (Roncato and Oselladore, 1923). *Capillaries* likewise are dilated by deficiency, and constricted by excess tension of oxygen (Krogh). Carbon dioxide also dilates the capillaries and arteries, but very low concentrations of CO₂ may be somewhat stimulant (Roncato and Oselladore).

Heart.—Oxygen deficiency is directly depressant, and this is indeed the most common cause of cardiac failure. A failing heart may therefore recover if an adequate oxygen supply can be restored; but if this cannot be done, cardiac “stimulants” could not be of permanent benefit.

Cyanosis.—The skin in oxygen deficiency assumes a grayish color, in contrast to the deep blue color of ordinary asphyxia (Haldane, 1918). The latter is due to the congestion of the veins with reduced blood.

Anoxemia without Carbon Dioxide Accumulation.—This may also exist in pneumonia and cardiac decompensation; namely, when obstruction of a part of the lungs is compensated by overventilation of other parts; this washes out the excessive carbon-dioxide, but does not materially increase the oxygen saturation of the mixed blood (R. G. Pearce, 1917).

Minor Grades of Oxygen Deficiency.—These have been studied by the Air Service Medical Research Board, because of their importance in aviation. It was found that even slight lowering of the oxygen tensions produces reactions of the respiration and circulation to compensate for the diminished oxygen supply of the tissues (Y. Henderson and Seibert, 1918).

The *chief reactions* are increased ventilation of the lungs and more rapid blood flow. In a few men there is also concentration of the blood.

The *great differences in tolerance* depend upon the completeness of these reactions. Some tolerate 6 per cent. of oxygen for brief periods; others are incapacitated by much smaller changes. The degree of tolerance and of the reactions is an objective test of general "fitness," and is diminished by any indisposition, colds, worry, etc. (Schneider, 1918).

Respiratory Response.—This generally starts about 16 to 14 per cent. of oxygen, and becomes marked with 12.5 to 9 per cent. It usually affects the depth more than the rate; indeed, the rate may stay unchanged especially if the reaction is good (Schneider, 1918). The respiratory stimulation is due to the development of acidosis, through failure to oxidize the fixed organic acids (lactic acid). It is therefore a relatively slow, cumulative process. The increased respiration exaggerates the loss of CO₂, and thereby further lowers the alkali reserve of the blood. This renders the respiration more shallow, and establishes a vicious circle (Y. Henderson and Haggard, 1918).

Haldane, 1919, states that the first response of anoxemia is periodicity of the respiration. With further reduction, the type becomes very rapid and shallow. Patients with "irritable heart" are especially apt to react in this way to exertion. Oxygen inhalation gives relief.

Cheyne-Stokes respiration is also referable to oxygen deficiency (Douglas and Haldane, 1909); the apnea lowers the oxygen and leads to accumulation of lactic acid. This increases the excitability of the respiratory center, so that a very low CO₂ tension suffices to produce hyperpnea. This lowers the CO₂ and increases the oxygen, so that the lactic acid is oxidized, apnea reappears and the whole process is repeated.

Heart Rate.—This is also a reliable index of the response. A slight quickening occurs at about 15.5 per cent. oxygen; becomes marked at 13 to 9 per cent.; and reaches 15 to 40 beats at 7 per cent. When the capacity of response is exceeded, the heart may either slow, or quicken by 50 to 90 beats (Schneider, 1918).

Blood Pressure.—This shows several types of response. *If the reaction is good*, it may be unchanged, or if the heart quickens, the systolic pressure may rise and the diastolic fall gradually.

If the reaction is poor, the systolic pressure falls suddenly, this is soon followed by fall of diastolic pressure and then slowing of the heart. These phenomena are often accompanied by fainting (Schneider, 1918).

Temporary Heart Failures.—This is not uncommon. It is shown by dilation of 3 to 5 cm., also followed by collapse and fainting, unless the oxygen is increased (Whitney, 1918).

Disturbances of Vision.—These are among the minor manifestations of oxygen deficiency (Wilmer and Berens, 1918).

Accommodation to Oxygen Deficiency.—Brouardel claims that an animal that has been asphyxiated slowly revives much more readily than one that was asphyxiated abruptly. For instance, a bird (I) is placed under a bell jar until it falls on its side; if at this moment a second bird (II) is also introduced, this will fall over at once. If both birds are now restored to the air, I generally recovers, but II does not. Similar observations have been made clinically. New born infants and animals also resist asphyxia (by drowning or strychnine) much longer than adults. New born babies have been revived after ten to fifteen minutes of immersion ("Les Asphyxies," p. 13).

Chronic Oxygen Deficiency.—As seen in anemias, etc., this causes considerable increased tissue destruction, fatty degeneration, and acidosis (ammonia in urine). Finally there is general paralysis of all organ functions.

Exposure to slightly rarefied air, as on mountains, causes "mountain sickness"—nausea, headache, insomnia, etc. This generally disappears after a few days. A curious phenomenon is a prompt and persistent increase in the corpuscle and hemoglobin content of the blood (by 25 to 40 per cent.). This is at first due to a diminution of the plasma, the total quantity of hemoglobin being unaltered. After a time, however, the absolute hemoglobin is also increased; the formation of corpuscles by the bone-marrow being stimulated (Dallwig, Kolls and Loevenhart, 1915; G. H. Martin, Bunting and Loevenhart, 1916). There is retention of N, S and P. The respiratory metabolism is increased. These effects are attributed to oxygen deficiency (Douglas; Haldane, Henderson and Schneider, 1913; Loevenhart).

HYDROCYANIC ACID AND CYANIDES

Hydrocyanic (prussic) acid is perhaps the most rapidly acting poison. It produces death under asphyxial symptoms, by hindering the oxidative

processes of the tissues. It also interferes with most other catalytic reactions and is therefore a general protoplasmic poison. Compounds containing the CN radical are toxic only if they can liberate HCN. Ferro-, ferri-, and sulphocyanides are stable and therefore do not show these effects.

Occurrence.—Hydrocyanic acid exists in glucosidal form as *amygdalin* in many plants, especially in the seeds and leaves of the cherry, almond, peach, etc. This amygdalin, when pure, is almost entirely harmless, except as it is decomposed in the body. But in most plants it coexists with the ferment emulsin, by which it is split up in the presence of water into hydrocyanic acid, glucose, and benzaldehyde.

One gram of cherry kernels yields 1.7 mg. hydrocyanic acid; 1 gram bitter almond pulp yields 2.5 mg. hydrocyanic acid.

The most important cyanogen (CN) compounds are the acid (prussic acid, official as the dilute, 2 per cent. solution) and cyanide of potassium. Mercury cyanide has mainly a mercury action. The cyanide action is also shared by the organic esters (*nitriles*); these differ from potassium cyanide only in the rapidity with which the cyanogen is liberated (Lang, 1894; Heymans and Masoin, 1897, 1900, 1901; R. Hunt, 1904). *Nitroprussides* liberate CN readily and agree with cyanides, except that they are less convulsive (L. Hermann).

Cyanogen chloride produces cachexia on long continued exposure (C. I. Reed, 1920).

Effects on Higher Animals.—When given in doses small enough to permit of watching its action, this is seen to consist in a *fleeting stimulation of certain parts of the central nervous system, followed by depression and paralysis*. The action *begins in the medulla*. The vomiting, respiratory, vagus, pupil-dilator, and vasomotor centers are all stimulated. Then comes *unconsciousness*, and after this *convulsions*. In man these are probably mainly medullary in origin. Then follows paralysis of the whole central nervous system. Involuntary evacuations of feces, urine, and semen are frequent.

The Respiration.—This is at first greatly increased, especially in depth; it then becomes slow, shallow, and irregular (Cheyne-Stokes' type). It stops considerably before the heart, paralysis of the respiratory center being the immediate *cause of death*.

The effects on respiration are central, for they are not affected by section of the vagi, or by atropine (Boehm and Knie, 1874). The smallest effective doses increase both the rate and depth of respiration; HCN being one of the strongest stimulants of the respiratory center. This is more sensitive to cyanides than the vasomotor center, and this again is more sensitive than the vagus center. Larger doses slow the rate, but greatly increase the depths of respiration. Toxic doses depress and paralyze the center. The respiratory effects are antagonized by iodosobenzoate, which yields active oxygen (Grove and Loevenhart, 1911).

In frogs, the respiratory center is also stimulated by small and depressed by large doses. Decerebrated animals require larger doses than normal to produce respiratory paralysis (Hepper, 1915).

Clinical Use for Respiratory Stimulation.—The intravenous injection of sodium cyanide is by far the most efficient of the available measures for stimulating the respiratory center. The effective dosage (0.05 mg. per Kg. for animals) is about $\frac{1}{20}$ of the minimal fatal dose, so that there is an ample margin of safety; and the cyanide is so rapidly detoxicated by conversion into thiocyanate, that cumulation can be easily avoided. The effects of a single injection are not lasting (rarely longer than ten seconds); but they can be repeated as desired, or they may be maintained by continuous injection. The usefulness is limited by the fact that the presence of cyanide prevents the tissues from utilizing the oxygen; but

this becomes available when the cyanide is destroyed. It therefore seems advisable to make the injections intermittently. In drowning and in anesthetic poisoning, the increased respiratory movements help to clear the air-passages of obstruction or poison. For this purpose, the starting dose, should be 5 c.c. of a 0.1 per cent. solution, for man. The ordinary dosage is 1 c.c. of this solution. This may be repeated indefinitely as needed, at a rate not faster than every 30 to 15 seconds. It should be discontinued on the appearance of marked pallor, nausea, marked increase of pulse rate, or depression of respiration. The solution must be freshly made by dissolving 100 mg. of sodium cyanide in 100 c.c. of normal saline, without the use of heat. Hypodermic or intramuscular injection is not feasible, as the dose and effect cannot be adjusted with sufficient accuracy (Loevenhart et. al., 1918).

Convulsions.—Rabbits deprived of their hemispheres exhibit the usual type of convulsions; but the course is more rapid (Morita, 1915).

The Effect on the Circulation.—This is entirely analogous to that of asphyxia. As in the latter, the heart may again execute a few movements after it has stopped for a time; but these do not suffice to maintain the circulation.

Vasomotor Center.—This shows intense stimulation, with corresponding rise of blood pressure. The effects correspond with asphyxia (Pilcher and Sollmann, 1915).

Peripheral Action on Vessels.—In *excised kidneys* perfused with saline solution, the addition of hydrocyanic acid causes a very marked dilation of the renal vessels. The effect is apparently due to a paralysis of the arterial muscle. It disappears promptly on removing the cyanide (Sollmann, 1908). The coronary vessels are also dilated (Loevenhart and Eyster, 1913). It is quite possible that these dilations are due to the interference with the oxidation of metabolic waste-products.

Heart.—Applied directly to the *frog's heart*, cyanides cause a standstill which is not removed by atropine; however, the heart responds strongly to electric or mechanic stimulation. The paralysis evidently involves the automatic property of the cardiac muscle. There is no evidence of this action on the blood-pressure tracings from mammals.

In limulus, weak concentrations stimulate the heart muscle and ganglia (Carlson, 1907).

Cyanide Action Explained by Tissue Asphyxia.—The phenomena of the action of hydrocyanic acid on the central nervous system—the stimulation of the medullary centers, the convulsions, the vascular paralysis, etc.—bear a close resemblance to those of asphyxia and it can easily be shown that oxidation is enormously diminished. There is, however, one very marked difference from ordinary asphyxia, for the blood remains of a bright arterial color, indeed, the oxygen content of the venous blood in typical cyanide poisoning approaches that of ordinary arterial blood (Cl. Bernard).¹ The oxygen is in the ordinary combination with hemoglobin, and can be removed as readily as normally *in vitro*, for instance, by a vacuum (C. L. Evans, 1910). It is therefore evident that the oxygen supply to the tissues is not lessened. The cause of the asphyxia, of the lessened oxidation, must lie in the protoplasm of the tissues. This undergoes what might be termed "*internal asphyxia*," in sight of abundant oxygen (Geppert, 1889). The interference with oxidation has also been demonstrated with "salted frogs;" excised kidneys (Vernon, 1906); many lower animals; and with ferments. It may therefore be assumed that the cyanide interferes with the fermentative processes by which the utilization of oxygen is accomplished.

Hyman, 1916, has measured the effects on oxygen consumption in *sponges*. They consist in a primary increase followed by diminution. The depression increases with the

¹ Chio, 1911, claims that the red color of the venous blood is not due to lessened oxidation, but to more rapid circulation from vasodilation and cardiac stimulation.

concentration of the cyanide, so that high concentrations produce practically pure depression.

In planaria, G. Allen, 1919, found the oxidation reduced by 30 per cent. through minute doses of cyanide. Larger doses caused a further reduction to 20 per cent.; beyond which there was no further reduction, even with larger doses. The action is reversible; *i.e.*, rapid and complete recovery occurs after removal of the cyanide.

Lund, 1918, could not confirm any direct effect of potassium cyanide on the intracellular oxidation of *paramecium*.

Action on Ferments.—Schoenbein, 1867, first showed that hydrocyanic acid inhibits oxidizing ferments, preventing the catalytic action of shed blood on H_2O_2 . The catalase is not destroyed, but only inhibited. (In acute cyanide poisoning, the inhibitory concentration is not reached; Duncker and Jodlbauer, 1911.) It has a similar inhibitory effect on many other organic ferments and inorganic catalyzers (spongy platinum). The effect on metals is probably produced by a minute film of cyanide, and its mechanism is therefore probably not analogous to that on organic ferments.

Action on Hemoglobin.—It is doubtful whether HCN combines directly with hemoglobin under ordinary conditions. Zeynek, 1901, states that cyanide does not combine at all with hemoglobin; and that with oxyhemoglobin it does so only after several hours; even at body temperature.

When added to methemoglobin, it causes the formation of cyan-hemoglobin (Kobert, 1891; v. Zeynek), which differs from ordinary hemoglobin in its bright red color and in a peculiar band (Fig. 23). This compound is responsible for the bright red ecchymotic spots seen after hydrocyanic poisoning. Methemoglobin can be used as a test for hydrocyanic acid.

Lower Organisms.—Cyanide is a *violent protoplasmic poison*, presumably through its restraint of the fermentations which play a most important role in life processes. All forms of life, all tissues and organs, are affected. Infusoria are killed in a concentration of 0.1 per cent. The growth of yeast and of higher plants, the germination of seeds, the contractility of animal cells, the conductivity of nerves, etc., are inhibited. If the action is sufficiently continued, all vitality is destroyed; but if the cyanide is promptly removed, complete recovery occurs. Its effects agree with those of deprivation of oxygen. J. Loeb, 1910, found in *arabica* ova that this lessens the toxic effects of a number of poisons (salts, saccharose, lipid-narcotics), and Warburg, 1912, claims that the combined inhibitory action of HCN and hydrocarbon narcotics is less than simple summation. In certain fish ova, cyanides also suspend the autolytic processes accompanying death, so that the cells remain in a condition between life and death for several days (Sollmann, 1906). Green plants are killed when the air contains 0.02 to 0.2 per cent. of HCN; the germination of seeds is stimulated by these concentrations (C. Wehmer, 1918).

Fumigation with HCN is used for the destruction of insects and larger vermin. Rather high concentrations are required (McClintock, Hamilton and Lowe, 1911), and fatal accidents are frequent.

Phagocytosis.—This is stimulated *in vitro* by traces of KCN; the effect being analogous to oxygen deprivation (H. J. Hamburger, 1915).

Inflammation.—Intravenous injections of cyanide intensifies mustard conjunctivitis (Amberg, Loevenhart and McClure, 1917).

Membrane Permeability.—Even very dilute cyanide solutions increase the permeability of *Tradescantia* cells. This effect is enhanced by very low concentrations of chloroform or alcohol; diminished by higher concentrations (Krehan, 1914).

Other Effects on Metabolism.—Severe cyanide poisoning increases the total N excretion, mainly as urea, both in starving and in fed animals.

Excised Intestines.—Potassium cyanide interferes with the contractions, especially of the higher portions, in which metabolism is probably more active (Alvarez, 1918).

Local Anesthesia.—Direct application of HCN, even to the intact skin, produces local anesthesia. It has been used as an anodyne in pruritus, and against cough and vomiting; but it is not very effective, and the danger of fatal mistakes renders its use inadvisable.

Fate.—Hydrocyanic acid is very unstable; it changes very readily, even by mere exposure to light and air; and it undergoes still quicker decomposition in the body. Part of it combines with sulphur-containing molecules to form thiocyanate. A part is excreted unchanged by the lungs. The fate of the remainder is unknown. Post-mortem, Waller, 1910, found the largest quantity in the heart and brain; but it disappears in a few days, by transformation into thiocyanate (Chelle, 1919).

Thiocyanate.—This is found in the human parotid saliva, while it is absent in that of all other animals. The nervous connection of the gland must be intact, for it is absent in middle-ear disease (for instance, Juergens, 1901). Gscheidlen found it constantly in human urine; and Nencki claims that traces exist normally in the stomach. Its signifi-

cance is not understood, but it does not result from bacterial decomposition as was formerly supposed. It is suggestive that some proteins with loosely combined sulphur convert KCN into KCNS *in vitro* at room temperature (Paschele). Its amount can be increased by taking HCN—even that existing in tobacco smoke causing an increase.

Acute Cyanide Poisoning.—Hydrocyanic acid is rarely used in criminal poisoning (0.5 per cent. of the recorded cases), because its quick action would soon lead to the detection of the crime. On the other hand, it or the cyanides are often employed in suicides. On account of the technical uses of potassium cyanide (in photography, electroplating, cleaning of metals, etc.), it can generally be obtained with little trouble. Some cases are also reported of accidental poisoning by the gaseous acid.

In the so-called *apoplectic form*; *i.e.*, when very large doses are taken, the patient may fall unconscious, often with a loud cry, within ten seconds,¹ and die within two to five minutes, after some convulsions. Ordinarily, the course is rather more prolonged; several minutes may elapse after taking the poison before any effect is noticed; death occurs between fifteen minutes to an hour.

The *symptoms* consist in vertigo, mental dimness, headache, palpitation; then dyspnea, which may be very great from stimulation of the respiratory center; the patient then becomes totally unconscious and shows violent convulsions. During this stage the heart may be greatly quickened. The respiration becomes first difficult and then ceases. The heart at this time is very much weakened, but still continues to beat for a short time and then stops.

The *mortality* is very high: 95 per cent. If the patient survives an hour, *recovery* is the rule. It is often followed by persistent headache, tremors, etc.

The prompt *diagnosis* of cyanide poisoning is very important in view of the treatment. The odor is quite characteristic. (The student should familiarize himself with the appearance and odor of potassium cyanide.) The very rapid onset of the symptoms is also characteristic.

Pure hydrocyanic acid is extremely volatile and very toxic. The famous chemist Scheele, who discovered hydrocyanic acid, was killed by the vapors set free in the breaking of a flask of this fluid. Many fatalities have been produced by the use of cyanide vapors as insecticide.

The *strength* of the official (dilute) acid should be 2 per cent.; but many samples are much weaker, on account of decomposition. Potassium cyanide is also very variable. The pharmacopœia requires a strength of 90 per cent.; but the commercial article sometimes contains only 30 to 40 per cent. This accounts in a part for the variability in the appearance and severity of the symptoms. Another variable factor is the *rate of absorption*, according to whether the stomach is full or empty. In the latter case, there is a much better chance of saving the patient. However, the absorption is always very rapid; it occurs even to some extent from the intact skin. Application to raw surfaces or to cuts has given rise to poisoning. Inhalation of the vapors has proven fatal.

The *fatal dose* of absolute HCN is about 0.05 Gm. (1 gr.); that of KCN is 0.2 to 0.3 Gm. (3 to 5 gr.); that of dilute hydrocyanic acid would be about 2.5 Gm.; 50 to 60 bitter almond seeds, would be fatal. Correspondingly larger doses are needed if the drugs are impure or decomposed. The impression prevails quite widely that prussic acid is one of the most powerful poisons. This reputation is justified by its *extremely rapid action*, rather than by its toxic dose.

Toxic Concentration in Air.—The minimum lethal concentration for cats is about 0.35 mg. of HCN per liter of air; severe but not fatal symptoms may arise with five or 10 minutes-inhalation of 0.1 mg. per liter (Flury and Wolfgang, 1919).

At the *autopsy*, the odor is also noticeable on opening the body. There are no peculiar lesions, except with potassium cyanide, which acts as an alkaline caustic. The blood is generally liquid, and remains so after removal from the body (by interference

¹ This is the shortest time reported—a fact which may be of some medico-legal importance.

with the fibrin ferment). Its color is stated to be very dark—but this is not true of all cases: it may be of a very bright arterial color. Bright red *ecchymotic* spots, due to cyan-hemoglobin, occur during putrefaction. The final *proof* of cyanide poisoning rests on chemic tests. The poison disappears within two weeks during putrefaction; but remains for a long time if the latter is prevented and if there is no evaporation.

Chronic Poisoning.—The repeated administration of sublethal doses of cyanides was said to lead to chronic cachexia, without altering the susceptibility to the poison (Schlegel, 1892). Peripheral neuritis has been reported (Collins and Martland, 1908). However, C. J. Reed, 1920, found neither chronic symptoms nor increased susceptibility in dogs exposed daily to sublethal doses of cyanide vapor.

Treatment of Cyanide Poisoning.—This must be very prompt. It consists in lavage with chemical antidotes, and in symptomatic stimulation. The chemic antidotes are oxidizing agents (H_2O_2 ; potassium permanganate, $\frac{1}{4}$ to $\frac{1}{2}$ per cent.); “arsenic antidote;” or sodium thiosulphate (“Hypo”), 1 per cent. These form harmless molecular compounds. Unfortunately, the absorption of the poison is so rapid that the antidotes are often ineffective.

Chemic Antidotes.— H_2O_2 is only effective if the stomach is empty. It forms oxamide: $(2HCN + H_2O_2 = (CO)_2(NH_2)_2)$. *Alkaline ferrous sulphate* forms ferrocyanide. It was advocated by Smith, 1884, and is indorsed by Sandwick, 1906. It is conveniently prepared by adding $FeSO_4$ to the official “arsenic antidote.” Cobaltous nitrate (0.5 per cent.) forms cobalto-cyanide; and thiosulphate forms thiocyanate. Thiosulphate has given especially good results as a prophylactic, and in nitrile poisoning in animals (Meurice, 1900), but is of little value in developed cyanide poisoning (Heymans and Masoin, 1897). It may be injected intravenously (0.5 to 1 per cent., added to 0.6 per cent. NaCl) or hypodermically (3 per cent.), using 100 to 500 c.c.

It has also been suggested to bleed the patient profusely, replacing the blood by saline solution.

The *symptomatic treatment* consists essentially in supporting the respiration. Brisk artificial respiration should be begun at once and maintained as long as the heart beats. This acts mainly by aiding the elimination of the poison through the lungs. Counterirritation, and general stimulants (caffeine and atropine) may also be used.

PREPARATIONS

Acidum Hydrocyan. Dil., B.P.—About 2 per cent. of HCN. Colorless liquid, with odor of bitter almonds. Incompatible with metals. *Dose*, 0.12 to 0.3 c.c., 2 to 5 minims, B.P.; *maximum dose*, 0.3 c.c., 5 minims.

On standing, it loses strength rapidly, decomposing into ammonium formate, CO_2 , cyanic acid, and a brown precipitate of paracyanogen (L. A. Brown, 1910). The decomposition is retarded by acid, alcohol, and acetanilide (Coblentz and May, 1908).

Pot. Cyan., *KCN*.—Occurs usually as white, opaque masses, with cyanide odor. *Dose*, 5 mg., $\frac{1}{12}$ gr. Commercial samples are often very impure.

Sodii Cyanidum (Sod. Cyanid.), NaCN.—White, opaque pieces, or granular powder; deliquescent in the air and exhaling the odor of hydrocyanic acid. Freely soluble in cold water.

Amygdala Amara, B.P.; *Bitter Almond*.—The ripe seed of *Prunus Amygdalus amara*. Contains amygdalin, fixed and volatile oil, etc.

Ol. Amygd. Amar., U.S.P.—The distilled oil. Yields not less than 85 per cent. of benzaldehyde, and not less than 2 per cent. nor more than 4 per cent. of hydrocyanic acid. *Dose*, 0.03 c.c., $\frac{1}{2}$ minim, U.S.P.

Benzaldehydum, U.S.P., $C_6H_5.CHO$.—An aldehyde produced synthetically or obtained from natural oil of bitter almond. A colorless or yellowish, strongly refractive liquid; bitter-almond-like odor; burning aromatic taste. Slightly sol. in water, miscible with alc., eth., and fixed and volatile oils. *Dose*, 0.03 c.c., $\frac{1}{2}$ minim, U.S.P.

Laurocerasi Folia, B.P.—The fresh leaves of *Prunus Laurocerasus* (Cherry-Laurel).

Aq. Laurocer., B.P.—0.1 per cent. of HCN. *Dose*, 2 to 8 c.c., $\frac{1}{2}$ to 2 drachms, B.P.

Prunus Virginiana, U.S.P.; *Prun. Virgin. Cort.*, B.P.; (Wild Cherry Bark).—The stem-bark of *Prunus serotina*. Contains tannin, amygdalin, and bitter glucoside. *Dose*, 2 Gm., 39 gr., U.S.P.

Syr. Prun. Virg., U.S.P., B.P. (Syrup of Wild Cherry).—15 per cent. *Dose*, 10 c.c., 2½ drachms, U.S.P.; 2 to 4 c.c., ½ to 1 drachm, B.P.; mainly as flavor for cough mixtures.

Tr. Prun. Virgin., B.P.—20 per cent. *Dose*, 2 to 4 c.c., ½ to 1 drachm, B.P.

PHYSICAL FACTORS OF SALT ACTIONS

The drugs so far studied produce their actions mainly by entering into *chemic* combination with the protoplasm. Since these chemic changes are distinct for each drug, the effects are also distinctive differing, in kind as well as in degree. Besides the properties which are ordinarily designated as chemical, substances in solution or suspension also possess certain *physical* properties, depending on their molecular state, and independent of their chemic composition. These properties are possessed both by the drugs and by the cells.

Molecules in solution have qualitatively and quantitatively identical effects on the boiling and freezing-point, on vapor pressure and on osmotic tension. Through osmosis they may alter the water and salt content of the cell, its internal pressure, the surface tension, and the electric surface potential, and consequently the functions. This may occur even though the substance itself does not enter into the cells. These effects are produced by all substances which form true solutions (the “*crystalloids*”). Since the results are proportional to the molecular concentration (the number of molecules dissolved in the unit volume of the solvent), their importance varies with the quantity of the drug that can be introduced without producing serious chemic changes. These physical actions are therefore physiologically insignificant for those substances which cause pronounced chemic effects. They are practically important mainly for the neutral salts of alkalies, and are therefore commonly called “*salt actions*.” Even these salts, however, or rather their constituent ions, produce in addition *specific* effects, due partly to their electric charges, partly to their specific chemic properties. These specific effects may be called “*ion actions*.” It must be remembered that the cells are normally bathed in a saline solution; the salt and ion effects are therefore due to a disturbance in the normal environment of the cell, to the relative diminution of the normal constituents, as well as to the increase of the added constituent.

The “*colloids*” of the cells likewise play a highly important part in these salt actions. Colloid solutions, such as those of the proteins, differ in important particulars from the true solutions, such as those of the salts, although there is a gradual transition. In true solutions, the molecules of the solute are dispersed through the solvent, and behave very much as do the molecules in gases. In colloid solutions, the solute occurs in smaller or larger groups or “*aggregates*” of molecules; and according to their size they approach more or less in their properties to mere suspensions of solids or liquids. They therefore lack (practically) the physical qualities of the true solutions. On the other hand, the suspensions exhibit the electric and surface phenomena of particles. Because of the relatively high state of subdivision, the “*surface phenomena*”—surface tension, adsorption, catalytic properties, etc.—are very conspicuous, and play a highly important part in the functionation of protoplasm. The consistency of the protoplasm, fluid or gelatinous, and the quantity of water imbibed, also depend on the colloids. These properties are greatly influenced by the physical, electrical and chemical conditions of the

medium in which the colloid is suspended. It is in this interaction of the saline medium with the protein and lipid colloids that the salt actions consist.

COLLOIDAL SOLUTIONS

Relation of Colloids and Crystalloids.—Graham, 1861, divided soluble substances into crystalloids and colloids, according to whether they diffuse through parchment and similar membranes. This criterion is a sharp one, and has been supplemented by others; but the division is important and has been retained. The terms "colloid" and "crystalloid" do not refer to any particular substance or class of substances, but to the physical state which may be assumed by any substance in a solution under suitable conditions. In other words, any matter assumes the colloidal state when it is suspended in sufficiently fine comminution, in a liquid that does not dissolve it materially in the molecular state. A "solution" may therefore be colloidal in one solvent (tannin in water), molecular in another (tannin in alcohol).

As the size of the aggregates of molecules which constitute the colloid state varies, the transition between the physical properties of the two kinds of solutions is not abrupt but gradual. Solutions containing discrete molecules (*i.e.*, true solutions of crystalloids) approach the colloid state especially when the solution is concentrated and the molecules are large; while colloid solutions approach true solutions when they are dilute and the aggregates are small.

Size of Particles.—This determines the character of the solution, *i.e.* the gradual transition in the size of the masses, between coarse powders and molecules, is reflected in a similar gradual transition of the physical properties. For some of the properties, the progress is in a straight line; in others, it occurs as a bent curve. In that case, the bend of the curve coincides, with the "ultramicroscopic" size of the particles. In other words, if the particles are larger than 0.1μ (*i.e.*, visible with the ordinary microscope), the mixture behaves as a suspension (if the particles are solid), or an emulsion (if liquid). These mixtures are separated more or less rapidly by gravity. When the diameter falls below 0.1μ sedimentation does not occur, and the solution assumes colloid characters. This holds down to 0.001μ , *i.e.* somewhat below the limits of the ultramicroscope (0.004μ). Below this limit, the characters are those of a true solution. It is believed that molecules are but little smaller than this limit (sugar, 0.0007μ ; NaCl, 0.00027μ).

Qualities that increase with dispersion, through the whole range, are especially: Brownian movement, diffusion, dialysis.

Those that *decrease* through the whole range: Turbidity, filtrability.

The following are *maximal in the colloidal region*: Opalescence, color, catalytic activity.

Properties of Colloids.—Each aggregate behaves like a single molecule, so that the molecular concentrations of colloid solutions is relatively low. Colloids therefore have little influence on the *osmotic pressure*, or boiling- or freezing-point. One of the most distinctive properties of colloid solutions is their *turbidity*, which may be perceived directly, or only by the Tyndall phenomenon (*viz.*, a beam of light becomes visible when passed through a colloid solution). The colloids *do not dialyze* through parchment or similar membranes. *Diffusion* through the solvent is very slow or practically absent.

The *electric properties* are characteristic: Colloids are usually electrically charged, the quantity and sign of the charge being variable at will. This is very different from ions whose charge is fixed in character and quantity. The important *surface actions* will be discussed later. The colloids easily undergo further aggregation to larger particles, *i.e.*, *coagulation*. This may be due to a variety of causes. For instance, with

suspensoids it is generally due to neutralization of surface charges; in emulsoids to withdrawal of solvent. Coagulation may also result from purely chemic changes. Colloid solutions are often permanently changed by temporary physical conditions, such as boiling, freezing or keeping (*hysteresis*).

Suspension and Emulsion Colloids.—Colloid solutions again fall into two classes: the suspension colloids, in which the particles behave as solids; and the emulsion colloids, in which they behave as fluids. The difference is probably one of affinity for the solvent. The emulsion colloids are hydrophilic, *i.e.*, they seem to attract the solvent into the aggregates which are thereby more or less liquefied; the suspension aggregates are hydrophobic, *i.e.*, they do not take up water, and therefore remain discreet and solid. The emulsoids approach more nearly to true solutions, and may sometimes consist of discrete but very large molecules. They are typified by gelatin and other soluble proteins and are therefore of a special biologic importance. Silicic acid also behaves as an emulsoid. The colloid metals and sulphides, congo red, etc., are suspensoids. The *emulsoids* form viscid solutions or jellies, lower the surface tension, and are coagulated only by large quantities of electrolytes. The *suspensoids* are not viscid, have little effect on surface tension, and are easily precipitated by traces of electrolytes.

Formation of Colloids.—Colloidal solutions may be formed either by the dispersion of larger particles, or by the condensation of molecular solutions, *i.e.* by partial precipitation. In precipitating solutions, colloidal solutions tend to be formed when very dilute or very concentrated solutions interact; whilst intermediate concentrations produce coarser or crystalline precipitates.

Permanence of Suspensions.—It is a familiar phenomenon (*f.i.*, in the case of oil or mercury) that small particles suspended in a liquid tend to coalesce by surface attraction, to form larger particles. The molecular particles in colloid solutions possess the same tendency, as is shown by the readiness with which they may be precipitated. They are only kept apart by their molecular motion, and by their electric charges. The more the motion is increased (*e.g.*, by increasing the quantity of solvent, or by raising the temperature within the limits which do not produce chemic changes) the greater will be the tendency of the aggregates to fly apart, and to form smaller aggregates. It is quite conceivable that this motion and separation are really electric phenomena. We know that the colloid particles may be charged with electricity, either positive or negative. Since all the particles in a solution are charged with electricity of the same sign (let us say with negative electricity, since this is the case with most protoplasm), they repel each other, just as do the gold leaves of an electroscope. Any increase of the charge (negative in our example) increases this repulsion, and consequently diminishes the size of the aggregates and the viscosity of the solution. If, on the other hand, a small amount of electricity of the opposite sign (positive) is introduced, some of the charges carried by the particles are neutralized and they tend to coalesce. If this (positive) electricity is increased beyond the point when all the original (negative) charges are neutralized, the particles will become charged with positive electricity, and again fly apart. These modifications may be produced by the passage of an electric current; and also, by the electric charges of the ions of electrolytes. The latter (salts, acids, and bases) may therefore influence the state of aggregation of colloids by withdrawing water

and by altering the electric charges. The state of aggregation may also be varied, viz., by *chemic action*. This introduces at once profound changes in the state of aggregation, and in the electric condition.

All these changes described for colloid solutions may be observed in living cells: Withdrawal of water, lowering of temperature, decrease of the electric charge, and certain chemic changes, render the protoplasm more viscid, opaque, and granular, and diminish its motility. A reversal of these conditions leads to the opposite effects.

Precipitation of Suspension Colloids by Electrolytes.—Since suspensoids have no affinity for the solvent, they are very readily precipitated when their electric charges are removed. This occurs most easily when their electric charge is already small, *i.e.*, when they approach the “isoelectric point.” Minute traces of electrolytes are then sufficient. The precipitation of positively charged colloids depends mainly on the anions, that of the negative on the cations (Hardy’s Law); the other ions playing practically no part. The precipitant power of the ions is a function of their valence (Schulze, 1882 and 1884), since this determines their electric activity. However ions of the same valence are not equally active. Commonly there are also chemic changes, so that the precipitation is generally irreversible.

Precipitation of Hydrophilic Colloids by Electrolytes.—These, like the suspensoids, are precipitated only by electrolytes, not by non-electrolyzed crystalloids (the precipitation of proteins by alcohol is attributed simply to insolubility). The process, however, is probably quite different. With the emulsoids, much higher concentrations of the salts are required; the precipitation is generally reversible; the electrolytes may also have solvent actions, the end result being the algebraic sum of the actions of the cation and anion (Pauli, 1905 and 1908).

Lyotropic Series.—The various ions form a regular series (“lyotropic series”), which is reproduced in many different phenomena. The anion series run $\text{SCN} < \text{I} < \text{ClO}_3 < \text{NO}_3$, $\text{Br} < \text{Cl} < \text{CH}_3 \cdot \text{COO} < \text{SO}_4$, $\text{PO}_4 < \text{tartrate} < \text{citrate}$.

With (negative) proteins, lecithin, etc., the left side of this series is solvent, the right side precipitant. They have a similar influence on heat-coagulation temperature; on the solubility of globulins; on the solubility of gases, alcohols, etc.; on the viscosity and surface tension of water; on the saponification of esters, etc. It has been suggested that all these phenomena can be explained by the progressive affinity of these salts for water, thus competing, *e.g.*, with the emulsion colloids.

The *alkali cations* are much less important. Their series runs rather irregularly; generally $\text{Mg} < \text{NH}_4 < \text{K} < \text{Na} < \text{Li}$ (Li being most precipitant). If the electric charge of the colloid is reversed, *f.i.*, by acids, then the anion and cation series are also reversed.

The *earthy metals* (Ca, etc.) form irreversible precipitates. They also reverse the charge and therefore the effects of the anion series (Mg acts like the alkali metals). The tendency to irreversible precipitation is very much greater with *metallic salts*.

Electric Condition of Proteins.—The amino-acid character of proteins renders them amphoteric electrolytes, in which the acid character predominates. They are generally positively charged in acid solutions, negatively in alkaline. If they are brought to the isoelectric point (H-ion concentration about 2×10^{-6}) all coagulation reactions reach their maximum, and the viscosity is lowest (Pauli, 1913).

The colloids of the living cytoplasm are predominantly electro-negative; hemoglobin is positive. Serum proteins are always positively charged in alkaline and neutral, as well as in acid solutions (Field and Teague, 1907).

Protein-ion Compounds.—It must not be forgotten that proteins are also capable of ordinary chemic reactions and combinations. They may form complex salts, not only

with acids and alkalis, but also with neutral salts; *f.i.*, with chloride ions (Oryng and Pauli, 1915).

J. Loeb, attributes the differences in the swelling of gelatin in various salt solutions to the formation of ionizable gelatin-anion salts.

Mutual Precipitation of Colloids.—Colloids of opposite electric charge precipitate each other by neutralization; but this may also be due to chemical action. Emulsoids may be precipitated by suspensoids, irrespective of the charge, perhaps by an adsorption process. On the other hand, excess of the hydrophilic colloid prevents precipitation, and protects suspensoids against precipitation by other substances. It is conceivable, in these cases, that the emulsoid envelops the suspensoid particles, and thus confers on them hydrophilic properties.

An important illustration of this phenomenon is the inhibitory action of serum on the precipitation of urates, calcium salts, etc. Colloids also modify the solubility of electrolytes (Pauli and Samec, 1909).

Electrolytes on Osmotic Pressure of Colloids.—Acids and alkalis increase the osmotic pressure, salts generally cause a decrease, while non-electrolytes are indifferent (R. S. Lillie, 1907).

Gels.—Solutions of hydrophilic colloids, when very viscid, tend to form jellies or "gels," such as gelatin, agar or protoplasm. The high viscosity means that there is but little solvent between the particles; either because the particles are naturally large or because the amount of solvent is relatively small. As the available solvent diminishes, the excess of colloid tends to separate in a more solid form, as a spongy framework, with a more dilute colloidal solution in the interstices. Such gel resembles a solid in preserving its form, when it is not subjected to external agencies. But it also resembles fluids in being readily changed by external causes, and in permitting the penetration of water, and the diffusion of crystalloids. The latter penetrate it almost as rapidly as they would water. Chemical reactions may occur in its interior very much as they would in water. Other colloids, however, can not diffuse through a gel. In fact gels retain all the characters of hydrophilic colloids, and are influenced in the same way by salts; as seen, *f.i.*, in imbibition.

The gel-formation is likely to be accompanied by chemical changes in the solid phase, especially by polymerization (M. H. Fischer and Coffman, 1918).

Imbibition.—Plates of gelatin (glue) or other hydrophilic colloids, when laid in water or watery solutions, imbibe a certain quantity of water and dissolved substance, and thus swell. The water is attracted and retained with considerable force, according to the affinity of the emulsoid for water. This mechanism is important in the regulation of the fluid content of the cells and tissues. The colloid must compete for the water with the other dissolved substances. The imbibition is therefore influenced by the anion series, in the usual order; iodide to chloride increasing, acetate to sulphate decreasing the imbibition (Hofmeister, 1891). The cations have relatively little effect. OH, and still more, H ions greatly increase imbibition (Spiro, 1904; Ostwald, 1905).

In agar jellies, the phenomena are exactly reversed. According to Ehrenberg, 1913, the lyotropic series is reversed for gelatin when the concentration of the salts is low ($\Delta < 0.5$).

Influence of Reaction.—Acids and alkalis increase the imbibition of gelatin, not only in water, but also in solutions of phosphates, citrates and carbonates (Fischer and Hooker, 1918). The reaction that gives the minimal imbibition is different for gelatin and fibrin (Fischer and Benzinger, 1918).

Concentration of the Salts.—The effect of electrolytes on imbibition is largely influenced by the concentration of the salt. Ehrenberg, 1913, found the lyotropic series reversed for gelatin when dilute solutions were used (Δ less than 0.5). Ostwald (1916)

also notes that the results differ according to whether dry gelatin is used (Ostwald) or moist gelatin (Lenk).

Lenk (1916) found that for the salts of most monobasic anions (chlorides etc.) the swelling increases with the concentration; whereas with dibasic and tribasic anions (sulphates, citrates, etc.) the maximal swelling occurs with medium concentrations.

Non Electrolytes.—The swelling of gelatin is also influenced by non-electrolytes, being decreased by sugars and glycerin, and increased by alcohol and especially urea (Pauli and Rona, 1902). In mixtures, the swelling corresponds to the simple algebraic sum of the effects of the constituents. Entirely analogous results are produced on the coagu, lability of gelatin solutions; this being increased by the substances which lessen swelling- and *vice versa* (Pauli, 1907).

Sugars retard the diffusion of H⁺ ions through gelatin (Graham and Graham, 1919).

Distribution of Salts in Imbibition.—The gelatin also takes up the solutes. Hofmeister found that the quantity taken up increases with the concentration of the solution, to a certain limit, which is reached late with the iodide end of the series, and early with the sulphate group. This influences the imbibition, for enough water must then be taken up to render the salt isotonic; and this would be greater for the large quantity of iodide than for the small quantity of sulphate which the gelatin has imbibed.

Subsequent Washing.—When powdered gelatin is soaked in salt solutions and then washed with water, the imbibition series is quite different from that of Hofmeister. J. Loeb (1918) considers that the phenomena suggest the formation of ionizable gelatin salts with the anions.

He also finds (1918) that neutral salts with monovalent cathions increase the *viscosity* of gelatin solutions; those with bivalent cations do not.

SURFACE PHENOMENA

Surfaces—the planes of separation of two phases—give rise to the important phenomena of surface tension and adsorption. These are especially prominent in colloids and therefore in protoplasm, the particles of which give rise to very extensive surfaces (A. B. Macallum, 1912 and 1913).

Surface Tension.—This is manifested in the tendency of liquids to assume a spherical form, so as to present the smallest possible surface. It may be explained by the mutual attraction of the molecules (estimated at 10,000 to 25,000 atmospheres). The molecules in the interior of the fluid are attracted equally by the molecules on all sides; but at the surface, the attraction of the molecules from within is not balanced by any molecules outward. Consequently, the surface molecules are subjected to a strong pull from the interior, constituting the surface tension (Segner, 1751, Laplace, 1845). Gases are not subject to surface tension, because the distances between their molecules are greater than the radius of molecular attraction.

The degree of this force depends on the nature of the fluid, on the temperature, and on electric forces: Heat and electric charges decrease the surface tension, because they increase the distance between the molecules and therefore diminish the molecular attraction (by the fourth power of the distance). Surface tension may also be resisted by the attraction of the second phase (the air, glass, etc.) on the surface molecules of the liquid. Surface tension may be measured by the rise of capillary surfaces, or by the number of drops delivered from a given surface (stalagmometer). Further details can be found in the book of Millons and Hatschek "Surface Tension and Surface Energy," 1923.

Biologic Importance of Surface Tension.—This is concerned in the shape and size of the cells; in the consumption or liberation of energy (for any change in surface tension implies a corresponding change in energy); and in the distribution of solutes. Only the last need be considered here.

Solutes on Surface Tension.—Dissolved substances generally modify the molecular attraction and therefore the surface tension. In watery

solutions, organic substances generally diminish, inorganic sometimes increase the surface tension; but there is no simple general law, and the effect is not simply proportional to the concentration.

Distribution of Solutes on Surfaces.—Solute which alter surface tension are not distributed equally through the fluid, but in such a way that substances which lower surface tension are more concentrated on the surface (positive adsorption) and *vice versa*; *i.e.*, the solute goes to the point where the tension is lowered. This is explained by the Willard Gibbs (1878)-Thomson (1886) principle (the concentration throughout a fluid system tends to be so adjusted as to reduce the energy at every point to the minimum). The absolute quantity of solute condensed at the surface must always be small, since the condensation is confined to a very thin film. The surface-adsorption is greater for solvents with high surface tension, such as water, than for alcohol and other organic solvents.

Distribution of Solutes in Cells.—Any reduction of surface tension, however produced, must increase the concentration of solutes at the surface, irrespective of their distribution under ordinary conditions. Accordingly, the distribution and transportation of substances in cells may be controlled by changes in their surface tension. Macallum has shown this to be true for K and Cl, and probably for other ions; and has pointed out the important part which this may play in the mechanism of secretion and absorption; ameboid and muscular movements; nerve impulse, narcosis, etc.

Solution-Affinity; "Haft-druck."—A substance that lowers surface tension passes more readily out of the solution and into the surface. In the phraseology of Traube, such a substance has a low solution-affinity or "Haft-druck." He believes that this favors the penetration of the substance into cells or through membranes, and that it is an essential factor in narcosis and osmosis. The concentration at the interface must favor the penetration of the substance through membranes and into cells, and solution-affinity must therefore be an important factor in osmosis, narcosis and other pharmacologic phenomena. However, the effect of a substance on the surface tension of a solution toward air is not necessarily an index of its effect on the interface between two liquids or between the solution and a solid membrane, but within the biologic range they generally tend to vary in the same direction (Howard and Sollmann, 1924).

Adsorption.—The concentration of solutes on surfaces is illustrated by the adsorption of dissolved substances by powders; *f.i.*, by the decolorization of potassium permanganate by filtering through sand; the adsorption of colors or alkaloids by charcoal, etc. This adsorption is a very rapid process. Sugars are not adsorbed because they have relatively little effect on surface tension. These adsorptions are reversible; *i.e.*, the adsorbed substance may be removed by the addition of another solute which lowers surface tension more powerfully. If several substances are present together, each is adsorbed less than if it is adsorbed alone. Salts may have a marked influence, *f.i.*, diphtheria toxin in pure solution is scarcely adsorbed by bone-black, but is perfectly adsorbed from normal saline or Ringer's solution (Jacqué and Zunz, 1909).

Adsorption is a matter of the relative affinity of the solute for the two solvents. This may be determined by the cohesive or adhesive forces that constitute surface tension; but in other instances other physical forces, such as the electric equilibrium, may come into play; others are more strictly chemical. The causes are often difficult to analyze. (A. P. Mathews, 1921.) The firmness of the adsorption varies greatly.

Adsorption on Chemic Reactions; Catalysis.—The surface condensation facilitates chemic reactions in accordance with the law of mass-action by bringing the dissolved molecules into closer contact. Accordingly, suspension-colloids, with their large surfaces generally function as catalysts; and enzymes in general probably act largely through surface action. The specificity of ferments may be due to special affinity for certain solutes. The application of adsorption to ferment action is discussed by Bayliss, 1915, in his paper on "Phase Boundaries."

Membrane Formation.—If the adsorbed substance increases viscosity, its concentration on the surface may produce resistant membranes, such as occur in the shaking of proteins, saponins, soaps, many dyes, etc. If a cell is wounded, the surface of the living protoplasm immediately condenses into a membrane.

The adsorption of colloids is generally irreversible; and the adsorption is not proportional to the concentration, as it is with crystalloids.

The Physical Status of Emulsions.—Emulsions consist of fine and permanent suspensions of one liquid in another immiscible liquid; *f.i.* oil in water, or vice versa. Surface tension tends to make immiscible liquids separate. This tendency may be counteracted by lowering the surface tension of the dispersing medium (as by saponin or soap) or by increasing its viscosity, and by adsorbing the water by hydrophilic colloids (as by gums and proteins). The essential feature of permanent emulsion, however, is the adsorption of the colloid on the surface of the oil droplets, coating these with a resistant membrane. Saponin, which has relatively little effect on surface tension, acts mainly in this manner (Howard and Sollmann, 1924). Emulsification by colloids is destroyed if an excess of water is added, or if the affinity of the colloid for salts is diminished (Fischer and Hooker, 1916; Roon, 1916.)

The water-soluble alkali soaps secure the suspension of lipoids in water, whilst the oil-soluble calcium soaps change the phases so as to suspend the water in the oil. With the alkali-soaps, droplets of oil are suspended in a continuous matrix of water; with calcium soaps, droplets of water are suspended in a matrix of oil. The addition of sodium or calcium ions therefore changes the phase of an emulsion. It also thereby influences the permeability; the effect of electrolytes on the permeability of soap-films being similar to their effects on the permeability of living cells; the sodium-soap system being freely permeable to water, the calcium system being impermeable (Clowes, 1914 to 1916).

Most protoplasm contains emulsions. Fischer looks upon fatty degeneration as due largely to the breaking up of these emulsions by diminished water-affinity of the cell colloids. The analogies of the fat in protoplasm with that in emulsions is discussed by Fischer and Hooker, 1916.

OSMOSIS

Osmotic Phenomena of Crystalloids.—These belong to the more important effects of the bio-chemically inactive salts and other crystalloids, and of water. They occur whenever two solutions of different (molecular) concentration are separated by a ("*semipermeable*") membrane that permits the passage of the solvent, but which interposes an obstacle to the free diffusion of the solute. Dissolved molecules always tend to distribute themselves equally throughout a solvent. If their passage is hindered

by a membrane, the equality can only be obtained by the passage of the solvent from the more dilute to the more concentrated solution. The more concentrated solution therefore tends to increase in volume. If this increase is prevented (*e.g.*, if the solution is inclosed by rigid walls), a certain "*osmotic pressure*" is developed. The phenomenon is illustrated by the swelling of red blood and other cells in water; and conversely, by the shrinking of plant cells, and crenation of red corpuscles in strong salt solution.

Osmotic Pressure and Molecular Concentration.—If the membrane is "strictly semipermeable"—*i.e.*, freely permeable to the solvent, but absolutely impermeable to the solute—then the amount of the osmotic pressure is strictly proportional to the difference on the molecular concentration of the two liquids, independent of the nature of the molecules. The stronger solution is said to be *hypertonic*, the weaker *hypotonic*. If the solutions on the two sides are equimolecular, *i.e.*, have the same molecular concentration, there will be no tendency to movement of the solvent and therefore no pressure; or more accurately, no difference in the pressure. The two solutions will be *isotonic*.

Strictly and Partly Semipermeable Membranes.—Only colloids, organic or inorganic, can form semipermeable membranes (Morse; Meigs, 1915). The envelope or boundary layer of all cells—and perhaps the interior cytoplasm (Kite, 1913)—offers more or less obstacle to the passage of solutes, and is therefore more or less semipermeable. Membranes produced artificially by precipitating ferrocyanide of copper in the pores of an unglazed porcelain cup are almost ideally semipermeable to sugar (Traube, 1867). They are, however, permeable to NaCl and KCl. The envelopes of certain vegetable and animal cells, *f.i.*, the red blood corpuscles, also approach fairly closely to the definition. Most cells, however, and dialyzing membranes in general, are not *absolutely* impermeable to the solutes, but differ only a partial obstacle ("*partly semipermeable membranes*"); so that the solutes pass the membranes, but more slowly than does the solvent. In this case, the concentration is equalized partly by the passage of the solute, and to a correspondingly smaller degree by the passage of the solvent; so that the osmotic pressure is correspondingly less than with strictly semipermeable membranes.

Differences in Permeability of Solutes.—Semipermeable membranes are not usually equally impermeable to all solutes, but permit some to pass rapidly, others more slowly. This establishes differences in osmotic pressure, because the dialyzable substance passes across to the non-dialyzable. Non-dialyzable solutes are therefore hypertonic to those which are easily dialyzable. It is important to note that the passage of the fluid and the osmotic pressure are governed not only by the molecular concentration, but also by the permeability of the membrane to different substances.

Empiric Laws of Osmosis.—For convenience, the data which have been discussed in the preceding paragraphs may be summed up in the form of laws:

1. Solutions separated by a membrane permeable to water tend to have an identical molecular composition, both in number and kind of molecules.

2. If the membrane is perfectly permeable to both solvent and dissolved substance, the exchange of molecules takes place without change in pressure or volume.

3. If the membrane is less permeable to the dissolved substance than to the solvent, and increase of liquid, or increase of pressure occurs in the stronger solution.

4. If a membrane is differently permeable to one dissolved substance than to another, equimolecular solutions of the less diffusible substance are hypertonic to the more diffusible.

Nature of Osmosis.—Several theories are current for the explanation of osmotic pressure. The most important are the kinetic motion theory of Van't Hoff; the solution-affinity theory of Kahlenberg; the hydration theory of Morse; and the surface-tension theory of Traube. None of these theories is conclusively proven to the exclusion of the others. It is conceivable that all these processes are concerned in the passage of the solution; but that the actual pressure is caused by the motion of the molecules, as formulated by Van't Hoff.

Van't Hoff's Theory of Osmotic Pressure.—This is the theory which has found the widest acceptance among physicists. From the observations of osmotic pressure by means of Pfeffer's ferrocyanide of copper cell, Van't Hoff (1885 and 1887) arrived at the conclusion that the phenomena of osmotic pressure are governed by the same laws as the pressure of gases, quantitatively as well as qualitatively. This would imply that the pressure in both cases is produced by the same cause, namely, the kinetic motion of the molecules bombarding the walls of the container. Dissolved molecules would behave precisely like gaseous molecules. The membrane would play a purely passive part; being important only by making the kinetic motion manifest to the senses.

According to the Van't Hoff theory, the molecules of both solvent and solute are in constant motion, moving with the same energy as if they were in the form of a gas. Every molecule, by striking against the walls of the container, or against other molecules, exerts a certain pressure, which is precisely the same whether the substance is in the form of a gas or of a solution. If the same number of molecules per cubic space exist in two solutions separated by a semipermeable membrane, the pressure will be equal on each side of the membrane. The nature of the molecules is immaterial in this, as long as they all penetrate through the membrane with equal readiness. If all the molecules can pass through the membrane, an exchange will take place; but since as many pass to one side as to the other, there will be no difference in the pressure in the two compartments. If, on the other hand, the molecules on the one side can pass through readily while some of the molecules on the other side are not capable of diffusing through the membrane, then the pressure in the two compartments will become unequal.

In an osmotic cell, the non-diffusible molecules all rebound from the membrane, and so remain confined to their own side. The diffusible molecules, like gases, tend to pass through, irrespective of the other molecules, until they exist in equal concentration on each side, *i.e.*, until the *partial pressure of each kind of molecule is the same on both sides*.

If a solution consisting of x molecules of salt and $(y - x)$ molecules of water per cubic centimeter were inclosed in a closed vessel and separated from water containing y molecules per cubic centimeter by a semipermeable membrane, then water would pass into the solution until it also contained y molecules of water per cubic centimeter. But it would then also contain x molecules of salt. Its total molecular concentration per cubic centimeter would therefore be $y + x$; higher by x than that of the liquid

outside of the vessel. The pressure in the vessel would therefore be increased by x molecules.

The process might be represented as follows:

Partial Molecular concentration:	$\frac{y\text{H}_2\text{O}}{y}$	$\frac{x \text{ salt}}{y - x\text{H}_2\text{O}}$	$\frac{y\text{H}_2\text{O}}{y}$	
Total Molecular concentration:	$\frac{y}{y}$	$\frac{x \text{ salt}}{y - x\text{H}_2\text{O}}$	$\frac{y\text{H}_2\text{O}}{y}$	$\frac{y\text{H}_2\text{O}}{y + x}$

tends to become

This excess of total molecular concentration constitutes the *osmotic pressure*.

An experiment analogous to osmosis can be performed on gases directly. Palladium is permeable for H but not for N. Ramsay, 1894, found that when a palladium vessel is filled with N, closed, and immersed in an atmosphere of H, the pressure rises within the vessel until it exceeds the outside pressure by the partial pressure of the H. However, this experiment could also be explained by the other theories.

Application of Gas Laws to Osmotic Pressure.—Van't Hoff claimed as chief support of his theory, that the osmotic pressure obeys quantitatively the laws of gas pressure. As applied to osmotic pressure, these would read: *Boyle-Mariotte's Laws:* With constant temperature, the osmotic pressure of a solution is proportional to its concentration. Under standard conditions, a gram-molecule distributed over a liter of space, exerts 22.34 atmospheres of pressure.

Gay-Lussac's Laws.—With equal concentration, the osmotic pressure grows by $\frac{1}{273}$ for each degree C.

Avogadro's Laws: With equal osmotic pressure and equal temperature, equal volumes of solutions contain the same number of dissolved molecules, and the same number as would be contained in an equal volume of gas of the same temperature and pressure.

Experimental Evidence.—The experimental confirmation of these laws is unfortunately very incomplete (Kahlenberg), because of the difficulty of constructing strictly semipermeable membranes which will resist the high pressures. The experiments which form the original basis of the Van't Hoff theory were very inaccurate. Since then, only a few rigorous determinations of absolute osmotic pressure have been attempted (especially by Morse, Holland and co-workers, 1911 and 1912). These showed a good agreement with the theory; but they were confined to a single type of membrane (ferrocyanide of copper) and to a single substance (cane sugar), within a limited range of concentration and temperature. Outside of these limits, there were considerable discrepancies. The numerous determinations of relative osmotic pressure, which can be easily made, are inconclusive; for while they agree with this theory, they also harmonize with the competing theories. On the other hand, Kahlenberg, using different, but typically semipermeable membranes, finds that the gas laws do not hold at all; and that the phenomena can be explained quite simply on an entirely different basis. The evidence for the Van't Hoff theory is therefore incomplete.

Advantages of the Van't Hoff Theory.—This is very attractive in that it reduces all the physical phenomena of gases and solutions to a common basis, and thereby permits convenient and far-reaching theoretical and practical deductions. For instance, by postulating that osmotic pressure is directly proportional to the molecular concentration, it justifies the substitution of an easy calculation for the very difficult experimental determination of the pressure. Since it assumes that the membrane is purely passive, it permits the calculation of osmotic pressure in situations which are inaccessible to direct experimentation. In a word, if it is correct, it makes the difficult method of direct experimentation more or less superfluous, substituting for it an easily applied formula. This would be highly convenient and desirable—but before relying on such deductions, the correctness of the formula must be more securely established.

Kahlenberg's Theory.—This has the advantage that it furnishes the simplest explanation of the nature of the osmotic exchange; and that it is in the best accord with these phenomena as exhibited in living structures. The theory refers osmosis to solution-affinity, and may be best understood from an experiment made by L'Hermite in 1854. A layer of chloroform is poured into a vessel, then a layer of water, and finally a layer of ether. Even if any mechanical mixing of the strata is carefully avoided, it will be found that the ether layer gradually diminishes, until finally there are only two layers, the upper containing mainly the water, the lower the chloroform and the ether. In other words, the ether has passed through the water into the chloroform, just as water passes through a semipermeable membrane into a salt solution. The analogy can be carried even further: If a cork saturated with water is firmly wedged between the ether and

chloroform layers and the chloroform compartment is connected with a manometer, a very considerable pressure will be developed. Analogous experiments have been devised by Nernst, 1890 (passage of ether into benzol, through pig's bladder), and by Gies, 1912 (passage of ether into oil, through rubber condom).

It is difficult to see in what essential respect these arrangements differ from an osmotic cell. In both cases two dissimilar fluids are separated by a septum. In both cases, one of the fluids passes into the other; and if this is prevented, a pressure is produced. In L'Hermite's experiment we can easily see the explanation: Ether is soluble in water, and therefore diffuses into the latter; it is, however, much more soluble in chloroform, and therefore the ether which is dissolved in the aqueous layer tends to pass into the chloroform. The watery layer therefore would lose some of its ether to the chloroform, and would then take up more from the ethereal layer; and this process would continue until practically all the ether had passed into the chloroform. In other words, the passage of the ether, and the pressure which may thus be developed, is not due to any gas pressure, but simply to the fact that ether has a solution-affinity for water, and hence passes into the latter; and that it has a still greater solution-affinity for chloroform and hence passes into this from the water. If we substitute the hypothetical "semipermeable" membrane for the water, we may say that "osmotic pressure" measures not the gas pressure, but the solution-affinity of the solvent for the solute, less the affinity for the membrane. Osmotic pressure results if the solute is relatively insoluble in the membrane, *i.e.*, if it has a greater affinity for the solvent than for the membrane. In the case of two solutions the transfer of fluid occurs in the direction of the solution which has the greater affinity; and osmotic pressure is simply the hydrostatic pressure which is required to prevent this attraction of fluid.

The theory supposes that the solution-affinity increases with the molecular concentration; and since it is a fact that equimolar solutions of all substances are isotonic—at least with strictly semipermeable membranes and aqueous solutions—it follows that the solution-affinity must depend solely upon the molecular concentration; *i.e.*, it must be independent of the nature of the dissolved substances.

Relation of Van't Hoff and Kahlenberg Theories.—The main facts of osmosis are explainable by either theory. The principal difference in their practical application lies in the fact that Van't Hoff's theory gives a definite formula for calculating the osmotic pressure from the molecular concentration; while Kahlenberg's theory does not attempt an exact quantitative formula. Presumably, however, even this difference is not of very fundamental practical importance; for the absolute osmotic pressure may well be that of the gas formula, whether it is produced by kinetic motion or by solution-affinity; indeed, as has been intimated, the pressure proper may be due to kinetic motion in either case.

Surface-tension Theory of Osmosis.—J. Traube (1904 and later) refers osmotic phenomena to surface tension. He observed that substances which lower surface tension, and which therefore accumulate at the surface according to the Gibbs-Thomson principle, penetrate through membranes more rapidly. Conversely, salts, etc., which increase surface tension, and which therefore accumulate in the interior, would attract the solvent to equalize the pressure. In other words, the fluid of lower surface tension would be drawn into that of higher surface tension. Since the distribution of solutes is an expression of their affinity for the solvent, Traube's theory does not differ materially from that of Kahlenberg.

Morse's Hydration Theory.—Morse attributes the passage of the water to unequal hydration of the colloids on the two sides of the membrane. The solutes dehydrate the side of the membrane in contact with them; and this is equalized by the attraction of water from the opposite side. The theory is somewhat related to that of Kahlenberg's; but it helps to explain why the *rate* of osmosis is not parallel to the semipermeability, or to the final osmotic pressure. Salts generally develop an osmotic pressure more rapidly than sugar, even when the final osmotic pressure of the salt solution is lower.

Differences between Rate of Osmosis and Osmotic Pressure.—These are often not parallel. For instance, the copper ferrocyanide is impermeable to sucrose, and fairly permeable to salt. A sugar solution will therefore be eventually hypertonic to a salt solution. In the start, however, *i.e.*, before the salt molecules have had time to diffuse through the membrane, water passes from the sugar into the salt; it is only as diffusion proceeds that the process is reversed as would be expected. Other membranes show similar phenomena (Meigs, 1915). Indeed, acids actually diminish in volume when diffused through a pig's bladder against water (Graham).

Morse explains these observations by the fact that neutral electrolytes dehydrate colloids more readily than non-electrolytes. The "negative osmosis" of acids is due to their hydrating action. Alkalies are intermediate.

Magnitude of Osmotic Pressure.—According to the gas laws, the pressure exerted by a *gram-molecule* (the molecular weight expressed in grams) or “*mol*” of any substance, when confined to a liter of space, equals 22.34 atmospheres. In a “molecular” solution therefore (one containing a mol dissolved in a liter of solvent) the osmotic pressure would raise a column of water to a height of about 725 feet! The osmotic pressure of the salts in the blood would raise it about 250 feet. This may suffice to indicate the enormous molecular force latent in solutions, even if it may not be absolutely correct.

An actual osmotic pressure will only be developed if the solution is confined; if it is free to expand, the incoming molecules merely increase the volume of the fluid.

In this way a single molecule of a non-diffusible salt would theoretically be capable of attracting an infinite amount of water across a semipermeable membrane—for it is evident that the number of H_2O molecules per cubic space would always be less, by the molecules of salt, than they are in pure water.

The rapidity with which water passes into the salt solution across the same semipermeable membrane depends of course upon the concentration of salt; *i.e.*, the partial vacuum of H_2O molecules in the solution. The rate of osmosis will therefore be slowed as the process progresses.

Direct Determination of Osmotic Pressure.—The absolute osmotic pressure would be measured by the rise of a manometer attached to an osmotic cell, *i.e.*, a rigid vessel filled with a solution, surrounded by a semipermeable membrane, and immersed in water. Perfect osmometers are difficult to construct, and perhaps theoretically impossible. However, even imperfect instruments give practically useful data as to the velocity and magnitude of osmotic pressure and these show at least an approximation to the gas laws.

Determination of Relative Osmotic Pressure.—This can be easily made by using artificial membranes, or more conveniently animal or vegetable cells; diluting the solution under investigation until its osmotic effects on the cells are identical with those of a known solution.

The earliest quantitative studies of osmosis (Historical Review, Hamburger, 1911) were made in this way by de Vries, 1882, by the use of certain plant cells (*Tradescantia*) which exhibit *Plasmolysis* (retraction of the protoplasm from the cellulose envelope) in hypertonic solutions. He was thus able to determine the isotonic concentrations of a long series of substances. H. J. Hamburger, 1883, introduced the *hemolytic method*, *i.e.*, the determination of the concentration which produces laking of red blood corpuscles. This is also isotonic, provided that the corpuscles are semipermeable, *i.e.*, that the substances do not penetrate. This may be ascertained by direct chemic analysis and holds practically for most salts and sugars, but not for urea, alcohols, etc. The changes in the *weight of tissues* after immersion in the solution may also be used as an index; but with these, partial semipermeability is much more common, and imbibition may come into play; thus, according to Overton, 1906, serum is isotonic with 0.9 per cent. NaCl; but when concentrated four times, it requires 5 per cent. NaCl; and when six times, 10 per cent.

Value of the Comparative Methods.—All these methods involve comparison with a known solution; and if the absolute osmotic pressure of the latter were known, and if the membrane were truly semipermeable, then the absolute osmotic pressure of the unknown solution could be easily calculated. This, however, is mainly of theoretical importance, for as has been repeatedly said, strictly semipermeable membranes probably do not exist in nature. The true values of these comparative estimations lies rather in the picture which they furnish of the direction and relative value of the osmotic pressure for the particular solution and membrane (or cell) with which they are made—often a matter of great biological importance.

Calculation of Molecular Concentration and Osmotic Pressure.—Since the osmotic pressure has a definite relation to the molecular concentration, the determination of the one quantity permits the calculation of the other.

If a cell-membrane were truly semipermeable, then two solutions which had the same effect on the cell volume (or laking) would need to have an identical molecular

concentration. The concentration of any unknown solution could therefore be determined by diluting or concentrating it until it became isotonic with a standard solution of known concentration. The semipermeability of certain cells is sufficiently complete to make this method available for practical purposes; but it is less exact and generally less convenient than the calculation from the freezing or boiling-point.

Estimation of the Molecular Concentration by the Freezing-point.—The depression of the freezing-point (denoted by Δ) is easily determined by the Beckmann apparatus. It is strictly proportional to the molecular concentration; every mol of substance per liter of solution depressing the freezing-point of water by 1.85°C . and this no matter what the nature of the substance (*Raoult's Law*), except as it is modified by electrolytic dissociation. The molecular concentration is therefore calculated by dividing Δ by 1.85; and the osmotic pressure by multiplying the molecular concentration by 22.34 atmospheres.

Molecular Solutions.—Some confusion exists in the use of this term (abbreviated "M"). The correct practice is to add the calculated quantity of solute to a liter of solvent (*Raoult*). It is inadmissible to dissolve the mol in water enough to make a liter (*Arrhenius's method*), as is commonly done in making chemical solutions.

Molecular solutions are sometimes called "normal." This is objectionable; for the *normal solution of chemists* differs from the molecular solution, in that the molecular weight is divided by the valence. The *normal solutions of physiologists* are again quite different from the above; they are saline solutions of a strength of 0.6 to 0.9 per cent.

Electrolytic Dissociation.—According to this law the molecular concentration, and therefore the freezing-point, osmotic tension, etc., should be calculable by dividing the per cent. of the solution by one-tenth the molecular weight of the dissolved substance. This is found to hold true for concentrated solutions of all substances, and for dilute solutions of *non-electrolytes*—substances which do not conduct the electric current, such as the sugars, urea, glycerin, alcohol, etc. Dilute solutions of *electrolytes*—salts, acids, or bases—however, show a greater concentration than would be deduced from *Raoult's law*.

A solution of NaCl containing 0.584 gram of NaCl per liter (equals $\frac{1}{100}$ mol) should depress the freezing-point by 0.0185° . It is found, however, that its depression is nearer to 0.03° ; almost twice as great as would be expected. Very dilute solutions of Na_2SO_4 have three times the calculated concentrations; those of H_3PO_4 , four times.

The dissociation of salts, as revealed by the freezing-point, bears a striking relation to the conductivity of salt solutions for electricity. It has been found that salt solutions conduct electricity proportionately better the more they are diluted. If, e.g., a solution which contains 0.1 mol has a coefficient of conductivity which we will call " K ," a solu-

tion which contains only 0.01 mol will have a coefficient higher than $\frac{K}{10}$. This increase is exactly proportional to the increased molecular concentration revealed by the freezing-point. The two phenomena must therefore have the same cause.

To account for the fact that electrolytes depress the freezing-point more than would agree with *Raoult's law*, *Arrhenius*, 1887, advanced the hypothesis that a certain proportion of the electrolytic molecules, by acquiring an electric charge, separate into their constituent ions: NaCl into Na^+ and Cl^- ; $(\text{NH}_4)_2\text{SO}_4$ into NH_4^+ , NH_4^+ and SO_4^{--} ; H_3PO_4 into H^+ , H^+ , H^+ and PO_4^{--} ; $\text{Ca}(\text{OH})_2$ into Ca^{++} , OH^- and OH^- . The $+$ and $-$ signs denote the nature and quantity of the electric charge. The metals of salts, and hydrogen of acids, carry a positive charge, and therefore wander to the cathode and thus constitute the *cations*. The "acid radicals" of salts, and the hydroxyl of bases, carry the negative charge, go to the positive pole, and are therefore the *anions*. The conduction of electricity through solutions occurs by the conveyance of these ions.

It is scarcely necessary to insist that the *ions are not identical with atoms* (from which they differ in that they carry charges), nor with the free elements (which exist as molecules). In a dilute solution of NaCl there does not exist metallic (Na) nor gaseous chlorine (Cl), but Na ions (Na^+) and Cl ions (Cl^-), whose properties are altogether different. It must also be remembered that this ionization exists in only a limited class of compounds, viz., in all acids, bases, and salts (*electrolytes*), and not in compounds which do not conduct electricity (*non-electrolytes*).

The electric charges are further important, since they may leave the ions to combine with the tissue elements, so that the electrolytes cause electric stimulation of the protoplasm.

Degree of Ionization.—This increases with the dilution of the solution until complete dissociation is attained.

With similar ions, the degree of dissociation is fairly constant for the same degree of dilution. In 1 per cent. solution of NaCl (and in blood) about 82.8 per cent. of the

molecules undergo this process, and about the same percentage in equimolecular solutions of KCl or NH_4Cl . Dissimilar elements, such as Mg, Ca, SO_4 , PO_4 , etc., have different constants. If several salts are present in a solution—particularly if they have a common ion—the degree of dissociation of each salt will be less than if it were present alone in the same concentration, but greater than if it were present alone in the concentration corresponding to the sum of the several salts.

Effect on Freezing-point, Osmotic Pressure, Etc.—Each of these fractions (ions) has the physical properties of molecules, and thus causes a corresponding depression of freezing-point or increase of osmotic pressure. These quantities would therefore be twice as great if the molecules had dissociated completely into two ions (NaCl); three times as great when dissociated completely into three ions (Na_2SO_4); four times with H_3PO_4 , etc. With partial dissociation, intermediate values would be obtained.

The total molecular concentration of a dilute solution of a single salt corresponds to the number of undissociated molecules, plus the number of dissociated molecules multiplied by the number of parts into which they divide. For instance, if 80 per cent. of the NaCl molecules in a solution are dissociated, the concentration will be $1 - 0.8 + (0.8 \times 2) = 1.8$ times the theoretical; if 80 per cent. of Na_2SO_4 is dissociated, it will be $1 - 0.8 + (0.8 \times 3) = 2.6$. (Tables of the dissociation of the various salts are given by A. A. Noyes and Falk; J. A. Ch. S., 1910.)

Limitation of Terms.—To avoid confusion it may be well to confine the term "*mol*," or better, "*molion*," to the molecular concentration actually deduced from the freezing-point (*i.e.*, 1.8 in the preceding example of NaCl); and "*gram-molecule*" to the concentration deduced from the molecular weight (*i.e.*, 1 in the example) without taking account of the dissociation. The abbreviation "*M*" is always applied to the latter. Several solutions may be related to each other in the following ways: *Equimolecular* (same number of gram-molecules); *Equiosmotic* (same number of molions); and *Isotonic* (same effect on a given cell). The term *isotonic coefficient* is applied to the factor by which the molecular concentration must be multiplied to obtain the molionic concentration.

Ion Actions.—In addition to the osmotic actions electrolytes show effects which are due to their constituent ions. These actions are generally proportional to the degree of ionization:

The comparatively firm mercuric albuminate is much less active than the ionized mercuric chloride; ferrocyanides, in which the iron does not exist as an ion, act quite differently from ferrous salts, and these again differ from ferric salts. Gaseous chlorine does not behave at all like the chloride ion of NaCl , etc. The chemic behavior varies in the same way with the degree and state of ionization. The ions may act by entering into chemic combinations with the protoplasm, producing various compounds, syntheses, and decompositions, and thereby lead to functional changes. They may also alter the permeability of the cell wall. Besides these chemic actions, it appears more than probable that the electric charges carried by the ions exert actions which are independent of the chemic nature of the ions. These latter actions may well be termed "*electron actions*." It is quite conceivable that the chemic actions are also in the last instance resolvable into electric manifestations. But since the proof for this has not yet been furnished, and since the two classes of actions exhibit striking differences, it is well to keep them apart in so far as this is practicable.

Electron Actions.—This term designates those actions which are produced by the electric charges carried by ions. These modify the electric condition of the protoplasmic colloids, and hence their aggregation. This leads to important modifications of functions.

The existence of these actions is shown by the fact that all electrolytes produce certain effects in common, which are not produced by non-electrolytes. For instance an egg-albumin solution can not be coagulated by heating when the electrolytes have been removed by dialysis. The coagulability is restored by the addition of electrolytes, but not by nonelectrolytes (sugar, etc.). These effects are largely independent of the chemic properties of the ions, but vary with their electric properties, such as the sign of their electric charge and the ease with which they part with this. The effects agree with those of positive and negative electric stimulation; anions and cations tend to produce opposite effects, the action of an electrolyte being determined by the predominating ion; analogous phenomena are exhibited when electrolytes are added to solutions of colloids.

The Relation of the Toxicity of Ions to Their Electric Properties.—The quantitative effects of ions on protoplasm can be estimated most exactly and most conveniently by observing the molecular concentration in which the solution will just cause death. This has been studied by a number of investigators. It was noticed that the *toxicity increases generally with the atomic weight* of the ion—Hg, for instance, being much more toxic than Na; but, on the other hand, H was found more toxic than the heavier Na. The *toxicity also increases generally with the valency*; but here also there are very striking exceptions, the monovalent Ag being more toxic than the trivalent Al. The general rule is so striking, both as to the atomic weight and valency, that some connection could not be doubted; but it is evidently not a simple one. The extensive experiments of A. P. Mathews (1904) on fundulus eggs, showed a remarkable agreement between the toxicity and the solution-tension of ions, *i.e.*, the tendency of a metal to go into solution, and thus to acquire an electric charge. However, the correspondence does not apply to all cells, nor does it explain the qualitative differences between related ions, such as the halogens, or the earthy metals.

OSMOTIC EFFECTS ON CELLS

It may now be attempted to apply these physical processes of salt action to the explanation of the phenomena of life. It will be remembered that the latter may be influenced by the osmotic, electric and chemic properties of the salts. The osmotic effects are independent of the nature of the molecules. The electric effects depend solely on the sign and transferability of the charge. The chemic effects are distinctive. All these effects are influenced by the special permeability of the cell membrane; by the solutes already present in the cell and in its surroundings; and by the special properties of the cell colloids.

Osmotic Actions on Cells.—These are due primarily to the changes in the total water or salt content of the cell. It is therefore necessary to distinguish between hyper-, hypo-, and isotonic solutions. In effect, however, the final functional results of different concentrations are often very similar.

Changes in the Composition of the Cells.—In a physical sense, a cell may be conceived as a solution, the protoplasm, chiefly of hydrophilic colloids and largely dissociated electrolytes; inclosed in a membrane (the cell wall) of characteristic permeability; and generally containing suspended lipoids or solid granules. The living cell walls (which may be conceived as cytoplasm modified by contact with the extracellular media) are usually easily permeable to water, impermeable to colloids and more or less difficultly permeable to electrolytes and other crystalloids. In this way they permit a certain amount of exchange between the cell and its surroundings (the lymph, etc.) which is necessary for metabolism. At the same time, since the permeability is limited, and varies for different substances, it enables the cell to preserve its own composition, which is quite different from that of the lymph. However, this protection is not perfect, especially if artificial changes are made. It is altered during stimulation, and is destroyed at death; *i.e.* dead cells are freely permeable.

The cell walls behave essentially like what we have defined as a “partly semipermeable” membrane (as suggested by Traube, 1867). If therefore the molecular constitution of the medium surrounding the cells be in any way changed, this will effect, in the first place, a change in the total water or salt content of the cell. A hypertonic solution causes the withdrawal of water, and a hypotonic solution the withdrawal of salts. If the ratio of the different salts in the surrounding medium is not the same as

that in the cells, their ratio in the latter will also be altered. Again, when salts are drawn out of the cell, certain of its salts leave more quickly than others. The changes will be the greater, on the whole, the more the composition of the surrounding liquid departs from that of the cell.

Molecular Concentration of the Blood and Tissues.—The total molecular concentration of the living cells is not accurately known. It is probably somewhat higher than that of the body-fluids. The plasma, lymph, and all other body-fluids (except urine and gastric juice) of all mammals, depress the freezing-point by about 0.56° , corresponding to 0.33 mol per liter. Relatively slight departures from this are promptly injurious. Its maintenance is therefore very important. Accordingly, the organism resists very powerfully any attempts to alter its osmotic concentration. The fluids of lower animals have a somewhat different concentration, adapted to their environment.

Protoplasm.—The osmotic pressure of cells can not be measured during life. Direct cryoscopy of the organs gives unreliable results. Buchner juices generally depress the freezing-point somewhat more than does blood, but this might be due to chemic changes. The intracellular pressure is not solely osmotic, but is also due to imbibition, surface tension, and the elasticity of the cell wall (Pfeffer, 1897).

Human Blood.—The extreme variations of the freezing-point in health are between 0.49° and 0.59° . The molecular concentration of the blood is not altered by the quantity of fluid or salt in the food; nor by hydremia produced by hemorrhage; nor by thickening the blood by profuse diaphoresis. The intravenous injection of anisotonic solutions alters it but temporarily. About the only method of raising it permanently consists in interfering with the regulating mechanism, by seriously injuring the kidneys; and then it proves fatal when the Δ approaches 0.8°C . The importance of comparatively slight changes in the concentration is also shown strikingly by the red blood corpuscles. These swell in hypotonic, and shrink (crenate) in hypertonic solutions. If the serum is diluted to about $\Delta 0.35$, the hemoglobin begins to leave the corpuscles, their structure being destroyed. There is reason to believe that the same holds for most other cells, and that the limits between which cells of mammals can functionate at all, are comprised between $\Delta 0.35$ and 0.6 or somewhat higher.

Osmotic Equilibrium of Lower Animals.—The narrow limits of mammals are considerably extended in the lower forms of life. With *marine animals*, up to the Selachians, the molecular concentration of the body-fluids approaches that of sea water, and becomes independent only in the Teleosteans. Dog-fish are intermediate (Scott, 1913). In the marine animals, a concentration equal to that of the serum of mammals would liberate the hemoglobin. In other words, the resistance of cells is somewhat adapted to their normal environment. This resistance is curiously developed in the small fish *Fundulus*, which thrives equally well in sea water and in distilled water. It is due, in this case, to a high degree of impermeability to both water and salts, so that osmotic pressure can not be developed.

Sweet-water animals have a considerable molecular concentration approaching that of mammals, the salts being probably retained by chemical or physical affinity for the colloids. The molecular concentration of *plant juices* is also considerably higher than that of water. *Fungi* often have a very high resistance against osmotic changes, presumably because their envelopes are relatively impermeable. *Torula*, e.g., can develop in a saturated solution of sodium or lithium chloride, the latter having an osmotic pressure of 2,760 atmospheres (Raciborski, 1906; see also L. A. Hawkins, 1916).

Structural Changes Resulting from Osmosis.—With most cells, however, any departure from the normal concentration of the liquid in which they are bathed, produces the structural changes which we would expect; these can be best seen in monocellular organisms, red or white blood cells, or ova: these show shrinkage or swelling condensation or liquefaction, precipitation or solution. These often lead to even more important *secondary decompositions*, which may cause the cells to swell even more in a hypertonic solution, than they do in water (Sollmann, 1904).

Osmotic Changes in Red Blood Cells.—Hypertonic solutions produce crenation; if the solutions are hypotonic beyond a certain degree, hemolysis occurs. The cells swell and lose their hemoglobin and salts. In life,

these changes could be produced only by intravenous injection of anisotonic solutions.

Specific Resistance to Osmotic Hemolysis.—This varies in different species; and somewhat even with individuals. The following figures are normal averages (Musser and Krumbhaar, 1916, and others):

	Laking begins with	NaCl per cent.	Is complete
Guinea pig.....		0.420	0.312
Human.....		0.450	0.360
Dog.....		0.462	0.330
Rabbit.....		0.526	0.395
Beef.....		0.580	
Horse.....		0.680	

These specific differences refer only to hemolysis; the osmotic swelling, measured by the hematocrite, being about equal in the different species. The specific difference to water-laking is generally inverse to that for saponin-laking (Rywosch, 1907).

Influence of Disease, Etc.—Changes in the resistance to hemolysis have been found in diseased conditions (tumors, etc.). It is diminished in purpura (Musser and Krumbhaar, 1916), practically unchanged in pernicious and in secondary anemias. The resistance is said to be increased by therapeutic doses of arsenic (L. W. Hill, 1915).

Laking Power of Various Salts.—Hemolysis depends not only on the concentration, but also on the nature of ions, following the usual lyotropic series. Hoerber, 1908, found the hemolysis least with the SO_4 and Na end, and most with the I and K end of this series. The sequence is reversed by combination with lipolytic agents, saponin or bacterial lysins. The differences are referable to the different permeability of the salts and to their effects on the cell membrane.

Hemolysis by Hypertonic Solutions.—This has been investigated by C. C. Guthrie and Lee, 1914.

Permeability of Red Blood Cells.—These are practically impermeable to most osmotic substances. However, both anions and cations pass to a slight degree, even under physiologic conditions (Hamburger and Bubanovic, 1807); and certain substances (ammonium ions, urea) pass very readily. In general, the permeability is proportional to the lipoid solubility. Ammonium salts are an exception for they are directly hemolytic; they lake even when added to isotonic NaCl solution. The permeability to other solutes is increased by combination with saponin and other hemolytic agents. In saponin-laking, an increased permeability of the cell membrane can be demonstrated directly, before the salts pass out of the cell (G. N. Stewart; Woelfel, 1908).

Aliphatic (Lipoid-solvent) Narcotics on Red Blood Corpuscles.—In anesthetic concentrations these substances decrease the volume of blood corpuscles and decrease swelling and hemolysis by hypotonic solutions. This is most simply explained by a condensing (dehydrating) effect on the proteins of the cell membrane, and perhaps other cytolytic and narcotic effects may be reduced to the same basis, rather than to a lipoid-solvent action. Laking and cytolysis would then be explained mainly by imbibition of liquid, changing the aggregation of the cell-colloids from the gel to the soluble state (v. Knauff-Lenz, 1918).

The permeability of the corpuscles for Na and K ions have been denied (Guerber 1895), but has been established by H. J. Hamburger, 1916. He also found that the addition, within physiologic limits, of CO_2 to the serum drives K ions into, and Na ions out of the corpuscles. NaCl drives Na and K out; and KCl does the reverse.

Rohonyi and Lorant, 1916, state that carbon dioxide causes the erythrocytes to take up chloride from the serum, with an increase of serum alkalinity. Similar changes occur in hemolysis.

Preservation of Living Erythrocytes.—Blood cells, when suspended in saline solution die rather rapidly, partly by mechanical and partly by chemical injury. Rous and Turner, 1915, found that the addition of gelatin protects them against the mechanical injury, but not against the chemical. The addition of glucose or saccharose, on the other hand, preserves them for a long time, so that they show no morphologic changes, and take up and surrender oxygen in the normal manner.

Sedimentation of Red Corpuscles.—The rapidity with which this occurs in shed blood varies with conditions. It is accelerated, for instance, when albumoses are injected; in the "hemoclastic crises" of colloidal and immunity reactions (Widal); in the cachexia and anemia of malignant disease (Gragert, 1923); in pregnancy (Fahracus, 1918); and in various pathologic conditions, especially those associated with fever and inflammation (vide Fiedler, 1923). However, there is no sharp demarcation between the normal and

pathologic states (Zeckwer and Goodell, 1925). The phenomenon is evidently due to alterations of the physico-chemical conditions of the colloids of the suspending plasma; but the details of the possible mechanisms (viscosity of the plasma or corpuscles; alterations in electric surface charges etc.) have not been worked out.

Selective Permeability of Cell Membranes.—This varies for each class of cells, some being impermeable to one substance, some to another. This is doubtless important for maintaining the normal differences of composition. It is subject to changes with the functional states of the cell. The permeability is often different in one direction from that in the other.

Permeability to Different Substances.—With most living cells, lipid-soluble substances penetrate more readily than those which are only water-soluble. The penetration is also influenced by the presence of lipolytic agents (anesthetics). The lipoids of the cell membrane are therefore important elements in determining its permeability. They are not, however, the only factor. The membrane is not absolutely impermeable to salts; and some substances penetrate independently of their lipid solubility. It is generally assumed that the membrane is a mixture of lipid and protein colloids, and that both play a part in the penetration.

When discussing the red blood corpuscles, it was stated that they were almost impermeable to most salts and sugars, but permeable to ammonium, urea and lipolytic agents. This applies also to plant cells, in which the phenomena have been most extensively studied. Klebs and de Vries, *fi.*, found that glycerin and urea do not produce plasmolysis. Overton, 1895 and 1899, has added many data.

A general discussion of cell-permeability and its applications is given by R. S. Lillie, 1918, in connection with sea-urchin ova.

Striped muscle is also nearly semipermeable (similarly to a celluloid membrane in which CaHP_2O_4 has been deposited); while smooth muscle is highly permeable to sugars and salts (Meigs, 1912 and 1913). The changes of weight in striped muscle in various conditions were investigated by J. Loeb.

With intact muscle, the changes in anisotonic sodium chloride solutions are purely osmotic. The osmotic property is destroyed by grinding with sand (H. Winterstein, 1916).

Lipoid Solubility as Condition for Entrance.—The numerous observations of Overton and others show no direct relation between chemic constitution and permeability. Traube, 1867, believed that the differences depend on the size of the molecule; but this is untenable. L'Hermite, 1855, attributed the penetration to solubility in the cell membrane. This is undoubtedly a prerequisite to absorption. Overton found that all lipid-soluble substances penetrate readily into all cells; and those which are not lipid-soluble penetrate with difficulty.

This rule, although not absolute, holds so widely, that it must be a simple passive physical phenomenon. It is not absolute, however, or metabolism would be impossible. Nathansohn, 1904, therefore assumed that the cell membranes consist of a mosaic of cholesterolin and protoplasm. However, this is not a necessary deduction; for Nathansohn, 1904, and Ruhland, 1909, showed that artificial lipid membranes, when soaked in water, become quite permeable to substances that dissolve in water, even if these are insoluble in lipoids; while water-free lipid membranes are impermeable to the water as well as to the solutes.

Calcium and magnesium phosphates perhaps also play a part in semipermeability; but the degree of impermeability is so different that they are probably unimportant factors (Meigs, 1915).

Permeability for Alkaloids.—This is easily observed in plants by the precipitation of the tannin within the cells. Only the free (basic) alkaloids penetrate; the alkaloidal salts enter very much more slowly, namely in proportion as they are hydrolyzed. Their toxicity is favored by the addition of alkalies; this applies also to fish and frog larvae. Harvey, 1913, found that cell membranes are readily permeable to weakly dissociated alkalies, but remarkably resistant to those which are strongly dissociated.

Absorption of Dyes.—Ehrlich, 1887 and 1893, found that vital staining occurs especially with basic dyes. Overton, 1900, referred this to their lipid solubility, and advanced the theory that all absorption occurs through the lipoids of the cell envelope. However, exceptions have been discovered. Certain lipid-soluble dyes are not absorbed; while others, which are insoluble in fats, are nevertheless absorbable. Indeed,

Asher and Gannus, 1911; Harvey, 1911; Kite, 1913; and others, have found little relation. Acid dyes stain the protoplasm diffusely, while basic dyes stain mainly the cell granules.

Permeability of Internal Cytoplasm.—Kite, 1915, found that incised and punctured cells offer the same obstacles to the penetration of dyes as do intact cells. This was originally interpreted as showing that the cytoplasm itself is semipermeable; but it is now attributed to the precipitation membrane which forms rapidly when naked living protoplasm comes in contact with watery fluids. Dead protoplasm is water-soluble, and therefore does not form the precipitation membrane (Seifriz, 1918). The existence of Brownian movement in living cells shows that their interior cytoplasm is liquid; but with adult cells it may become gelatinous (Chambers, 1917). With death, the protoplasm coagulates and the Brownian movements are arrested.

Changes of Permeability in Stimulation.—The permeability of the cell membrane appears to increase suddenly at the moment of stimulation; the resulting change of surface potential being a necessary part of the stimulation-phenomena.

The influence of stimulation, narcotics and salts on cell-permeability was pointed out by Osterhout, 1912; R. S. Lillie, 1912; J. Loeb, 1913. Stimulation decreases the electric polarization; it causes the diffusion of intracellular pigment (Lillie); the diffusion of ions from frog eggs (McClendon, 1915); the entrance of rubidium and cesium into perfused muscle (Mitchell) etc.

Asher observed that the vital staining of gland cells is greatly influenced by their functional activity, being increased by pilocarpine and diminished by atropine. Temperature influences the plasmolysis of plant cells (v. Rysseberghe, 1901); CO₂ increases the permeability of erythrocytes (Hoerber, 1904).

The semipermeability of *artificial membranes* can also be varied at will, especially by the strictly physical conditions of hydration. The permeability of celloidin membranes, for instance, depends on the degree to which they are dried before water is applied; the less the drying, the greater their permeability (Meigs, 1915).

Electrolytes on Permeability.—Immersion in NaCl increases permeability and stimulates. This is antagonized by calcium or magnesium.

J. Loeb and Cattell, 1915, observed that electrolytes increase the diffusion of K and H ions (Loeb, 1915) out of fundulus ova but retard their passages into these cells. The degree of the effect is parallel to the lyotropic series of anions. They attribute the diffusion to combination of the K or H with the colloid anions of the cell membrane; this combination being diminished by the mass-action of excessive anions in the surrounding solution.

Clowes, 1916, showed that the influence of electrolytes on cell permeability is similar to their effect on the permeability of soap films.

Semipermeability Persists only During Life.—It is lost when the cells die, so that dead cells merely imbibe solutions, like gelatin or fibrin. Acids also destroy the semipermeability (J. Loeb, 1913). Living tissues resist the entrance of all acids (except salicylic), while dead tissues are freely permeable to them (Harvey, 1914).

Functional Responses to Osmotic Changes.—The alterations in the composition of the cells entail corresponding changes in their functions, consisting in a mild or strong stimulation, often irritative; passing into depression and finally disorganization of the cell if the changes have been large.

With unspecialized cells the main changes fall upon their metabolism. Specialized tissues respond by their proper functions: Abstraction of water from a *nerve or muscle* causes contraction; the unfertilized eggs of certain marine animals undergo parthenogenetic development, etc. (J. Loeb, 1899, 1901).

If a very strong salt solution is injected directly into the circulation, the main symptoms arise from the central nervous system. They consist in stimulation, with subsequent paralysis, being similar to the effects of asphyxia.

Brain Volume.—Intravenous injection of hypotonic solutions increases the bulk of the brain, and therefore the intracranial pressure, and the tension of the cerebrospinal

fluid. Hypertonic injections, after a initial rise, produce a marked shrinkage of the brain and fall of cerebrospinal pressure. The alterations may be so great as to produce histologic changes (Weed and McKibben, 1919). Haden, 1919, tried this means with promising results for the relief of the cerebral compression of meningitis. He injects intravenously, in the course of an hour, 250 c.c. of sterile 25 per cent. glucose solution, 2 or 3 times per day.

Epinephrine Output.—Stewart and Rogoff, 1919, found this markedly increased by the intravenous injection of small amounts of concentrated sodium carbonate solution. They attribute this to osmotic stimulation of the bulbo-spinal centers.

Salt Action on Phagocytosis.—The sensitiveness of cells to small changes in osmotic concentration is shown by the phagocytic power of leucocytes. According to H. Hamburger and his pupils, 1908 and 1910, the phagocytic power is decreased by very small changes of the osmotic concentration of the serum, such as may occur under physiologic conditions. All anisotonic solutions are injurious, but especially increased concentrations. The leucocytes recover when the normal concentration is restored. NaCl causes but little injury apart from the osmotic effect. NaI is more toxic than NaBr. Of other ions, a slight excess of calcium stimulated, while decreased activity resulted from a larger excess, and from reduction of calcium as by fluorides or citrates. Ba and Sr do not have the stimulant action, so that it is not due to valence. Diminution of the normal alkalinity was deleterious, and to a less degree also an excessive alkalinity.

Osmotic Permeability of Muscle.—E. B. Meigs, 1912, 1914, concluded that the sarcolemma of living striped muscle acts like a semipermeable membrane, similar to artificial collodion- $\text{Ca}_3(\text{PO}_4)_2$ membranes. With death the sarcolemma becomes permeable. This he attributed to the solution of calcium phosphate by the acid that is formed in rigor. The calcium theory of semipermeability would require more direct evidence.

Fatigue increases the molecular concentration (depression of freezing point) of excised skeletal muscle by 36 per cent., by the breaking down of molecules. This does not occur when the circulation is intact, for the differences are then equalized by exchange with the blood (A. R. Moore, 1916).

Osmotic Permeability of Smooth Muscle.—E. B. Meigs, 1912, 1914, also concluded that smooth muscle is not protected by a semipermeable membrane, and reacts towards solutions solely by imbibition, like fibrin or gelatin. The absence of semipermeability appears improbable, and should be further checked.

Response of Muscles and Nerves to Osmotic Changes.—All forms of muscle, striped, cardiac, and especially smooth appeared to be stimulated by moderately hypotonic, and depressed by hypertonic solutions. Nerve trunks, on the other hand, are stimulated by hypertonic and depressed by hypotonic media.

Osmotic Response of Striped Muscle.—Immersion, or perfusion with hypotonic solutions produces twitchings, contracture and rigor.

Osmotic Response of Uterus.—Marked stimulation occurs even with slight hypotonicity (Dale, 1912; Goto, 1916; Voegtlin and Lake, 1917); and the depression by hypertonicity can be evoked even by oral administration in intact animals (Barbour and Rapoport, 1922). Hypotonicity also increases and hypertonicity depresses the response to anaphylactic stimulation (Dåle, 1912).

Osmotic Response of Intestines.—The tone and excitability are increased by hypotonic solutions, in living animals as well as in excised intestines. Hypertonic solutions depress, after a very brief stimulation. The latter tend to expell the hypertonic solution from the lumen before it can become depressant; so that the practical effect in living animals may appear entirely stimulation (Goto, 1911; Baur, 1925; v. Oettingen and Sollmann, 1926).

Osmotic Effects on Heart.—Goto, 1916, investigated these on the perfused turtle heart. Hypotonic solutions increase the tone, and the height of the contractions, shorten the A-V interval, but slow the rate. Hypertonic solutions produce the opposite effects.

Osmotic Response of Nerve Trunks.—The excitability and the rate of conduction are increased by hypertonic, depressed by hypotonic solutions (Ishikawa, 1912).

Ion Effects on Muscle.—The immersion of muscle in various solutions produces marked effects even when osmotic changes are excluded by

having the solutions isotonic. These must therefore be referred to ion actions. The muscles lengthen or shorten; the excitability may be diminished or increased; spontaneous rhythmic contractions may appear; or the muscle may develop "contact irritability" so that it will react to stimuli which are ordinarily ineffective. Invertebrate and mammalian muscles exhibit similar phenomena if proper conditions are maintained.

Importance of Electrolytes.—Muscles soon lose their excitability completely in solutions of non-electrolytes; but this returns when they are replaced in saline solutions. A medium containing electrolytes is therefore essential to muscular contraction; indeed, any change in the ions produces alterations in the muscular functions. The different ions are not equally effective. It appears that the nature of the cathions is more important than the anions. The ions arrange themselves in the usual lyotropic series, the Na and I end being the most favorable, and the K and citrate end being the most unfavorable to striped muscle, and to the rhythm of the heart. With smooth muscle, on the other hand, moderate concentrations of potassium increase the tonus and the peristaltic contractions (uterus, Tate and Clark, 1921). Potassium also stimulates the tonus waves of turtle's auricle. Calcium is generally antagonistic to the effects of potassium, on all forms of muscle.

Toxic Action of Single Salts.—Immersion in any solution of a single salt also renders muscle inexcitable, but with very different rapidity. These differences follow the lyotropic series in the same sense.

Rhythmic Contractions of Skeletal Muscle.—These generally develop before the irritability is lost, when muscle is immersed in solutions of a single electrolyte (Loeb, 1899). If a certain proportion of a calcium salt is added, the rhythmic property disappears again. The rhythmic contraction of the *cardiac muscle* or of medusæ also disappears when too much calcium is added. Rhythmic contractibility is not therefore a property characteristic of cardiac muscle, but is inherent in all muscular tissues. The reason why the contraction of the heart is ordinarily rhythmic, and that of skeletal muscle not, lies in the fact that the ions in the heart are balanced so as to favor rhythmic contractions, and in the skeletal muscle they are not so balanced.

Ciliary and Muscular Movement.—R. S. Lillie (1902) has studied the effects of ions on the larvæ of a sea-worm (*Arenicola*), which executes both ciliary and muscular movements. He found that the presence of magnesium in the mixture favors the contraction of the cilia, calcium of the muscles; potassium hinders both. Parker (1905) found that potassium reverses the stroke of certain cilia.

Ion Actions on Heart.—These are highly important to the cardiac contractions. The excised hearts of cold-blooded animals soon stop their beat when immersed in solutions of non-electrolytes (Carlson); but they continue to contract rhythmically for a long time in certain salt solutions. Analogous phenomena are observed in the perfusion of mammalian hearts. The solutions must contain Na, K, and Ca ions; and these must be in a fairly definite "balanced" ratio, as in Ringer's or Locke's solutions or their modifications. Deficiency or excess of these ions cause derangement of function and are equally fatal. For moderate changes, the ratio is much more important than the absolute quantity of the ions. The anions are relatively indifferent.

Effects of the Individual Cathions on the Heart.—These are complex and rather confusing, because the response of each is modified by the presence of other cathions. There are also marked but generally only quantitative differences between the different portions of the heart.

In living animals, departures from the normal ion ratio cannot be maintained for sufficiently long time to be of practical importance (Schafir,

1915) or even to be conveniently investigated. *Perfused hearts* respond to changes of the ion-ratio of the Ringer's solution according to the direction of the K:Ca ratio, practically regardless of whether the ratio is changed by increasing the one ion or by decreasing the other. The K or Ca predominance become conspicuous when the percentage of the one is about 3 or 4 times that of the other (Boehm, 1914).

Increase of the K:Ca Ratio, i.e. Potassium Excess or Calcium Deficiency.—The effects resemble those of vagus stimulation; *i.e.* weakening of the contractions and decrease of the rhythmicity, resulting in heart-block, intermissions and arrest; and in synergism with the parasympathetic stimulants (acetylcholine etc.) and mutual antagonism with sympathetic stimulation, through the accelerator nerve or by epinephrine; and with the muscular stimulants, *i.e.* the digitalis group. Contradictory results are reported as to the excitability of the vagus trunk.

The resistance to potassium increases with the inherent rhythmicity of the cardiac tissue, in the order of: Sinus (most resistant), ventricle base, ventricle apex, and auricular muscle (least resistant). The percentage of potassium in normal blood tends to inhibit spontaneous ventricular and auricular rhythm, and therefore renders the heart muscle more amenable to the pacemaking function of the nodal tissue.

Increase of the Ca:K Ratio, i.e. Calcium Excess or Potassium Deficiency.—This has essentially the opposite effects, resembling both accelerator stimulation with epinephrine, and muscular stimulation with digitalis. The contractions are strengthened and often quickened, with a systolic tendency which increases to prolongation and fusion of the systoles, and culminates in systolic arrest. Calcium excess is synergistic with accelerator stimulation by epinephrine and with the systolic effects of digitalis. It is antagonistic to vagus stimulation and to the parasympathetic stimulants and may apparently cause these to produce abnormal effects.

Functions of the Individual Ions.—These may be studied in strips from the various regions of the turtle's heart. These do not beat rhythmically in solutions of the non-electrolytes, but do so only if NaCl or other appropriate sodium salts are added. Sodium is therefore indispensable to the rhythmicity. The addition of Ca does not appear to be especially important for the rhythmicity, but rather to antagonize the eventual toxicity of Na and of K. The addition of potassium has a marked inhibitory effect on the rhythm, which is much more marked for the cardiac muscle proper than for the nodal tissue, and which may therefore be important chiefly for subjecting the cardiac muscle to the control of the normal pace-maker.

References for the effects and antagonisms of ion-ratios: See especially the papers of Ringer, 1882; Howell, 1898, 1902, 1906; Burridge, 1912; Boehm, 1914; Sakai, 1914; O. Loewi, 1921, 1915, 1917, 1918; Brine, 1917; Kolm and Pick, 1920; Andrus and Carter, 1921; Daly and Clark, 1921; Ten Cate, 1921.

For the phenomena of cardiac strips see Howell, 1898, 1902; C. W. Greene, 1898; Lingle, 1901; Martin, 1904; Sollmann and Chu; Chu and Sollmann, 1925.

For cardiac gradient, see Brouwer, 1916; Daly and Clark, 1921; Kolm and Pick, 1920; Sollmann and Chu; Chu and Sollmann, 1925.

Hypotheses of Ion-relations.—Howell, 1898 and 1906, suggested that Ca is concerned in the contraction and K and Na in the relaxation; that these ions enter alternately into relation with the contractile substance; that accelerator stimulation liberates Ca and vagus stimulation K ions. Martin, 1913, assumed with Howell that Ca promotes the conversion of stable into unstable energy-yielding material; that Na brings about the actual dissociation and thus initiates the beat (Lingle); and that K antagonizes both the Na and Ca.

Hydrogen-ions on Heart.—In the perfused turtle heart, increase of alkalinity (to pH 7.8) increases the tonus and rather decreases the amplitude; decrease of alkalinity (to pH 7.3) increases the output by lowering the tonus, thus permitting greater distention and excursions (Andrus, 1918).

Abnormal Ions.—These have been studied, *e.g.*, by Lussano, 1913, by modifying the constituents of Ringer's solution. Sr and Ba can not replace Ca, but their effects correspond to those of excessive Ca. Li is not toxic, but causes some osmotic slowing; NH_4 slows, but increases the irritability and strength. The effects of lithium etc. on turtle heart-strips were studied by Lingle, 1902.

Radioactive Metals.—Zwaardemaker, 1918, claims, that the potassium in Ringer's fluid may be replaced by any radioactive elements, in equi-radioactive proportions. A. J. Clark, 1920, failed to confirm this generalization.

Arterial Muscle.—Prochnow, 1911, tried the replacement of NaCl by other anions. The tone was raised by $\text{F} > \text{I} > \text{Br}$. Hatcher, 1906, tested the excitability of the kidney vessels to epinephrine and found this preserved twice as long in Locke's fluid minus glucose, as in 0.9 per cent. NaCl. With glucose, the excitability remained eight times as long. The ability to reduce hemoglobin behaved similarly.

Ion Actions on Nerve.—Nerves also lose their irritability in solutions of non-electrolytes, and recover in salts. The cation series is similar to muscle, but the anion series is reversed.

The reaction of motor-nerves to electrolytes has also been shown to be an additive function of the two ions: the anions (alkalies or increase of valency) stimulating the sciatic nerve of the frog, while cations (acids) lower its irritability (A. P. Mathews, 1902). This agrees with the old observation of Galvani (confirmed by Grandis, 1902), that the nerve is stimulated when it is charged by induction with negative electricity, and depressed by a positive charge. Mathews assumes that the stimulation is caused by the precipitation of the (positive) colloids of the nerve by the anions, and *vice versa*. This demands further proof, especially before it is extended to other forms of protoplasm.

Cations may, however, also be stimulant; for instance, $\text{N}(\text{C}_2\text{H}_5)_4$. Cl is very stimulant, whereas NH_4Cl is indifferent (J. Loeb and Ewald, 1916).

Ca and K on the Nervous Centers.—Hooker, 1913, perfused solutions of these chlorides through the *respiratory center* of frogs, and found that increase or omission of K from balanced solutions produces depression; decrease of K causes stimulation. With Ca, increase and omission produce stimulation; diminution depression. The perfused *spinal cord* of frogs gave similar results (Hooker and Reese, 1914). As to the perfusion of the *medullary cardiac centers*, predominance of K stimulated the vagus and inhibited the accelerator; while predominance of Ca stimulated the accelerators (Hooker, 1915). The perfused *central nervous system of mammals* preserves its activity best with a solution of 0.9 per cent. NaCl and 0.05 per cent. CaCl_2 . These can not be replaced by related ions. Even traces of potassium are harmful (P. Gerlach, 1914).

Ion Effects on the Kidneys.—The polyuria and glycosuria which follow the intravenous injection of large quantities of most sodium salts (especially in slightly hypertonic solutions) perhaps also involve ion action; at least (W. H. Fischer and O. H. Brown, 1903) the addition of a small proportion of CaCl_2 stops the *diuresis*, which may then be started again by injecting sodium acetate. Sr or Ba salts prevent the *glycosuria* without affecting the polyuria.

Sollmann (1905) found that calcium also hinders the filtration of urine and impedes the circulation in excised kidneys, while magnesium favors them. These effects may be referred to ion actions on the renal protoplasm. The effects of most other ions which were investigated in this manner are referable to osmotic changes, due to differences of penetrability.

Guthrie, 1910, claims that direct perfusion of the kidney vessels with saline solutions, even for a short period, is followed by hemorrhagic and degenerative changes in the kidneys, leading to uremia and death after a few weeks or months. Simple anemia of equal duration is much less detrimental. Carrel claims that he has not observed these results.

Balanced Salt Ratios.—A solution containing a single electrolyte, no matter what the chemic nature of the latter, is fatal to all forms of life. The toxicity can be greatly lessened by the addition of a second salt. This is called the "antitoxic action" of ions. For perfect functioning, several salts are necessary, in a definite "balanced" ratio (J. Loeb, 1900). Departures from this ratio modify the function of the cell, and larger changes are fatal. The mineral constituents of cells are therefore indis-

pensible to life. The phenomena are probably produced by modifications in the permeability of the cell membrane.

Ions Essential to Life.—The following salt ions are absolutely necessary to plants: K, Mg, PO_4 , CO_3 (Na and Cl are not necessary); Ca to all but the lower fungi and algæ. Mn forms an essential constituent of vegetable oxidizing enzymes. NO_3 and SO_4 act as nutrients.

Animals require Na, Cl, CO_3 , Ca, K, Mg, I, Fe, PO_4 , SO_4 . It is very doubtful whether other elements existing only in traces (such as Fl) are necessary, or merely accidental.

The microchemic investigations of A. B. Macallum (1905) indicate that the electrolytes are localized in certain portions of the cell by surface tension.

Mineral Salts in Nutrition.—McCollum and Davis, 1913, found a definite salt mixture in the food to be essential to the growth of rats. Osborne and Mendel, 1912, also found that rats fed on a diet free from inorganic salts declined continuously in weight, and that a definite mixture of salts must be supplied.

Subsequent work (Mendel and Osborne, 1917) showed that rats require considerable calcium and phosphorus, but may grow on very little of either Mg, Na, K or Cl. However, simultaneous lowering of K and Na checks growth. The salt content of the milk undoubtedly plays an important part in the nutrition of infants. Cows' milk is considerably richer in all the important salts than is human milk, but the difference is probably compensated by the better utilization of the salts of human milk.

Antitoxic Action¹ of Ions.—As far as known, no cell can remain alive unless it contains some electrolytes. If these are reduced below a certain minimum, the cell dies rapidly. But in many cases it dies even more promptly if it is placed in a solution containing but a single electrolyte. This is the toxicity which was described in the preceding paragraphs. It would seem therefore that *several electrolytes, in a certain ratio, are required in order that the cell may perform its functions.* This was confirmed by J. Loeb (1901), who showed that the toxicity of an electrolyte can be very greatly lessened by the addition of another electrolyte, sometimes in very small proportion. (For instance, the addition of $\frac{1}{4,000}$ m. CaCl_2 neutralizes the toxic action of $\frac{5}{8}$ m. NaCl on *Fundulus ova*.) The antagonism is mutual, at least to some extent.

Instructive examples of antagonism are furnished by J. Loeb, 1911. From his observations, Loeb at first concluded that the cations are responsible both for the toxic and antitoxic actions; and that cations of different valency neutralize each other. The extensive experiments of A. P. Mathews (1905) modify these theories: It would appear that cations and anions are both concerned in the toxic and antitoxic actions (although the cations are probably the more important); and that the valency has no direct connection with either the toxic or antitoxic action (Loeb, 1914). The decomposition-tension seems to be of subsidiary importance in the antitoxic action, and it appears to be necessary to invoke several mechanisms for its explanation. The antagonism is evidently a complex phenomenon, involving also the specific ion actions. It may be noticed, for instance, that certain ions (NH_4 and Li) are particularly difficult to neutralize; Ca is especially antitoxic; Mg much less so; Ni scarcely at all. The optimum ratio and the degree of antagonism vary for different classes of cells. Closely related ions sometimes have very different effects, and can not replace each other. Even when the antagonism of two salts is at its best, it is never perfect; it requires the addition of one or more further salts to enable the cell to perform its functions properly. Indeed, *a strictly normal condition is not reached until the cell is placed in a solution, the cations of which are within narrow limits the same qualitatively and quantitatively as those of its normal surroundings.*

Nature of Ion Action.—There are reasons for believing that the ion actions may be exerted only on the surface of the cell, especially by altering the permeability of the envelope (plasma membrane); and that the anti-

¹ The term "antitoxic action," applied to ions, means something very different from the same term when it is used in connection with bacterial poisons.

toxic actions are also exerted mainly on the permeability. The high resistance of cells to the penetration of ions makes any internal effects very improbable. With potassium, *f.i.*, which is highly toxic to muscle cells, it has been shown that it passes neither into nor out of the cells (Urano; Fahr). The same is true of calcium (W. Straub, 1912). The promptness with which the effects can be removed by the addition of a second salt also speaks against absorption. It is very probable that the single-salt solutions disturb the semipermeability of the membrane (J. Loeb, 1905, 1914), thus interfering with the maintenance of the electric potential which determines irritability. The increased permeability would also produce chemic changes by permitting the entrance of foreign ions.

However, the mechanism is not always the same: *f.i.*, Loeb and Wasteneys, 1910, found that the immediate toxicity of NaCl for sea-urchin eggs is due mainly to greatly increased oxidation; and Warburg, 1910, found accordingly that the toxicity is diminished by the addition of NaCN. On the other hand, the toxicity of NaCl for the neuro-muscular mechanism of medusæ is quite different; in these it diminishes oxidation, and cyanide is therefore not antitoxic.

Electrolytes on Diffusion through Living Cells.—J. Loeb, 1916, found that the presence of electrolytes has a markedly favorable effect on diffusion from or into *Fundulus* ova. Presumably this holds also for other cells. Excess of electrolytes, however, again hinders diffusion. In this way, the penetration, and therefore the effects, of a salt may be either aided or hindered by the presence of a second salt.

Mechanism of Antitoxic "Action."—G. N. Stewart, 1903, suggested that the antagonism of salts may be explained in some cases by alteration of permeability, preventing osmotic changes or the penetration of harmful ions. This has been confirmed by J. Loeb, 1905, 1911, 1912 and 1914. It is probable that K "loosens" the plasma membrane and thus abolishes excitability; and that Ca counteracts this effect. The reasons for the necessity of Na and Mg have not been explained.

The whole phenomenon is rather analogous to the behavior of soaps (Clowes, 1916). Osterhout, 1911 to 1918, arrives at similar conclusions. He finds that all substances (non-electrolytes as well as electrolytes) that affect permeability belong to one of two classes, which antagonize each other:

- (1) NaCl type, increasing permeability from the start to death;
- (2) CaCl₂ type (including also Sr, Mg and H, as chlorides), decreasing the permeability to a certain concentration; beyond this acting like NaCl.

Growth of cells occurs only in solutions that preserve the normal permeability. All deleterious conditions alter the normal permeability; and cells of abnormal permeability have a lowered vitality.

Other factors may conceivably coöperate, such as the electric and chemic changes, decrease of dissociation (as in the effect of citrates on Ca; Sabbatani, 1901). Finally, the antagonism may be functional, for it has been noticed that calcium also antagonizes some poisons which are not electrolytes (veratrine, Ringer, 1884; physostigmine, S. A. Matthews and O. H. Brown, 1904; cascara, MacCallum, 1904), and to which it is opposed in its functional effects. Similarly, magnesium is mutually antagonistic with physostigmine (Meltzer).

Magnesium and Calcium Antagonism.—This presents several special features. Increase of either Ca or Mg ions depresses muscle and nervous structures. Nevertheless, the effects of the Mg may be removed by addition of Ca. Ca also antagonizes the inhibitory effects of K, as well as the stimulant effects of Na (Meltzer and Auer, 1908). Strontium does not take the place of Ca in these reactions.

Even more complex relations have been discovered (Joseph and Meltzer, 1910): in frogs, injection of Mg into the lymph sac produces a curare action, paralyzing the muscle-nerve endings, but not the muscle. The excitability is restored by Ca. Perfusion of Mg paralyzes the muscle as well as the endings. Ca has no restorative effect Na restores only the muscle; Na + Ca restores also the endings.

Gaubert, 1910, asserts that the velocity of the diffusion of Ca ions through colloids (for instance milk) is increased by the presence of Mg salts; whereas the diffusion of Mg ions is retarded by Ca salts. On the other hand, the diffusion of glucose through vegetable cells is favored by Ca and retarded by Mg.

"Physiologic" or "Normal" Saline Solutions (Artificial Serums).—

The deleterious effects of single-salt solutions have led to the introduction of solutions better adjusted to the physiologic requirements. These balanced solutions are necessary when experimenting on excised tissues. They are less important for injections into living animals, in which even single-salt solutions are rapidly adjusted by exchange with the tissues.

These solutions have been devised partly empirically, partly by imitating the salts of the blood serum or sea water. Different tissues may require modifications to secure the optimal effects. The following are the most important:

Isotonic NaCl Solutions.—Nasse, 1869, determined experimentally that 0.6 per cent. is the best concentration for preserving the irritability of frogs' tissues. Later, it was shown that this solution was not indifferent: Kronecker and Stirling observed stoppage of the heart; Ringer, twitching of muscles; Locke, contractures and increased irritability. Carslaw and Locke, curare action, etc. These effects can be overcome by balancing the solution with other salts. However, the solution is practically isotonic with frog's blood, and therefore obviates osmotic changes. On the other hand, it is hypotonic to mammalian blood, which requires about 0.9 per cent. NaCl. Solutions of 0.8 to 0.9 per cent. are therefore generally preferred for mammals. The concentration of the U.S.P. is 0.85 per cent. Abel, however, found in vividiffusion that a lower concentration, about 0.6 per cent. prevented edema more effectively.

Balanced Solutions.—The ideal solution for maintaining the functions of excised tissues would presumably reproduce the ion-ratio of blood-plasma; but this cannot be deduced accurately from the serum-ash, since the degree of ionization in the plasma is problematical, particularly as regards calcium. The formulas in actual use represent modifications of the ash-ratio that have been found practically useful. They embody the following features (the number referring to the anhydrous constituents):

NaCl, 0.6 to 0.7 per cent. for frogs, 0.6 to 0.92 for mammals. The lower concentrations are more stimulant; this means better functionation, but shorter survival of the excised tissue. The same contrast between functionation and duration of survival applies to the other ingredients.

KCl, 0.01 to 0.04 per cent. The lower the concentration, the higher the rhythmicity.

CaCl₂, 0.01 to 0.26 per cent. of the anhydrous salt. The concentration is adjusted to balance the potassium. "Crystals" of calcium chloride contain varying proportions of water, so that their molecular formula should be stated.

Magnesium (0.01 per cent.) is added to a few solutions, especially those intended for excised intestines. It depresses the rhythmicity and so prolongs survival.

Buffer Alkali.—This is secured by sodium bicarbonate, 0.003 to 0.15 per cent.; sometimes with the addition of the sodium phosphates.

Dextrose, 0.1 to 0.15 per cent. This is added to the more active muscles as a nutrient.

Aeration.—This assists both functionation and survival.

The table gives the actual composition of the more commonly used solutions. The Howell solution may be recommended for frogs and turtles; the Locke solution for mammals.

TABLE OF COMMONLY USED BALANCED SOLUTIONS
Percentages

Author	Adapted to	NaCl	KCl	CaCl ₂ (anhydrous)	NaHCO ₃	Other ingredients
Ringer.....	Frogs	0.6	0.0075	0.01	0.01	Dextrose, 0.1 { MgCl ₂ , 0.01 NaH ₂ PO ₄ , 0.005 Glucose, 0.1
Howell.....	Frogs	0.7	0.03	0.026	0.003	
Clark.....	Frogs	0.7	0.014	0.012 (dried)	0.02	
Locke.....	Mammals	0.92	0.042	0.018	0.015	
Tyrode.....	Mammals	0.8	0.02	0.01	0.1	

NOTE 1.—In making solutions containing NaHCO₃, this must be completely dissolved before the CaCl₂ is added.

NOTE 2.—Other solutions are described in "Digests of Comments on Pharmacopoeia," 1911, p. 611.

Locke's Solution.—This is intended to be used with a stream of oxygen. It was originally devised for the mammalian heart; but it also maintains the vitality of arteries (Hatcher, 1906), and of nervous and other tissues (Hedon and Fleig, 1905).

Herlitzka, 1910, found the addition of *urea* and glycerin to Locke's solution essential for the excitability of the nervous system of frogs. Presumably they influence the permeability of the lipoids. Bombiani, 1913, finds that the favorable effect of urea on the selachian heart is not shared by related substances, and therefore considers it chemic. It dilates the perfused vessels of the frog (Hooker, 1911).

Cations in Human Serum.—A. B. Macallum, 1926, obtained the following percentages, which for convenience are expressed as the chlorides:

	Na	K	Ca	Mg
Cations	0.30 to 0.31	0.020 to 0.022	0.008 to 0.011	0.0018 to 0.0034
Chlorides.....	0.76 to 0.80	0.038 to 0.042	0.022 to 0.030	0.007 to 0.014

Sea Water.—This contains the important ions in about the same ratio as the artificial solution; *e.g.*, for 100 molecules NaCl there are the following molecules of other salts:

	KCl	MgCl ₂	MgSO ₄	CaCl ₂
Sea water.....	2.2	7.8	3.8	2.3
Ringer-Locke solutions.....	17-2.4	...	...	1.1-1.6

A. B. Macallum, 1910, suggested the interesting theory that the composition of the blood is a survival of the evolutionary adaptation of animals to their original marine environment.

The composition of sea water is somewhat different in different oceans. In the English channel 1,000 parts by weight contain:

NaCl.....	27.0	MgCl ₂	3.7	CaSO ₄	1.4
KCl.....	0.75	MgBr ₂	0.027	CaCO ₃	0.03
		MgSO ₄	2.3	Iodides, etc.....	traces.

American analyses are furnished by Wheeler, Jour. Amer. Chem. Soc., 32, 646, 1910.

The freezing-point of sea water is: -2.29°C . at Naples (Bottazzi, 1897); -1.90° at Pacific Grove, California; and -1.82° at Wood's Hole, Massachusetts (Garrey, 1905).

Osmotic Exchanges in the Body.—Osmosis tends to operate within as without the body, so as to bring all the fluids into osmotic equilibrium, and if possible, to establish an identical composition. If a foreign solution is introduced—*f.i.*, into the intestines, or peritoneal cavity, or blood—the osmotic forces very rapidly bring its total molecular concentration to that which is normal for the tissues. This exchange could be effected either by the passage of water; or by the passage of the foreign salts out of the solution into the tissues; or by the passage of the normal salts from the tissues into the solution. In fact, all three processes generally participate, their

share varying according to the special permeability of the tissues. In general, the exchange occurs mainly in the direction which will favor the normal physiologic functions; *i.e.*, in the direction of *absorption*.

When the molecular concentration of the blood has been reached, there remains less scope for osmotic exchanges, and the further absorption must occur by other forces (filtration, imbibition, etc.), generally much more slowly. The rôle of osmosis in absorption is therefore important, but limited. Its active share in the *secretion* of the body-fluids, *f.i.*, the urine or lymph is normally small; it is important mainly by setting limits to the real secretory forces.

The Rôle of Osmosis in the Absorption of Solutions from Serous Cavities and Lymph Spaces.—This absorption is almost entirely physical, for it occurs quite well in dead animals, although it is naturally more rapid when the circulation is intact, because the absorbed products are then more rapidly removed. Osmosis plays an important part in the absorption, especially if the solutions are anisotonic. If a hypotonic solution is introduced, osmosis causes the rapid absorption of water; with hypertonic solutions, the volume of the fluid will at first increase, until it has become equimolecular with the plasma. At this time, however, the fluid is really hypotonic to the non-diffusible constituents of the cells and blood, so that it would be eventually absorbed, by the operation of osmosis alone. The osmotic absorption, for instance from the peritoneum, is quickened if the body fluids are rendered hyperosmotic, as by nephrectomy, or ligation of the renal vessels, or indeed by operations generally, or by epinephrine. Etherization alone does not affect the osmotic absorption. Caffeine lessens it in normal animals, but increases it after nephrectomy (Fleisher and L. Loeb, 1910).

Ordinarily, however, the osmotic absorption is very slow after the solution has become isomolecular; and other factors intervene to hasten the process. Of these filtration and imbibition are the most important. The *filtration pressure* is furnished especially by muscular, respiratory, and peristaltic movement. The intraperitoneal pressure amounts to 2 to 25 mm. of water (H. Emerson, 1907). It may be increased by massage.

Imbibition in Absorption.—The term "*imbibition*" is applied to the familiar phenomenon of the swelling of pieces of glue, gelatin, agar, tissues, and other colloid gels, when these are placed into solutions (F. Hofmeister, 1890 and 1891). This process is quiet distinct from osmosis, although both may take place side by side. Imbibition is probably analogous to adsorption.

Hamburger has shown that when a solution is placed in a gelatin cylinder, and this is immersed in a circulating current of the same solution, the stagnant fluid in the cylinder passes gradually through the gelatin into the circulating fluid. The phenomenon is obviously analogous to the absorption of isotonic solutions from serous cavities, and helps to explain the latter. Hamburger considers this process an imbibition effect.

Absorption of Effusions or Serum from Serous Cavities.—In this, the cooperation of osmosis is almost excluded, for these contain non-diffusible protein constituents, as well as the tissues. However, the proteins of these fluids tend to break down constantly into more diffusible molecules (as shown by the fact that exudates generally depress the freezing-point somewhat more than does the blood). Osmosis therefore plays a part, but this must be relatively small. The existence of proteins also limits the operation of imbibition, for proteins are not imbibed by colloids. This leaves filtration as the main factor in the absorption of protein-containing fluids. The absorption of these liquids is consequently a much slower process than that of salt solutions.

Absorption from the Alimentary Canal.—This is probably even more dependent upon forces other than the osmosis than is absorption from serous cavities.

Filtration aided by the intrainestinal pressure is an important aid (Hamburger). There are also other processes, ill-understood: Thus if an excised and surviving intestine is immersed in a solution, a passage of fluid takes place from the lumen to the surrounding fluid, even when the two fluids are identical (Cohnheim, 1899). Hamburger, 1906, attributes this to imbibition, and finds that even the dead intestine is differently permeable in the two directions. Sodium sulphate, for instance, passes much more readily from the lumen to the exterior than in the reverse direction. He has also demonstrated a "polarity" of absorption in artificial membranes, in which the two surfaces

have a different composition. The diffusion through excised intestine is markedly influenced by salicylates and some other substances (Hanzlik, 1912). The absorption of ions from the excised intestine has been investigated by Benedicenti, 1906, and by Hoeber, 1903. The latter found the anion series, $\text{Cl} > \text{Br} > \text{I} > \text{NO}_3 > \text{SO}_4$. Lipolytic substances (short of the narcotic concentration) are absorbed more readily than non-lipoid solutes. From analogy with dyes, Hoeber assumes that the lipolytic are absorbed through the cells, and that the absorption of non-lipoids is confined to the intercellular substance.

Brodie and Vogt, 1910, showed that the oxygen-consumption of the intestines is increased during the absorption of normal saline, water and peptone solutions; indicating that the cells also play an active part in the process.

Absorption Curve.—Hanzlik and Sollmann (1909 to 1913) have found that the absorption of phenol, alcohol, iodide and presumably other substances from intestinal loops follows a uniform curve, the rate being very rapid for the first ten to thirty minutes, and then very much slowed. Various factors seem to be concerned in this phenomenon. The rate of absorption, under these conditions, is not greatly influenced by the concentration of the solution or by the extent of the intestinal surface.

Importance of Osmotic Exchanges in the Intestine.—Osmosis has at least a modifying influence on intestinal absorption. The time during which the food remains in the alimentary canal is ample to effect osmotic exchanges between the intestinal contents and the blood. An isotonic condition becomes established quite promptly (but is not completed in the stomach; E. Otto, 1905).

This equalization, with the absorbable salts, is mainly in the direction to facilitate absorption: hypertonic solutions being rendered isotonic rather by the absorption of salt than by the pouring out of fluid; while hypotonic solutions are rendered isotonic by the absorption of their water. (In other situations than the alimentary canal, the equalization takes place more uniformly in both directions.)

These changes result in corresponding alterations in the composition of the cells of the gastric and intestinal mucosa, which are therefore also subjected to osmotic salt action. This causes irritation. When the irritation is mild, it increases secretion, absorption, and peristalsis. More severe grades of irritation, however, produce emesis and inflammation.

Salts which are not absorbable by the intestine (*cathartic salts*) are reduced to isotonic conditions by the absorption of fluid. This fluid is retained in the intestine with the salts, increasing the bulk and fluidity of the intestinal contents, and serving as a mechanical stimulus to peristalsis. This explains largely the cathartic effects of these salts.

Absorption from Colon.—Goldschmidt et al., 1919, found that diffusion occurs in both directions. With fluids below a certain threshold (about 0.16 per cent. NaCl, with $\Delta 0.134$) chlorides pass from the blood into the colon. With hypertonic solutions (above $\Delta 0.786 = \text{NaCl } 1.2$ per cent.) fluid at first goes into the colon. Finally, the Cl and the freezing point comes into equilibrium with the blood.

Molecular Concentration of Gastric Juice.—Carlson, 1915, found the freezing-point of normal human "appetite juice" as -0.55 to -0.62 ; that of hunger juice as -0.47 to -0.52 . Similar results were obtained with dogs.

Osmotic Effects on the Blood and Lymph.—Fate of Salt Solutions within the Body.—In whatever concentration and by whatever channels salts are introduced into the body, they tend to increase the quantity of blood, or rather of plasma; and to render it more watery and less viscid; in other words, to produce *hydremic plethora*. If isotonic or hypotonic solutions are introduced, they dilute the blood by their own fluid; if hypertonic solutions are injected, the blood draws fluid from the tissues until it has resumed its original concentration. The result will be

hydremia in either case. If *anisotonic solutions* are introduced, they temporarily alter the *molecular concentration* of the plasma.

However, *the blood possesses a remarkable power of resuming its normal condition, its total molecular concentration, ratio of individual constituents, ratio of corpuscles to plasma, and total quantity (in about this order)*. This process of restitution takes place very rapidly; it is far advanced before a quick intravenous injection can be completed; the molecular concentration returns to very near normal within ten minutes; the quantity of blood and individual constituents are restored somewhat more slowly; but they are almost normal in half an hour; after two hours, the blood presents only very slight abnormalities, even when very large injections have been made (Magnus, 1901; Sollmann, 1901).

The *total molecular concentration* is the first factor to be restored; this is accomplished mainly by the passage of the dissolved molecules: If a *hypertonic solution* is injected, the injected molecules leave the blood very rapidly. Other molecules leave more slowly, and water is taken up into the blood. As soon as the normal molecular concentration is restored, the phenomena become identical with those following the injection of isotonic solutions.

If a *hypotonic solution* is injected, the principal phenomenon at first is the passage of molecules into the blood, the injected molecules leaving the plasma very slowly. The water also leaves only gradually, *i.e.*, mostly after the normal concentration has been reached; and then by the same process as with isotonic solutions.

If an *isotonic solution* of a single salt (sodium chloride or sulphate) is injected, both the fluid and the injected molecules leave the circulation; the molecules somewhat more rapidly. At the same time, other molecules enter the circulation. This process continues (for about two hours), until the original quantity of blood and its original composition have been practically restored.

Mechanism of Restoration.—The restitution of the blood consists in a process of exchange with the remainder of the body. The tissues (especially the striated muscle cells, Engels, 1904; Jappelli, 1906; and the liver, Sherrington and Copeman, 1893; Uschinsky, 1905) play the most important rôle in the rapid exchange which we have so far described.

With intravenous injections of hypertonic solutions, the *muscles* supply most of the water, and take up a large part of the salt; although their salt percentage does not increase as much as that of some other tissues (Wahlgren, 1909). The quantity of material of which tissues can dispose, without visible change, is astonishingly great. In rabbits, the tissues may take up Ringer's solution amounting to four times the quantity of the blood (Bogert, Underhill and Mendel, 1916). However, very large injections give rise to ascites, effusions, etc.

In addition to the tissues, *the lymph and urine flow and all the secretions of the body are also increased*; and to them falls the task of finally removing the injected substances from the tissues out of the body. The tissues act the part of elastic reservoirs, as it were, quickly relieving the blood of the disturbing element, again to give up the abnormal substances as rapidly as they can be removed by the more slowly acting excretory mechanisms.

Physical processes, notably osmosis and filtration, play a very important part in the exchange with the tissues, and in the increased lymph flow. Indeed, it is scarcely necessary to invoke any vital mechanism for their explanation.

Conditions of Delaying the Restoration of the Blood-volume.—Bogert, Underhill and Mendel, 1916, confirm that in normal dogs and rabbits, the blood-volume returns to normal within half an hour after the intravenous injection of warm Ringer's fluid, equivalent to the total blood-volume. This is delayed by morphine, and by nephritis (uranium, chromate or tartrate), but not by ligation of the kidney vessels. The restoration is not affected by the addition of 0.4 per cent. sodium carbonate, either in normal

or in nephritic animals. Gelatin solutions (2 per cent.) may leave the blood as rapidly as plain saline, although more commonly from 11 to 27 per cent. are still present in the blood after half an hour. The gelatin leaves the blood in the same ratio as the fluid (Boycott, 1914) and is partly excreted in the urine.

Salt-actions on the Urine.—The hydremic plethora results in an increased elimination of urine. The excretion of water and the injected substance is especially increased. The other urinary constituents are generally decreased, as concerns their percentage; although their absolute quantity may be increased. (The saline diuresis would therefore result in a “flushing of the body.”)

The diuretic action of saline solutions is largely physical, and can be reproduced point for point in dead kidneys (Sollmann, 1903 to 1905) (except the effect on the composition of the urine). It is explained by the hydremic plethora; the increased glomerular pressure, and the lessened viscosity of the blood. This is aided, in the case of hypertonic solutions, by the dehydration and shrinkage of the renal cells. All these processes favor glomerular filtration.

The urine flow and kidney volume of excised and re-implanted kidneys react the same as normal kidneys to urea, hypertonic salt solutions, and to the methyl-xanthines (Quinby, 1917).

The physical element in the diuresis is especially conspicuous in the early periods of the diuresis, when the changes in the blood are relatively large.

It has been observed, however, that the urinary changes may persist, in a slight degree, after the blood has apparently returned to normal. This suggests the coöperation of a vital stimulation, produced by the (very slightly) altered composition of the blood.

The concentration of the urine varies with the concentration of the solution which has been introduced: it may fall as low as $\Delta 0.12$, or rise as high as $\Delta 3.0^{\circ}\text{C}$. On the whole, the composition of the urine approaches the more closely to that of the blood, the faster the diuresis.

The *degree* of diuresis (the total quantity excreted) depends largely on the quantity of solution (both of the dissolved substance and of the water) which has been introduced; but the *rate* of diuresis (the quantity excreted within a short time after injection) depends largely on the concentration of the solution, if this is given intravenously (water, which is so strongly diuretic when taken by mouth, may diminish the urine when injected by a vein).

Fischer and Sykes, 1913, claim that the diuretic effect of intravenous saline injections is proportional to their dehydrating action on colloids (fibrin). This would lessen the affinity of the tissues for water, and would therefore place a larger quantity of fluid at the disposal of the kidneys. It may be an additional factor in saline diuresis, but requires further confirmation.

In the *ordinary secretion of urine*, osmosis *appears* to be an obstacle, rather than an aid; for the molecular concentration of urine differs quite widely from that of the blood (Δ *urine*, ordinarily, 0.9 to 2.1; *extremes*, 0.12 to 3.0; Δ *blood*, 0.55 to 0.60); and the kidney has to perform a very considerable labor to overcome the difference in osmotic pressure. However, this work seems to be in no way injurious to normal kidneys.

Work Performed in Urine-formation.—This cannot be calculated directly from the total molecular concentration, since the departure of every constituent from its concentration in the blood requires work. Barcroft and his co-workers have investigated the problem qualitatively by the increase of oxygen consumption which accompanies work. They found

that the diuresis following the injection of isotonic solutions does not involve work; but that the oxygen consumption increases when hypertonic urines are secreted in response to sulphate injection. Caffeine diuresis also involved work.

Cushny's Theory of Urine Formation.—Explanations of the mechanism of urine formation are still largely hypothetical. That advocated by Cushny is especially satisfactory for saline diuresis. It is essentially the filtration and reabsorption theory of Ludwig, but supplements the understood physical forces by unexplained forms of energy.

Glomerular Filtration.—The theory assumes that all the urinary constituents are separated from the plasma by filtration through the glomerular capsule. This could be accomplished by the blood-pressure, if the composition of the glomerular filtrate is that of protein-free plasma, *i.e.*, essentially a "Locke's Fluid." (This, however, has not been proven directly.)

The rate of filtration would be modified by the renal circulation; by the viscosity of the blood; and presumably by the permeability of the glomerular cells. However, the kidney would not expend any energy or work in the process.

Tubular Absorption.—The theory assumes that the glomerular fluid on passing through the tubules, is changed into urine by the absorption of certain of its constituents by the epithelium. This alters the total and the partial molecular concentration, requiring the expenditure of energy by the epithelial cells, and is therefore an active process.

Concentration of Constituents.—The substances excreted in the urine may be arranged into two classes:

Class I.—Urea, ammonium, phosphate and sulphate ions, and most foreign substances have ordinarily a much higher concentration in the urine than in the plasma.

Uric acid and potassium are also more concentrated in the urine, but the difference is not as great.

Substances of Class I tend to pass into the urine whenever they are present in any quantity in the plasma. They are "*non-threshold substances*."

Class II.—Na and Cl occur in the urine in concentrations that ordinarily are not much greater than in the plasma. Dextrose and colloids fail to pass into the urine.

Substances of Class II are excreted only when their concentration in the plasma surpasses a certain level. They are "*threshold substances*."

Selective Absorption.—Cushny's theory assumes that the solutes of Class I are not reabsorbable by the tubular epithelium and those of Class II are reabsorbable. Those of Class I are therefore concentrated in proportion to the amount of fluid that is reabsorbed from the glomerular filtrate (estimated to vary between 50 to 99 per cent.).

Class II (the threshold substances) are not reabsorbed indiscriminately, but in about the proportion in which they exist in the *normal* plasma. The *absorbed fluid* is therefore assumed to be slightly alkaline, and to contain sugar, amino-acids and other similar food substances, chloride and Na.

When the percentage of any of these in the plasma is abnormally high (for instance, as in diabetes), the glomerular filtrate would contain a correspondingly high percentage. Since the reabsorption, however, occurs in the normal percentage, a part of the solute will remain unabsorbed and appear in the urine.

Variations of Concentrations in Diuresis.—During diuresis there is less time for tubular reabsorption. The composition of the urine therefore tends to approach that of the plasma. The elimination of all the constituents is increased in absolute amount per unit of time. The percentage of non-threshold substances (Class I) is invariably diminished; that of the threshold substances is also often diminished, but may actually rise—according to whether they were previously above or below the concentration of the blood.

Lymph Formation.—The lymph comes from the tissue spaces; and whatever alters tissue fluid must alter the lymph.

Lymph formation would be increased by osmotic pressure, whether as the result of tissue-activity, or of hypertonic injections.

Filtration probably plays a part in the increased lymph-flow of hydremic plethora, although filtration does not seem to be an adequate explanation of *normal* lymph formation (Carlson and pupils, 1908; Boehm and Asher, 1909).

Viscosity of Lymph.—Normally, this is not greatly diminished, even by large intravenous saline injections. After hemorrhage, however, saline injections diminish the lymph viscosity very considerably: the lymph evidently returning to the plasma the fluid that has been filtered into the tissues (Burton-Opitz and Nemser, 1917).

Asher, 1913, points out that filtration can not be an important factor in the secretion of *saliva, sweat* and *bile*, since the secretion pressure exceeds the blood pressure. The physical-chemical condition of salivary secretion have been investigated by Japelli, 1906; those of tears and collyria by Cerrano, 1909.

Edema.—Salt action, osmosis, and colloid imbibition are important factors in edema, *i.e.*, the excessive accumulation and retention of fluid within and between the cells.

The edema fluid is analogous to lymph, and may therefore be increased by the same agencies which increase lymph flow; hydremic plethora; lymphagogues of the "second class" (peptones, etc.); increased blood pressure; venous obstruction; injury to the vascular endothelium, etc. However, for the retention of fluid it is further necessary that the drainage of the lymph be obstructed; or that there be an increased affinity of the tissues (or colloids) for fluid. In fact, the coöperation of several of these factors is generally necessary for the production of noticeable edemas. Experimental edemas, resembling the clinical, require the simultaneous presence of nephritis, hydremic plethora and vascular injury (Pearce, 1909). Extensive intravenous injection of salt solutions produce ascites and edema of the internal organs, but not of the normal skin or subcutaneous tissue. To effect these, the skin must be irritated (Cohnheim and Lichtheim, 1877); or the vessels injured, as by arsenic (Magnus) or uranium.

Normal Variations of the Water Content of Tissues. These depend mainly on age and nutrition. The average water of human tissues decreases from 94 per cent. in the three-month fetus, to 69 to 66 per cent. at birth, and 58 per cent. in adults. It is higher in emaciation, varying inversely to the fat (Albu and Neuberg, 1906).

Salts and Edema.—Effusions of a molecular concentration inferior to that of the blood would be promptly absorbed; or rather, they could not be formed. Since they, like other body fluids, owe their concentration mainly to their content of sodium chloride it is evident that a deficiency of this salt in the body will tend to lessen the production of effusions, and hasten their absorption. This is the rational basis of *the treatment of nephritic edemas by withholding salt from the food* (advocated by Wical and Javal, 1903). The treatment is not always entirely successful (Blooker, 1909), for the salt may not be the cause of the edemas, but only a factor in their production. However, actual salt retention occurs in some types of nephritis (especially chronic interstitial) and other conditions (Magnus Levy, 1910), owing to diminished permeability of the kidney to salts. These would be most favorably affected by salt-withdrawal. In other cases, the effusions are removed more effectively by administering salts, through their diuretic action. Actual trial alone can decide which form of treatment is needed in a given patient. The salt-poor diets are discussed under "Sodium Chloride."

Colloids and Edema.—Martin Fischer (1908 to 1915) believes that the circulation has little if any direct connection with edema; but that this is due practically entirely to changes in the affinity of the tissue colloids for water and salts, strictly analogous to the swelling of gelatin or fibrin.

This is modified to a varying degree by electrolytes; not by non-electrolytes. It is especially increased by acids; and the production or accumulation of acid, including CO₂ in inflammation, venous stasis, etc., would therefore be the principal cause of edema (and the concomitant salt retention), and incidentally of nephritis. Fischer is also inclined to deny that osmosis has any part in these or other vital phenomena; and to refer to imbibition all the phenomena which are generally classed as osmotic.

The influence of acids and electrolytes on imbibition can not be doubted. It is therefore very probable that imbibition plays an important rôle along with other factors; but serious objections have been raised to some of Fischer's deductions. It would require much stronger evidence to place such sweeping statements on a firm foundation.

Fischer's theory fails to explain the close resemblance of some of the vital and ordinary osmotic phenomena; *f.i.*, the equivalent effects of isotonic solutions; the semipermeability of blood cells and striped muscles, etc.; the fact that these phenomena are not modified seriously by the addition of gelatin or serum (Beutner, 1913), etc. The

absorption of water by the skin of the frog is shown by Maxwell, 1913, to be mainly osmotic. Beutner, 1913, and Moore, 1915, point out the differences between osmotic and colloid swelling of muscle. J. Loeb, 1913, believes that the osmotic processes predominate so greatly during life that imbibition does not become important until the semipermeability of the cell has been destroyed by death.

The increase of free acid, on which Fischer bases his theory of edema and nephritis, is only hypothetical. Henderson and pupils, 1914, emphasize that tendency toward acidity in the organism is not usually accompanied by edema; while the acidity of the urine has no relation to albuminuria or nephritis. There is no direct evidence that the free acidity is ever increased to an effective degree during life (Goodridge and Gies, 1911). Koppel, 1913, and L. J. Henderson, Palmer and Newburgh, 1914, point out that the range of variation of H-ion-concentration, even in the urine, does not affect colloid imbibition. Even if it were granted that this may occur in some cases, there is no evidence that it is a universal or important phenomena; nor would the results of such acidity be uniform; for Pincussohn, 1912, found that acids, while they increase the imbibition of gelatin and muscle, lessen that of kidneys, liver, spleen and lung. Hirschfelder, 1916, finds that the conjunctiva in mustard edema is not acid; nor does the excised eyelid or conjunctiva swell in acid Ringer's fluid. Incidentally, there are agencies other than acids which influence imbibition, *f.z.*, proteoses (Tracy and Gies, 1912). The effects of inflammation may also be explainable on an entirely different basis. Oswald, 1911, found that inflamed cells become permeable to colloids (proteins), especially in acute inflammation. He explains this by increased "quellung" of the cell membrane.

The practical application of Fischer's theories to glaucoma and nephritis, has given results so discordant that they are not supports of the theory.

CATHARTIC SALTS

A number of soluble salts are not absorbed readily from the alimentary canal. These therefore do not produce any marked direct systemic actions, unless they are injected into the circulation. When they are given by the mouth, their direct action is confined to the intestine; they cause *catharsis* with soft or fluid, painless stools. The salts of magnesium, and the sulphates, phosphates, tartrates and citrates of sodium or potassium are chiefly used as saline cathartics. Through the catharsis they may produce, indirectly, a drying of the tissues and a slight increase of gaseous metabolism. The cathartic action is mainly the result of the retention of fluid in the intestine by the osmotic action of the unabsorbed salt, for this must retain sufficient fluid to preserve itself isotonic with the blood (Wallace and Cushny, 1898). The distention by this fluid provokes the intestines to contraction, and the contents are thus rapidly propelled (Trendelenburg, 1917). The passage through the intestines is therefore hastened, although the salts as such do not directly increase peristalsis (Legros, 1869; Hay, 1883; Padtberg, 1909). The contraction waves so set up may travel rapidly over the intestines, and secure evacuation before the cathartic salt itself has reached the rectum (Hurst; Best; Herz et al., 1908). Hypotonic solutions also cause direct stimulation of the muscle; hypertonic solutions produce short stimulation followed by depression; but the stimulation may expel the solution before the depression sets in (Baur, 1925; v. Oettingen and Sollmann, 1926). In any case, however, the solutions would soon become isotonic. It is possible that cathartics may also more directly stimulate the sensory nerves in the rectum, and possibly other structures in the intestines; but of this there is as yet no evidence. On the contrary, magnesium at least is directly depressant to the intestinal muscle. Ordinarily this depression is more than offset by the distensive stimulus; but it may be important for overcoming intestinal spasm (Sollmann and Rademaekers, 1925).

Studies with the X-ray method (Padtberg, 1909) show that MgSO_4 delays the emptying of the stomach, but hastens the passage through the intestines, so that the solution arrives in the colon in one and one-half to two hours. The colon antiperistalsis is not inhibited; but it does not lead to the concentration of the contents, because of the osmotic retention. The fecal matters in the colon are therefore rendered more fluid, and this hastens their expulsion. The saline catharsis is not checked by morphine, unless this is timed so as to secure gastric retention of the salts.

In man, Herz, Cook and Schlesinger, 1908, found that drachm doses of epsom salt may cause watery evacuations within an hour. Their fluid is greater than could be explained by osmosis. Moreover, the stools of the following morning, which contain distinctly more of the salt, had a normal solid consistency.

The salt itself, however, may travel rapidly through the intestines; for instance 5.7 Gm. of magnesium sulphate was recovered from a stool that was passed three hours after the administration of 10 Gm. of magnesium sulphate in 400 c.c. of water (Ury).

Osmotic Factor in Cathartic Action.—Poiseuille, 1828, invoked osmosis to explain the cathartic effect, not only of the salts, but also of the vegetable purgatives. This was mainly hypothetical; and Aubert, 1851, showed that there is no direct ratio between the osmotic and purgative strength of the different salts (since the absorbability was not taken into account). Buchheim, 1854, claimed that the increased water in saline catharsis comes from the alimentary canal, and not from the blood. Colin, 1854, showed that concentrated solutions of cathartic salts increase in volume when placed in an intestinal loop. It was clear therefore that the salts could either attract or hold water in the intestines. Wallace and Cushny, 1898, demonstrated conclusively that saline solutions placed in the intestines become and remain isotonic with the blood; and that therefore the amount of fluid held in the intestines depends strictly on the amount of salt which remains unabsorbed.

Interchange of Ions in Colon.—The colon behaves toward sulphate ions as a fairly typical semipermeable membrane; *i.e.*, it is practically impermeable to sulphate (and also to magnesium) ions, but permits free passage to water till isotonicity is reached. It is freely permeable to chloride ions. Calcium lactate at first accelerates, then retards the absorption of chloride ions (S. Goldschmidt et al, 1919).

Difficultly Absorbable Ions.—The most important cathartic ions are: of the cations, Mg; of the inorganic anions, SO_4 and PO_4 ; of the organic, tartrates, citrates, lactates and malates. Certain sugars, particularly milk-sugar, and mannite, also act as cathartics in the same way. Many other solutes that are difficultly absorbable are not available as cathartics; *f.i.*, Ca and Sr are largely converted into insoluble carbonates, and so become osmotically inactive; oxalates and fluorides are toxic; the metallic ions precipitate proteins and act as astringents.

Easily Absorbable Ions.—Of the *cations*, ammonium is the most readily absorbed; then come the alkali metals. The earthy metals are not easily absorbable. Of the *anions*, the chlorides, bromides, iodides, nitrates and acetates are rapidly absorbed.

Cause of Different Absorbability.—This has not been satisfactorily explained. There are striking analogies between the absorption of ions by the intestine and by muscle, and the solubility of their soaps and calcium salts, but it is not yet clear whether this is a mere coincidence or has a deeper meaning.

Conditions of Absorption.—None of the cathartic salts are altogether unabsorbable; their absorption is favored and their cathartic action correspondingly lessened, if they remain for a long time in the alimentary canal. This is apt to occur if the tissues are very dry. Matthew Hay, 1883, found the cathartic action of salts less extensive if the intake of fluid is restricted; and that the activity is not increased by the injection of water into the blood. The rate of absorption depends also on the *concentration of the salt*: Concentrated solutions are generally absorbed more readily than dilute. This is one cause of the somewhat different activity of dilute and strong solutions.

The effect of concentration on absorption has been studied by Merck, 1906; Weise, 1911; and Cobet, 1913. Weise showed that the sulphates become isotonic within half an hour. The sulphate ion is absorbed in the same proportion from Na_2 and MgSO_4 . The percentage of Mg absorbed increases with the dose. The upper and lower intestines do not show essential differences.

Source of the Fluid in the Stools.—If the cathartic salt is administered in hypertonic solution, it must withdraw some fluid from the tissues (unless water is swallowed at practically the same time). The amount of fluid needed for this is not large; *f.i.*, the official (crystalline) magnesium sulphate requires 15 parts of water to render it isotonic. The official full cathartic dose, 15 Gm., would therefore require 225 c.c. of water; and since it is usually given with at least 100 c.c. of water, it could not osmotically draw more than 125 c.c. from the tissues; and since about half the salt is usually absorbed, with a corresponding amount of water, very little fluid would be removed from the tissues by this means. Ordinarily, however, the quickened peristalsis interferes with the reabsorption of other fluids that happen to be present in the intestines, and this may increase the fluid of the feces by considerably more than the amount held by the unabsorbed salt. About three to five liters of fluid are daily excreted into the digestive tract of man, and one or two liters more are introduced with the drink and food. As the normal daily feces contain only about 100 cc. of water, the daily absorption of liquid from the intestines is over four liters; *i.e.*, considerably more than is needed to furnish all the liquid of severe saline catharsis. The latter, therefore, does not directly abstract water from the tissues or effusions; but tends to dry them in the same manner as if the water income were restricted by any other means.

Intravenous and Hypodermic Injection.—It has been claimed by several observers that the cathartic salts stimulate peristalsis even when they are administered parenterally. This has been taken as evidence of direct stimulation of the intestinal muscles. However, these observations seem to have been based on experimental errors; and even if true, they could not explain the ordinary cathartic effect, since this does not involve any marked increase of peristalsis.

Experimental Data on Parenteral Administration.—Catharsis was reported from intravenous, hypodermic or intramuscular injection of sodium or magnesium sulphate by Aubert; Bernard, 1857; Agulhon; and more recently by J. B. MacCallum, 1903 and 1906; and by Bancroft, 1907. Most observers, however, have failed to obtain any increase of peristalsis and catharsis when proper precautions were taken to exclude exposure and asphyxia (Buchheim and Wagner; Donders; Vulpian; Jolezet and Cahours; Rabuteau; Bert; Moreau; Hay; more recently Auer, 1906 and 1908; Meltzer and Auer, 1906; Frankel, 1907; Mendel and Benedict, 1909). Joseph and Meltzer, 1910, and Sollmann and Rademaekers, 1925, found indeed, with a careful technic, that intravenous or intra-muscular injection of magnesium inhibits peristalsis.

Hypodermic Injection is also without result, except when made under the abdominal skin. The success in this case is entirely reflex, for injections of NaCl or ZnSO_4 in this region are also cathartic (Hay).

Excised Intestines.—The phenomena will be described under the respective ions.

Other Theories.—In place of osmosis, a number of other factors have been suggested, such as inflammatory irritation, stimulation of intestinal secretion, and muscular stimulation by osmosis, ion action, or by the withdrawal of calcium. None of these rest on adequate evidence, and they probably play at most a minor part.

Secretion Theory.—This was fathered especially by M. Hay, 1883, who did excellent experimental work on the cathartics. He believed that the salts excite a secretion of

fluid into the intestines, which is partly balanced by absorption. However, his experimental results are explainable more simply on the basis of osmosis.

Headland, 1867, believed that the salts are first absorbed but reëxcreted into the intestines, and that they stimulate secretion during their elimination; but Thiry, 1864, had found no secretion in his fistula. The theory of Carl Schmidt, 1850, that the fluid is a transudate, is without foundation.

Brodie, Cullis and Halliburton, 1910, showed that the oxygen consumption of the intestines is not increased by hypertonic magnesium sulphate, so that its dilution must be a purely physical process.

Relation to Calcium.—Chiari, 1910, suggests that the precipitant effect of most of the cathartic ions for calcium could increase the excitability of the intestine. This may play a part; but at present is only hypothetical.

Relation to Imbibition.—Fisher noted that the cathartic anions, belonging to the right hand side of the lyotropic series, diminish the imbibition of fibrin in dilute acids. This has been confirmed by Hirschfelder, 1916; but he finds that most of these salts diminish the H-ion concentration, thus explaining the effect. Sulphates, however, are not covered by this explanation.

Fate of the Cathartic Salts.—The portion which is not absorbed is of course eliminated promptly by the *feces*. The other salts of the *feces* are also markedly increased; the organic matter only slightly (Hay). The sulphates are in part reduced in the colon to sulphides, which give their characteristic odor to the *feces* (R. Kochmann, 1920).

After absorption, the cathartic ions are eliminated largely by the urine, producing a diuretic action. The urinary excretion is inverse to the purgative effect. With sodium sulphate, one-third to one-half of the excreted salt is in the urine. A considerable portion of the sulphate of magnesium may be retained in the tissues, the excretion extending over several weeks (Hay; Mendel and Benedict, 1909).

Absorption of Other Substances.—Intestinal absorption in general is delayed and diminished by catharsis through sodium or magnesium sulphate. This may be of some importance in the treatment of poisoning (Macht and Finesilver, 1922).

Diuretic Action.—All the cathartic anions are readily excreted by the urine, and therefore act as saline diuretics; rather more effectively than equivalent amounts of sodium chloride. However, because of the abstraction of water by the *feces*, the urine flow is generally decreased in the first twelve hours; it is then increased for about a day (Hay). The diuretic effect is proportional to the quantity of the salt absorbed, and therefore inverse to the catharsis.

Sodium sulphate diuresis increases the gas consumption of the kidney (Bainbridge and Evans, 1914).

Reaction of Urine.— $MgSO_4$ markedly increases the ammonium and acidity of the urine; Na_2SO_4 and MgO decrease the acidity, with subsequent return to the normal reaction (de Jager, 1911).

Concentration of the Blood.—Hay found that this is increased shortly after the administration of concentrated but not of dilute solutions of cathartic salts. The blood count rises from 5,000,000 to 7,000,000 by the abstraction or retention of fluid in the intestines. It returns to normal within four hours, even if no fluid has been taken, since the saline solution is gradually absorbed from the intestines. When diuresis sets in, the blood count again rises to 6,000,000; and this even if the salt has been taken diluted.

Metabolism.—This is not measurably increased by the increased peristalsis of saline cathartics (Benedict, 1914).

Temperature.—Saline cathartics have been used in fevers, for their supposed "cooling" effect. Hay found no reduction of the internal temperature, but believes that the skin may be cooled through splanchnic dilation. This is somewhat doubtful.

Therapeutic Uses.—The cathartic salts are used to empty the intestines in constipation, etc.; and to dry the tissues in edemas. Their intro-

duction is of comparatively recent date (Glauber, about 1658). They are useful and effective as simple cathartics, especially in digestive disturbances, and against occasional constipation; but they do not meet the motor deficiency of chronic constipation as efficiently as the cascara group; they are often rather unpleasant to the patient; they may lose in efficiency on continued use; and they are not very effective in obstinate constipation or mechanical obstruction. As hydragogue cathartic for the removal of edemas, the absence of irritation renders them generally superior to the drastic vegetable cathartics; their diuretic effect is a further aid.

Administration as Laxatives.—For this purpose, the salts should be given in dilute solutions (teaspoon to tumbler; or as the natural mineral waters—Carlsbad, Hunyadi, etc.), since these are less distasteful and act more promptly (one to four hours). The laxative dose of the usual salts is 5 to 10 Gm. (1 to 2 drams). (Larger doses are supposed to accustom the intestines to an abnormal type of peristalsis; Bastedo, 1914.) They are best administered before breakfast, to hasten their passage through the stomach. If this is delayed, they are less efficient and somewhat irritant. For this reason they are less useful with bedridden patients, for with these the passage of food from the stomach to the intestine is a rather slow one. Some exercise is useful after taking salts, and this is one of the reasons why patients receive benefits in watering places which they fail to secure at home.

Administration in Dropsy.—Large doses (15 to 30 Gm., $\frac{1}{2}$ to 1 ounce) should be given in concentrated solution ($\frac{1}{2}$ tumbler), also before breakfast. The concentrated solutions act more slowly than the dilute mainly because they tend to close the pyloric sphincter; but they remove more fluid since they also increase diuresis. These concentrated solutions are also employed to reduce the secretion of milk.

Catharsis on Excretion.—The possibility of sparing the kidneys by catharsis is illustrated by data of Myers and Fine, 1919, on the percentile ratio of the fecal excretions to the total (*i.e.*, urine plus feces) excretion of the following constituents:

Consistence of stools	Moisture content of stools	H ₂ O	N	S	Cl	P	Ca	Mg	K
Well formed.....	76	6	10	10	3	36	90	72	18
Diarrheal.....	84	16	15	19	9	33	89	88	27

The Choice between the Cathartic Salts.—This is very largely determined by their *taste*. The sodium sulphate has, perhaps, the most disagreeable taste; the magnesium sulphate somewhat less so. Sodium phosphate and Rochelle salt are perhaps the least disagreeable and act very promptly, usually within an hour after breakfast. MgO and MgCO₃ act as alkalies as well as cathartics. Acid sodium phosphate renders the urine acid.

The best corrective for the *taste* of the salts is ample dilution with water, when this is permissible. Some of the salts are official in *effervescent form*; *i.e.*, mixed with sodium bicarbonate and citric or tartaric acid.

MAGNESIUM COMPOUNDS

The magnesium ion depresses all nervous and muscular functions, and this even in very dilute solutions (1:25,000). However, the salts of

magnesium are relatively little absorbed, and therefore act as osmotic cathartics. With magnesium sulphate, both ions have this effect, so that the salt is particularly effective. Magnesium oxide and carbonate act also as alkalies. Being very sparingly soluble, their antacid action extends into the intestines, with but little interference with the stomach. They are converted in the alimentary tract into the soluble and therefore cathartic magnesium bicarbonate. MgO (magnesia) is preferred to the usual alkaline carbonates when the stomach should not be burdened with CO_2 gas. It is therefore the best antidote against poisoning by acids.

Magnesium is somewhat absorbed by the alimentary canal, so as to produce some diuresis; but not sufficiently to cause toxic effects, unless very large doses of a concentrated solution are taken. When injected hypodermically or into the circulation it is highly toxic by depressing the heart-muscle, and the central and peripheral nervous system. It is antagonized by calcium. Magnesium sulphate has been used as a local intraspinal and general anesthetic, against tetanus; but the effective dose is dangerously close to the fatal (paralysis of respiration), so that its usefulness is limited.

A saturated solution of magnesium sulphate is used as a local dressing in *erysipelas* and similar inflammations; but it is doubtful whether it is more effective than other moist dressings.

Normal Occurrence of Magnesium.—Magnesium occurs in the body mainly as phosphate and in association with calcium, in the bones, and in larger absolute quantity in the other tissues. The concentration of magnesium in the plasma is about 18 to 34 mg. per liter.

The red corpuscles (Abderhalden, 1898) and striped muscle (Katz, 1896; Huerthle, 1903) contain more Mg than Ca. The daily requirement is estimated as 0.6 Gm. The ordinary diet contains 0.19 to 1.2 Gm. (H. C. Sherman, Mettler and Sinclair, 1910).

Cows, during lactation, lose considerable Mg, Ca and P, even on a liberal diet. The Mg and Ca loss can not be corrected by the addition of these elements to the diet (Forbes et al, 1917).

Absorption.—This occurs mainly from the small intestines. Metallic magnesium is also absorbed from the subcutaneous tissue (Fromherz, 1909).

Changes in the Digestive Tract.—During their passage through the small intestines, the magnesium salts are mainly changed to the soluble bicarbonate ($\text{MgSO}_4 + 2\text{NaHCO}_3 = \text{Mg}(\text{HCO}_3)_2 + \text{Na}_2\text{SO}_4$). Their effects are therefore identical; except that the difficulty absorbable sulphate ion would act independently as an osmotic cathartic. Magnesium oxide, hydroxide and carbonate are first partly converted into chlorides, by neutralizing the gastric acid. The magnesium bicarbonate is apt to form soaps with free fats in the intestine. When epsom salts and olive oil are given together, this soap may be passed as lumps which have been mistaken for gall-stones.

Excretion.—After absorption, and with parenteral administration, the excretion occurs practically exclusively by the kidneys (Meltzer and Lucas, 1907), only in small part from the large intestine. A considerable quantity may be retained in the body over two weeks. The urinary excretion of calcium is increased (Mendel and Benedict, 1909). This lessens the lime-deposition in young animals (Malcolm, 1905). The normal human urine contains 0.2 to 0.3 Gm. of Mg. per day (Nelson and Burns, 1916).

(M. Jacoby claims that in the human subject after parenteral injection of large doses of magnesium against tetanus, the greater part is excreted by the intestines, although its concentration in the urine exceeds that of calcium.)

The administration of *hydrochloric acid* increases the urinary excretion of magnesium, and still more that of calcium (Stehle, 1917; Givens and Mendel, 1917). The total balance of Mg, Ca, or N, however, is not materially altered (Givens, 1918).

The normal food-magnesium is also excreted mainly by the urine (Forbes et al, 1918).

Cathartic Action.—Magnesium sulphate is employed as laxative in doses of 2 to 10 Gm., 1 to 25, in dilute solution; and especially as hydragogue cathartic in doses of 10 to 15 Gm., 2 to 45, in concentrated solution. The dilute solution may be mixed with NaHCO_3 , but not with Na_2CO_3 . It may also be given as an effervescent salt. Solution of Magnesium Citrate is a pleasantly flavored and effervescent draught, dispensed in bottles containing 12 ounces. The dose is from $\frac{1}{4}$ to 1 bottle. Magnesium carbonate and the oxide are administered as powder, $\frac{1}{4}$ to 2 Gm., 5 to 30 gr. "Milk of Magnesia" (Magma Magnesiae) is a suspension of magnesium hydroxide, used as a laxative in doses of 1 to 4 teaspoons; and as an alkaline dentifrice.

Mechanism of Catharsis.—The available data indicate that this is due entirely to the distensive stimulus of the retained fluid. The direct effects of magnesium on intestinal muscle appear to be purely depressant, but ordinarily this is over-balanced by the mechanical stimulus. The depression is seen especially in excised intestine, and with intravenous or hypodermic injection, where it antagonizes excessive peristalsis induced by ergot, physostigmine or barium (Meltzer and Auer, 1906); but it may also be demonstrated by perfusing isotonic magnesium sulphate solution through the lumen of the intestines of living animals (Sollmann and Rademaekers, 1925). The tone and peristalsis is decreased more markedly than the pendulum movements, and the normal propulsion of the contents is therefore diminished by all effective doses (contrary to the suggestion of Meltzer, 1914). However, in conditions of excessive tone or spasm of the intestines, magnesium may result in increased propulsion, by relieving the spasmodic closure. This may explain its special usefulness in colics; for instance in chronic lead-poisoning.

The sensitiveness of the intestinal muscle to magnesium is very high: 1:25,000 of magnesium salts, *i.e.*, half of the plasma concentration, is distinctly depressant to the excised intestines; but the zone of action is quite wide, so that the pendulum movements may still be quite vigorous in 1:1,250 (Rademaekers and Sollmann, 1924). For the lumen of the intestines of living animals the concentrations must be much higher, because the magnesium ions are but slowly absorbed, and are rapidly diluted by the blood-stream before they reach the muscle. However, isotonic solutions (3.5 per cent.) are definitely, though only slightly, depressant (Sollmann and Rademaekers, 1925).

Duodenum-bile Reflex (Meltzer-Lyon Test).—Since magnesium solutions relax the intestinal muscle, Meltzer, 1917, suggested that if a strong solution of magnesium sulphate were injected into the duodenum, by the duodenal tube, it might relax the muscle of Oddi's sphincter, which closes the orifice of the common bile duct; and that this would lead to evacuation of the gall bladder, probably with the aid of contraction of the muscle of the gall bladder, according to the frequent rule of reciprocating action (the "Law of Contrary Innervation," as Meltzer called it), and in analogy with a similar effect obtained by Rost from the injection of peptone into the duodenum. Meltzer suggested that this effect, if it occurred, might be useful in the treatment of jaundice and biliary colic.

The suggestion was put to the test by B. B. V. Lyon of Philadelphia, 1919, 1920, 1922. He found that when 40 c.c. of 33 per cent. solution of magnesium sulphate are introduced by the duodenal tube, the duodenal contents contain at first little or no bile; shortly after, they contain a light yellow bile, and a little later, a darker and more viscid bile, the so-called

"B" bile. Lyon assumed that the latter comes directly from the gall-bladder, as suggested by Meltzer; and believed that its content of pus cells, bacteria, crystalline material etc., reflects the condition of the gall-bladder; and that repeated "drainage" by this means would be beneficial in cholecystitis. A similar flow of bile is produced by a variety of substances, for instance by hypertonic salt solutions in general; by 0.5 per cent. HCl; and by 5 per cent. peptone. The latter is preferred by some clinicians as less irritant than the magnesium test (Bassler, Luckett and Lutz, 1921).

There is no doubt as to the temporary increase of bile-flow (Friedenwald et al., 1923); but there has been some question as to whether this is due to evacuation of the gall-bladder, or to increased secretion of bile by the liver, (as was suggested by Einhorn, 1921). It has been shown directly, however, that the application of magnesium to the duodenal surface relaxes Oddi's sphincter (Reach, 1924), and that this is sometimes, though not always, followed by evacuation of the gall-bladder (Matsuo, 1924); but the bile flow may also be increased if the gall-bladder had been excised (Dunn and Cornell, 1921), or the cystic duct ligated (Mendenhall et al. 1926). This is probably due to the diminished resistance to the bile flow, rather than to hepatic stimulation; but it makes it uncertain whether in a given case, the bile comes from the liver or the gall-bladder (at least unless the test is used in conjunction with the injection of dyes, as suggested by Matsuo). In any case, however, the diagnostic value of the test is limited by the admixture of duodenal contents. Therapeutically, the "drainage" could scarcely be made sufficiently thorough or frequent to be of material value in cholecystitis. It might possibly be of some use in catarrhal jaundice, but the benefit would be difficult to demonstrate.

Systemic Actions of Magnesium.—These do not ordinarily occur when magnesium salts are taken by mouth, because of the relatively slow absorption and the rapid excretion. However, toxic effects may follow on large doses of the sulphate, and more readily of the nitrate (Meltzer, 1907); and especially on hypodermic or intravenous injection. They consist in muscular and nervous depression or paralysis; the chief phenomena being analgesia, anesthesia, paralysis of the respiration; and with intravenous injection, direct paralysis of the heart. The motor depression is useful in the symptomatic treatment of traumatic tetanus; but great caution is necessary to obviate respiratory paralysis. The analgetic action is not sufficiently marked, with safe doses, to be useful in itself; but it is being employed in obstetric practice to reinforce the analgetic action of morphine and ether.

Toxicity from Alimentary Canal for Rabbits.—Intestinal injection with the stomach tied produces death by respiratory paralysis in about twenty-five minutes with a dose of 10 c.c. of 20 per cent. magnesium chloride. When administered to rabbits by mouth, even very large doses are not fatal (Auer and Meltzer, 1914).

Intravascular Injection.—This produces immediate and severe, often fatal depression of the heart and central nervous system. It resembles potassium, but this acts more on the heart, magnesium on the respiration. The effects are seen in blood-pressure experiments, if the magnesium sulphate solution of the manometer inadvertently enters the artery. There is a sharp fall of blood pressure, and the heart may be arrested promptly. If the effect is not fatal, recovery occurs quickly, since the excretion is quite rapid.

Cardiac Effects.—These consist in slowing with moderate dilation; then incoördination; then sudden dilation and standstill. The heart may be kept beating by electric stimulation, by stimulation of the accelerators, and by epinephrine (Matthews and Brooks, 1910).

Respiration.—The cessation is due mainly to the curare action, the center being ordinarily not paralyzed except with considerably larger doses (Matthews and Brooks, 1910).

Deglutition.—Graded doses paralyze the central mechanism before the peripheral (Auer and Meltzer, 1916).

Curare Action.—This was discovered by Jolyet and Cahours, 1869; and has been confirmed by Guthrie, Meltzer and others. Meltzer and Auer, 1906, also found that, like curare, it antagonizes the physostigmine twitchings. Further antagonisms to physostigmine were studied by Joseph, 1909. Isolated *bronchial muscle* is slightly dilated (Trendelenburg, 1912).

Rigor Mortis.—Meltzer and Auer, 1908, found that the hypodermic injection of calcium hastens, and magnesium delays the development of rigor in skeletal muscles and heart. In calcium rigor, the extensor muscles prevail; in magnesium, either the flexors, or the position at the time of death.

Temperature.—In rabbits, this is lowered by magnesium injection, parallel to the paralytic action, but preceding the latter. It is an independent phenomenon, for it occurs also if the narcosis is prevented by calcium (Schuetz, 1915, 1916).

Effects on Urine Ions.—The injection of magnesium chloride causes a marked rise of urinary acidity; the phosphate excretion is only slightly increased (C. Mayer, 1917).

Renal Irritation.—The intramuscular or intravenous injection of magnesium salts or sulphates into dogs causes the appearance of *hyaline casts* in the urine. There are no other casts, albumen or other sign of nephritis (Gates and Meltzer, 1914). These occur also when toxic doses of magnesium are injected into the ligated small intestine (Gates, 1914).

Glycosuria.—Parenteral injections produce moderate hyperglycemia and glycosuria. Underhill and Glosson ascribed these to asphyxia; E. Hirsch, 1915, to narcosis and asphyxia; but Kleiner and Meltzer, 1916, find them even with artificial respiration.

On the other hand, Airila and Bardy, 1915, state that intravenous injections of magnesium inhibit epinephrine glycosuria and clinical diabetes; presumably by depression of the sympathetic system.

Magnesium Anesthesia.—Meltzer and Auer (1905) found that a general anesthesia, with abolition of reflexes, may be produced by the subcutaneous injection of magnesium salts (1.5 Gm. of crystalline magnesium sulphate per kilogram of body-weight, used as 25 per cent. solution). The injection causes but little pain, since the magnesium is also a local anesthetic. The anesthesia is complete in half an hour or an hour, and lasts about two hours. The blood pressure is but little lowered; there is some diuresis, but no diarrhea. The recovery is perfect. Somewhat larger doses are fatal, paralyzing the respiration before the heart. The effective dose approaches the fatal so closely that this method is not generally advisable for man. However, relatively small and clinically safe doses appear to intensify and prolong the effects of morphine and ether (Gwathmey, 1921, 1925; see Index). The effect is simply additive, and not potentiated (Beckman, 1925).

Nature of the Anesthetic Action.—There has been considerable discussion whether the effects of magnesium consist in a true abolition of sensation (Meltzer); or whether they consist mainly in a paralysis of muscular response by the curare action (Guthrie), and in asphyxia. There is no doubt that the muscular and possibly the asphyxial factors may play a part; but that magnesium produces direct sensory paralysis, both central and peripheral.

Evidence for Sensory Paralysis.—Guthrie and Ryan, 1910, and Matthews and Brooks, 1910, brought evidence that paralysis may occur by the curare and asphyxial action of magnesium, when the sensation is still preserved. However, Meltzer and Auer claim that, with proper dosage, it is possible to secure anesthesia when the asphyxial factor is entirely excluded and the muscles are still responsive. Indubitable proof of direct central anesthesia is furnished by the results of careful *intravenous injection in human subjects*, reported by Peck and Meltzer, 1916. This produced unconsciousness and complete surgical anesthesia, with incomplete motor paralysis.

The immediate revival of the animals by the intravenous injection of calcium chloride (Meltzer, 1909) also speaks for a direct central action. Further, they find (1913) that small intracerebral injections produce central anesthesia (also V. E. Henderson, 1909); and that the effects of magnesium and ether are additive. Gensler, 1915, and v. Issekutz, 1915, also find additive effects with the aliphatic hypnotics.

Mansfeld and Hamburger, 1915, conclude that magnesium increases the anesthetic action of urethane by altering its distribution; for calcium does not remove the summation if the magnesium has been administered *with* the urethane; but does remove the narcosis if the magnesium was injected some time after the urethane.

Distribution of Magnesium.—Mansfeld and Bosanyi, 1913 and Gensler, 1915, find that the magnesium and calcium of the brain substance are not changed during the narcosis or calcium recovery, and therefore conclude that the altered Mg-Ca ratio acts on the plasma membrane. Stronsky, 1914, also found that the Mg content of the plasma increased, and the Ca diminished, during the narcosis; while the organs were unchanged. The urinary excretion of both Mg and Ca was increased. J. Schütz, 1915, reports accumulation of magnesium in the brains of rabbits subjected to repeated magnesium narcosis.

Local Anesthesia.—The effects of direct application of magnesium solutions to *exposed nerve* are described rather differently. Meltzer and Auer, 1906, maintain that concentrated solutions paralyze without previous stimulation, having a selective action on the different functional fibers somewhat analogous to cocaine. Liljestand, 1909, and Guthrie and Ryan, 1910, claim that the paralysis is preceded by stimulation and that the Mg action is not specific, but very similar to that of NaCl, while Ca salts are much more effective. However, Wiki, 1911, found that the hypodermic injection of 15 to 25 per cent. $MgSO_4$ into guinea pigs produces much more local anesthesia than equivalent solutions of other salts. It seems therefore that the local anesthetic action of magnesium is relatively, if not absolutely specific.

Subdural Injection of Magnesium.—The hypodermic use of magnesium being too dangerous for man, Meltzer and Auer, 1909, introduced its use by lumbar subdural injection, using 1 c.c. of the 25 per cent. solution. This produces sensory and motor paralysis of the legs and pelvic region, occurring in three to four hours, and lasting eight to fourteen hours. There is also retention of urine for one or two days. *Untoward results* are cited in Merck's Report, 26:266.

Magnesium in Tetanus.—This has been found useful, at least symptomatically and in conjunction with antitoxin. Kocher considers it the best remedy in developed cases. The spasms are temporarily relieved, but return, requiring repeated (at least daily) injections. The dosage presents serious difficulty; the dose that paralyzes the respiratory center being but little above dose required for the therapeutic effect.

Lazarus also reports success in strychnine poisoning.

Administration in Tetanus.—The doses refer to crystalline Magnesium sulphate (Kocher, 1915; Meltzer, 1916):

For slight initial symptoms, hypodermic injections may be used, 1.2 c.c. of a 25 per cent. solution, per kilogram body weight, 3 to 5 times daily. This has been continued for 6 to 18 days without damage. It causes but little irritation. It is safe, but not sufficiently effective for severe cases. In these, the salt may be used *intramuscularly*, 0.6 c.c. of 25 per cent. per kilogram; six times daily.

In severe cases, however, it is better to proceed at once to the more effective *intraspinal injection*; using 1 c.c. of 25 per cent. per 20 lb. of body weight (0.1 c.c. of 25 per cent. per kilogram), by lumbar injection. This gives prompt relief, generally lasting 24 hours, when the procedure may be repeated. If the respiration should become depressed, the solution should be washed out of the canal.

Intravenous injection has also been used. It is not generally advised, the effects being short and dangerous, but it may be justified when the spasms threaten the respiration. Straub injects in 2 minutes a total of 100 c.c. of 2.5 per cent. solution; repeated every half hour to hour. Meltzer prefers a 6 per cent. solution, injected at the rate of 2 to 3 c.c. per minute, stopping as soon as the respiration becomes depressed. If the respiration does not improve 2.5 per cent. calcium chloride must be injected slowly.

The relaxation of the tetanus is not a complete curare action; for the respiratory movements continue with proper doses (Auer and Meltzer, 1919).

Literature.—Cohen, 1912; Dodd, 1912; Arnd, Dreyfus, 1914; Th. Kocher, 1915; H. E. Robertson, 1915; Meltzer, 1916.

Chorea.—K. Schroeder, 1916, recommends the hypodermic injection of 20 per cent. magnesium sulphate, increasing slowly from 0.2 to 3 and even 8 gm. of the salt per day.

Treatment of Magnesium Poisoning.—When using effective doses of magnesium, the physician should be prepared to combat failure of respiration, by artificial respiration, together with physostigmine ($\frac{1}{2}$ to 1 mg. hypodermically) or calcium chloride (50 c.c. of 2 per cent., intramuscular; or 0.02 per cent. in normal saline, intravenous, to 600 c.c.).

In children extra caution must be used. The doses of magnesium should generally be somewhat smaller, supplementing them if necessary by ether or the aliphatic hypnotics. Morphine potentiates the respiratory depression, and should therefore not be combined with magnesium (Issekutz, 1915).

The administration of liberal quantities of water, to induce diuresis, would be useful especially in subacute poisoning (Meltzer, 1907).

Antagonism of Magnesium and Calcium.—This was mentioned in the general discussion. *Oxalates* enhance the action of Mg, presumably by removing the antagonistic effect of the tissue-calcium (Gates and Metz, 1913). On the other hand, small doses of Mg reduce the toxicity of oxalate, by diminishing the over-stimulation (Gates and Meltzer, 1913, 1917).

Magnesium against Erysipelas and Other Inflammations.—This was introduced by H. Tucker, 1907 and 1908. A thick compress (15 layers of gauze) is immersed in a saturated solution of $MgSO_4$, applied to the inflamed region, covered with oiled silk, and renewed every two hours (Choksy, 1911). It is claimed that this subdues the inflammation, the pain, swelling and temperature, if applied in cellulitis, arthritis, epididymitis, etc.; and its use has been suggested particularly for facial erysipelas. It probably acts merely by its water-content, *i.e.*, like any evaporating lotion.

Meltzer, 1918, describes a beneficial effect of 25 per cent. magnesium sulphate on experimental burns, but demonstrable only within a narrow range of injury. Sollmann has been unable to obtain this effect.

Inefficiency in Cancer.—Itani, 1919, failed to confirm any effect on experimental tumors.

Phagocytosis.—Delbet and Karajanspoulo, 1915, claim that the intravenous injection of magnesium chloride (dogs, about 15 c.c. of 1.21 per cent. anhydrous, per kilogram) greatly increases phagocytosis. It does not inhibit the migration of leucocytes from the inflamed mesentery of frogs (Ikeda, 1916).

PREPARATIONS

***Magnesii Carbonas** (Mag. Carb.), U.S.P., B.P.—A mixture of hydrated magnesium carbonate and hydroxide. According to its preparation, it occurs as a more or less bulky powder (*Magn. Carb. Levis* and *Ponderosus*), or as white, friable masses, of slightly earthy taste. Practically insol. in water. *Dose*, antacid, 0.6 Gm., 10 grs.; laxative, 8 Gm., 2 drachms, U.S.P.; 0.3 to 1.2 Gm., 5 to 20 gr., repeated; single, 2 to 4 Gm. $\frac{1}{2}$ to 1 drachm, B.P.

Liq. Mag. Bicarb., B.P. (Fluid Magnesia).—Equivalent to 2 per cent. of Mag. Carb., about 10 gr. per ounce. *Dose*, 30 to 60 c.c. 1 to 2 ounces, B.P.

***Liquor Magnesii Citratis** (Liq. Mag. Cit.), U.S.P.—An effervescent solution containing a mixture of neutral and acid magnesium citrate, corresponding to not less than 1.5 per cent. of Mg O.; prepared in bottles of 350 c.c., 12 ounces, which may be taken as a single dose or divided.

Magma Magnesiae (Magma. Mag.), U.S.P.; B.P.C. (Milk of Magnesia).—A creamy smooth suspension containing not less than 7 per cent. of the hydroxide, $Mg(OH)_2$. *Dose*, antacid, 4 c.c. 1 drachm; laxative, 15 c.c., 4 drachms; U.S.P.

Mag. Oxid., U.S.P.; *Mag. Levis*, B.P. (Light Magnesia; Calcined Magnesia); MgO .—White, very bulky, and very fine powder, without odor; earthy taste. Almost insol. in water; insol. in alc. *Dose*, as *Mag. Oxid. Pond.*

***Magnesii Oxidum Ponderosum** (Mag. Oxid. Pond.), U.S.P.; *Magnesia Ponderosa* (Mag. Pond.), B.P. (Heavy Magnesia); MgO .—White, dense, very fine powder; insol. in water or alc. *Dose*, antacid, 0.25 Gm., 4 gr.; laxative, 3 Gm., 45 gr., U.S.P.; 0.3 to 1.2 Gm., 4 to 20 gr., repeated; single, 2 to 4 Gm., 30 to 60 gr., B.P.

***Magnesii Sulphas** (Mag. Sulph.), U.S.P., B.P. (Epsom Salts), $MgSO_4 + 7H_2O$.—Small prismatic crystals, of cooling, saline and bitter taste. Very sol. in water (1:0.75); practically insol. in alc. It contains about 50 per cent. of water of crystallization. A saturated solution contains about 50 per cent. of the crystals, or 25 per cent. of the absolute $MgSO_4$. *Dose*, 15 Gm., 4 drachms, U.S.P.; 2 to 6 Gm., 30 to 90 gr., repeated; single, 8 to 16 Gm., 2 to 4 drachms, B.P.

Mag. Sulph. Eff., U.S.P., B.P.—5 per cent. *Dose*, 4 to 12 Gm., 1 to 3 drachms, repeated; single, 16 to 32 Gm., 4 to 8 drachms, B.P.

SODIUM SULPHATE

This is a typical cathartic salt, almost free from ion action. It has no action on metabolism. On account of its disagreeable taste, it is not

much used, except in veterinary practice; but it forms an important ingredient of many mineral waters, *e.g.*, Carlsbad.

The kidneys are even more permeable to sodium sulphate than to NaCl, so that its intravenous injection produces a copious diuresis. The secretion of gastric juice is not increased.

The stimulant actions of hypodermic or intravenous injections of sodium sulphate on the circulation and respiration appear to surpass those of sodium chloride. An isotonic solution (2 per cent. of the dried or 4 per cent. of the crystalline salt) is used in quantities of 500 to 1,000 c.c.

PREPARATIONS

Sodii Sulphas (Sod. Sulph.), U.S.P., B.P. (Glauber's Salt), $\text{Na}_2\text{SO}_4 + 10\text{H}_2\text{O}$.—Large or granular colorless crystals, of bitter saline taste. Freely sol. in water (1:1); practically insol. in alc. All sulphates are *incompatible* with calcium and lead. *Dose*, 15 Gm., 4 drachms, U.S.P.; 2 to 8 Gm., $\frac{1}{2}$ to 2 drachms, repeated; single, 10 to 16 Gm., $2\frac{1}{2}$ to 4 drachms, B.P.; diluted.

Sodii Sulphas Effervescens (Sod. Sulph. Eff.), B.P.—A mixture of dried sodium sulphate, sodium bicarbonate, and tartaric and citric acids; representing 50 per cent. of the ordinary sulphate. *Dose*, 4 to 8 Gm., 1 to 2 drachms, repeated; single, 10 to 16 Gm., $2\frac{1}{2}$ to 4 drachms, B.P.

Pot. Sulph., B.P., K_2SO_4 .—Sol. in water (1:10); insol. in alc. *Dose*, 1 to 3 Gm., 15 to 45 gr., B.P.

TARTRATES

These are difficultly absorbable, and therefore typical saline cathartics, possessing the advantage of a relatively unobjectionable taste. The potassium-sodium tartrate or Rochelle salt is commonly used. Acid potassium tartrate (cream of tartar) acts as a mild acid; and being relatively insoluble, the acid-action extends into the intestines and here stimulates peristalsis. It is therefore more actively cathartic.

Cream of tartar and tartaric acid effervesce with sodium bicarbonate, and are used in baking powders, effervescent drinks, etc.

The tartrates are not readily burned in the body, and therefore do not act as alkalis and diuretics as powerfully as do most other organic anions. When introduced into the circulation, they have a rather high toxicity by immobilizing calcium, and injuring the renal epithelium; but this need not be feared from therapeutic doses (Post, 1914).

Toxic Actions of Tartrates.—The effects on calcium are similar to those described under Citrates. Small doses produce only the renal injury; larger doses also muscular and nervous symptoms. The cardiac excursions are decreased, especially in systole, with moderate slowing. The blood pressure is unchanged, the kidney volume slightly increased. The effects may be acute or subacute, according to dose (Salant and Smith, 1914). The four stereochemic isomers behave somewhat differently toward calcium and therefore have a different toxicity (Chio, 1912). Salant and Smith, 1913, found that the d. and l. had the same toxicity for frogs and rabbits; but the resistance of different animals varies greatly.

Excised Intestine, and Isolated Frog Heart.—The effects of the various tartrates, succinates and malates, on the small and large intestines are complex. The isolated heart is depressed (Salant et al, 1917).

Renal Action.—Underhill, Wells and Goldschmidt, 1913, and Pearce and Ringer, 1913, found that Rochelle salts produced marked renal changes when given hypodermically in doses of 0.25 Gm. per kilogram to phlorhizin rabbits; somewhat larger doses caused the same changes without phlorhizin. Oral administration also produced nephritis, with doses of 3 Gm. per kilogram. Five Gm. per kilogram was fatal in fasting animals. The toxicity is not as great in well-fed animals; when diarrhea occurs; or when alkalis are administered. Acetates, citrates and carbonates do not produce these renal changes. Analogous effects are produced on dogs.

The epithelial changes are confined mainly to the convoluted tubules, with some extension to Henle's loops. The glomeruli and interstitial tissue are intact. The lesions

result in retention of the tartrate so that only traces are excreted by the urine even on intravenous injection.

In the acute nephritis of rabbits, the phthalein excretion is materially diminished. In chronic cases, the excretion again improves somewhat with time. The nitrogen excretion is scarcely altered (Underhill and Blatherwick, 1914). Hippuric acid synthesis is not impaired (Kingsbury and Bell, 1915).

The excretion of injected urea, and the excretion of N and dextrose in phlorhizin animals is hindered, but the NaCl excretion is normal (Baer and Blum; Underhill, 1912). The restoration of the blood-volume after injection of saline solution is delayed (Bogert, Underhill and Mendel, 1916).

The vascular reactions of the kidneys in dogs are practically unaffected by the tartrate nephritis. The diuretic response to caffeine is somewhat diminished (Karsner, 1917).

Diet on Nephritis.—With rabbits, but not with cats, the diet has a marked influence on the resistance to tartrates. The toxicity is highest when rabbits are fed with oats, hay or cabbage; considerable protection is conferred by food rich in sugar, especially by young carrots. The factors that might be involved have not been differentiated (Salant and Swanson, 1918).

Habitation.—Continuous administration of tartrates to rabbits somewhat increases the tolerance; whilst citrates and oxalates lead to cumulation (Salant and Swanson, 1918).

PREPARATIONS

Acidum Tartaricum (Acid. Tart.), U.S.P., B.P., $C_2H_2(OH)_2(COOH)_2$.—A dibasic organic acid obtained from wine lees or argol. Colorless crystals or white powder of acid taste. Very sol. in water (1:0.75); freely sol. in alc. (1:3.3). *Dose*, 0.5 Gm., 8 gr., U.S.P.; 0.3 to 1.2 Gm., 5 gr., B.P.

**Polassii Bitartaras* (Pot. Bitart.), U.S.P.; *Pot. Tartr. Acid.*, B.P. (Cream of Tartar), $KHC_4H_4O_6$.—White, somewhat gritty powder, of pleasant acid taste. Slightly sol. in water (1:155); nearly insol. in alc. *Dose*, 2 Gm., 30 gr., U.S.P.; 1 to 4 Gm., 15 to 60 gr., B.P.; suspended in water.

Pot. Tart., B.P., $K_2C_4H_4O_6 + \frac{1}{2}H_2O$.—Freely sol. in water (1:1). *Dose*, 2 to 16 Gm., $\frac{1}{2}$ to 4 drachms, B.P.

**Pot. et Sod., Tart.*, U.S.P.; *Sod. et Pot. Tart.*, B.P. (Rochelle Salt; Soda Tartarata), $KNaC_4H_4O_6 + 4H_2O$.—White powder or colorless crystals of cooling saline taste. Very sol. in water (1:0.9); practically insol. in alc. *Dose*, 10 Gm., $2\frac{1}{2}$ drachms, U.S.P.; 8 to 16 Gm., 2 to 4 drachms, B.P.

**Pulvis Effervescens Compositus* (Pulv. Eff. Comp.), U.S.P.; *Pulv. Sodæ Tart. Eff.*, B.P. (Seidlitz Powder; Pulv. Sod. Tart. Co.).—The blue paper contains Pot. et Sod. Tart., 7.5 Gm. and Sod. Bicarb., 2.5 Gm.; the white paper, Ac. Tart., 2.17 (U.S.P.), 2.5 Gm. (B.P.). The contents of the blue paper are first dissolved in a third of a tumbler of cold or warm water and the contents of the white paper, also dissolved in water, are then added.

SODIUM PHOSPHATE

This name is used in medicine and pharmacy for the disodium salt Na_2HPO_4 . The dihydrogen salt, NaH_2PO_4 , is official as "sodium biphosphate," and since it is of feebly acid reaction, it is also called "acid sodium phosphate." The di-sodium salt is a feeble alkali. Both salts have considerable buffer-value, and together they help to maintain the normal reaction of body fluids, especially of the urine.

The phosphate ion is relatively non-absorbable, so that sodium phosphate is a typical saline cathartic. The biphosphate is also cathartic, but produces more local irritation because of its acidity. It is administered to increase the acidity of the urine, especially to permit the liberation of formaldehyde from methenamine (Hanzlik and Collins, 1913). Sodium phosphate does not alter the true reaction of normal urine.

The acute systemic effects of phosphates are slight, even on intravenous injection, and quite insignificant on oral administration.

The phosphate content of the body has important relations to the ionization of calcium, and therefore to calcium concentration. It is ordinarily maintained at a constant level, and cannot be materially

modified by the administration of phosphate. Even parenteral injection is rapidly compensated. Disturbance of the normal phosphate level is a characteristic feature of rickets.

Use as Cathartic.—Sodium phosphate is used especially as a laxative. A solution of 2 to 4 Gm. in a glass of hot water (it is but slowly soluble in cold water) does not have a very disagreeable taste and when taken before breakfast, it usually produces a single soft but not liquid stool, within an hour. It may be administered in this manner, as needed, for considerable periods, without producing habituation.

Effects of Intravenous Injection of Sodium Phosphate.—Moderate quantities act mainly as indifferent saline fluids, *i.e.*, similarly to isotonic sodium sulphate. They are said to stimulate the vagus endings. Large doses (0.7 Gm. per Kg.) of sodium phosphate (absolute) injected into dogs produces tetany. The Ca content of the blood also drops by 40 per cent. (by dilution?). The calcium reduction is not the essential cause of the tetany, for phosphoric acid injection produces a similar fall of Ca without tetany (C. Binger, 1917; Greenwald, 1918; the older work of Starkenstein, 1914, appears open to criticism).

Pyrophosphates.—Crawford, 1900, found these markedly toxic, producing gastrointestinal irritation, hemorrhages and ulcerations; changes in the liver; with continued administration, nephritis and edema. Metaphosphates acted similarly but weaker; while the ordinary orthophosphate was non-toxic. Crawford believed that the pyrophosphates are responsible for the toxicity of certain cotton-seed meals, but Withers and Ray, 1913, contradict this conclusion.

Absorption of Phosphates and Other Phosphorus Compounds.—A variable fraction of the phosphates is absorbed, mainly from the upper portions of the small intestines. The quantity so absorbed depends partly on the time that the phosphate sojourns in the body, and partly on the amount of calcium in the intestines; for this tends to deflect a large proportion of the phosphate to the feces. The insoluble calcium phosphate, administered as such, is largely dissolved by the hydrochloric acid of the stomach, so that a part of this phosphate may be absorbed. Hypophosphites are absorbed, and for the most part excreted unchanged. Glycerophosphates and all organic phosphorus compounds are almost completely hydrolyzed in the digestive tract (Plimmer, 1913), and absorbed and excreted as inorganic phosphate (Oeri, 1909). Opinions differ as to the importance of the small fraction (if any) that escapes decomposition. Further details will be given under the individual drugs.

Excretion of Phosphates.—This occurs by the urine and feces. The path of phosphate excretion is markedly influenced by the calcium of the food. With a high calcium income, the phosphate is excreted mainly by the feces as calcium phosphate; whereas the urinary phosphates increase with a lime-poor diet (Zuelzer, 1905).

The greater part of the normally excreted phosphate is derived from the metabolism of the tissues and therefore generally varies in the same direction as the nitrogen excretion, although they are not necessarily proportional. "*Phosphaturia*," the deposition of phosphates in the urine, is due to alkaline reaction of the urine, and not to increased phosphate excretion; indeed, the excretion is generally diminished.

When injected subcutaneously the phosphates are rapidly excreted by the intestine and kidneys. The feces contain phosphates even in starvation. The urinary phosphates are generally increased by water diuresis (Baetznr, 1913).

Phosphorus Compounds of Urine.—Practically all the phosphorus of the urine is normally in the form of inorganic mono- and di-hydrogen phosphates. A variable fraction may exist in organic form, as glycerophosphoric and phosphoric acid.

The organic phosphorus is increased in fasting, chloroform anesthesia, morphine poisoning, and some pathologic conditions.

Phosphorus Compounds of the Feces.—These are derived partly from unabsorbed phosphates, from intestinal secretions, and from the bacteria. They include various organic forms, nucleins, lecithins, etc.; as well as calcium and other inorganic phosphates.

PREPARATIONS

**Sodii Phosphas (Sod. Phos.)*, U.S.P., B.P., $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$.—Large colorless crystals or granular powder, of cooling saline taste. Freely sol. in water (1:2.7); practically insol. in alc. *Dose*, 4 Gm., 1 drachm, U.S.P.; 2 to 8 Gm., $\frac{1}{2}$ to 2 drachms, repeated; single, 10 to 16 Gm., $2\frac{1}{2}$ to 4 drachms, B.P.

Sodii Phosphas Effervescens (Sod. Phos. Eff.), U.S.P., B.P.—A mixture of exsiccated sodium phosphate, sodium bicarbonate, and tartaric and citric acids, representing about 50 per cent. of the ordinary or 20 per cent. of the dried phosphate. *Dose*, 10 Gm., $2\frac{1}{2}$ drachms, U.S.P.; 4 to 8 Gm., 1 to 2 drachms, repeated; single, 10 to 16 Gm., $2\frac{1}{2}$ to 4 drachms, B.P.

Sodii Phosphas Exsiccatus (Sod. Phos. Exs.), U.S.P.; Na_2HPO_4 .—Sodium phosphate, from which the water of crystallization has been expelled by heating at 110°C . It is about two and one-half times as strong as the ordinary phosphate. *Dose*, 2 Gm., 30 gr., U.S.P.

Liq. Sod. Phosph. Co., N.F.—Sodium phosphate liquefied in its water of crystallization by sodium nitrate and citric acid. 100 c.c. represents 100 Gm. of sodium phosphate (about two-thirds in the forms of acid phosphate, W. F. Horsa, 1910). *Dose*, 10 c.c., $2\frac{1}{2}$ drachms.

**Sodii Biphosphas (Sod. Biphos.)* U.S.P., *Sodii Phosphas Acidus* (Sod. Phosph. Acid., B.P., Sodium Acid Phosphate (mono-sodium phosphate).—Contains at least 85 per cent. of NaH_2PO_4 , U.S.P.; 70 per cent. B.P. Large colorless crystals or granular powder, of saline and somewhat acid taste. Very sol. in water; insol. in alc. *Dose*, 1 to 1.5 Gm., 15 to 20 gr., in water; repeated every one to four hours until the urine becomes acid; 0.6 Gm., 10 grains, U.S.P.; 2 to 4 Gm., 30 to 60 gr., B.P. It should not be mixed with methenamine.

A solution may be prepared extemporaneously by adding Dilute Phosphoric Acid to a solution of the official di-sodium phosphate until it no longer precipitates a solution of CaCl_2 ; or as follows: Sod. Phosph., 10 Gm., Ac. Phosph. Dil., 25 Gm.; Water, q.s. ad 150 c.c.; a tablespoon of this mixture contains about 1 Gm. of the acid phosphate.

PHOSPHORUS COMPOUNDS IN METABOLISM

Occurrence.—Phosphorous compounds make up a considerable proportion of the weight of the body, equivalent to about 0.7 per cent. of P (young dog, Heubner, 1914). It occurs in three classes of compounds: in the bones as insoluble calcium and magnesium phosphate; as soluble phosphate ions in the plasma and other body fluids; as organic compounds, nucleins, lecithins, and phosphatides, in the tissues and plasma. The organic phosphorus compounds of the serum are almost exclusively phospho-lipins (Greenwald, 1916; Bloor, 1918; Meigs et al., 1919). About three-fourths of the total phosphorus is in the bones; the muscles contain more than the combined total of the central nervous system, skin, liver and kidneys (Heubner, 1914). Milk contains a considerable amount of phosphorus compounds.

A very full review of these subjects, with bibliography, is given by Forbes and Keith, 1914.

Daily Phosphorus Requirements.—Under ordinary conditions, the daily phosphorus excretion of normal human adults is equivalent to about 1.5 to 1.75 Gm. of P, or about 3.5 Gm. of PO_4 . This must be replaced by a corresponding income to preserve a balance. The ordinary diet contains about this amount (from 1.52 to 5.88 Gm., average 3 Gm., of PO_4 ; Sherman, Mettler and Sinclair, 1910). Under special conditions of diet, equilibrium may be preserved temporarily with 0.9 Gm. of P. This is also the average daily excretion in fasting.

Phosphorus Balance.—Increased intake of phosphorus compounds is followed by increased elimination: in carnivora mainly by the urine; in herbivora mainly by the feces; in omnivora by either, according to the diet. A portion of the excess is retained.

especially in growing animals or after wasting diseases. The retention is diminished by deficiency of calcium or excess of magnesium in the food. The bones constitute important depots for a phosphate reserve. The deposition of phosphate in them is hindered by inorganic acids, calcium-precipitating ions, or high potassium or low sodium content of the ration.

Cows during lactation lose considerable phosphate. This may be corrected by the addition of bone and calcium carbonate to the food (Forbes et al., 1917, 1918).

Excision of the parathyroids is followed by marked retention of phosphorus, increasing its concentration in the blood (Greenwald, 1916).

Deficient Phosphorus Income.—If this falls below the normal requirement, the excretion, and finally the phosphorus content of the tissues, is diminished.

The phosphorus of the plasma, both organic and inorganic varies rather widely and is influenced by the food (Meigs et al. 1919). Its diminution soon leads to disturbances of growth and nutrition, the spongy tissue of the bones being most affected (Masslow, 1914). The bones become soft and flexible when their phosphorus content has fallen by one-sixth (Heubner, 1914). In fasting, the loss of phosphorus is considerable.

Growth that has been interrupted by phosphor-deficiency, is resumed when phosphorus compounds are added. Inorganic phosphates are perfectly efficient for their purpose (Osborne and Mendel, 1918).

Rickets.—This is conditioned on a serious disturbance of phosphate metabolism, reflected by a marked diminution of the phosphate content of the plasma. This lies normally between 7 and 9 mg. per 100 c.c.; in rickets it falls to 3 or 4 mg. The calcium level is but little decreased (Howland and Marriott, 1917). It is also reflected in the impaired calcification of the bones, which consist normally mainly of calcium phosphate. In rickets the cellular tissue proliferates, but the mineral matter diminishes, sometimes to half of the normal. The condition may be induced in young animals by food deficient either in inorganic phosphate (Sherman et. al.) or in vitamine; and animals so prepared may be used to test the effectiveness of antirachitic agents (rats, McCollum et. al., 1921; rabbits, Goldblatt and Moritz, 1926). The most effective antirachitic agents are cod liver oil (see index) and actinic light.

Role of Organic and Inorganic Phosphorus Compounds in Nutrition.—The absorbed phosphate is utilized in the construction of bone and in the synthesis of the various forms of organic phosphorus compounds in the body. These can be constructed completely from inorganic phosphates. Animals which receive an adequate supply of inorganic phosphates require very little, if any, organic phosphorus compounds (Review, Marshall, 1915). The presence of some organic phosphorus in the food appears to favor nutrition; but this is probably due to contamination with vitamine (see index, Lecithin).

Use of Lecithin and Other Phospho-lipins and Nucleins, Glycerophosphates and Hypophosphites as Tonics.—The unfounded assumption that these compounds would be more easily assimilated by the tissues, and particularly by the brain, gave rise to their employment as tonics and "brain foods" in all sorts of depressed conditions: Scrofula, incipient phthisis and cachexia; neurasthenia and tabes; neurites and neuralgias, etc. There is no evidence for the better utilization of these compounds; and in any case the ordinary diet furnishes a very free supply of lecithin and other phosphorus compounds, so that is it difficult to see how the small quantities added in the form of more or less expensive medicines could have any other than psychic effects. When the psychic element is excluded, they are ineffective.

Glycerophosphates.—These are absorbed in part unchanged, but for the greater part are decomposed in the intestines into ordinary phosphates (Plimmer, 1913). The excretion is entirely as phosphate.

Since lecithin is split into glycerophosphates in the intestines it was suggested by Pasqualis, 1894, Buelow, 1894, and Robin, 1894, that the direct administration of the cheaper glycerophosphates (especially the calcium salt) should accomplish the same results. However, according to Willstaetter, the synthetic glycerophosphoric acid is not identical with that formed from lecithin. In any event, the evidence of its usefulness is even less convincing than for lecithin (Report, Counc. Pharm. Chem., 1916, J.A.M.A., 67; 1033).

A proprietary compound of glycerophosphates and casein has been widely and extravagantly advertised as "Sanatogen." It is a very costly food, in no sense superior to ordinary casein, such as cottage cheese (Street, 1914).

Calcii Glycerophosphas (Calc. Glycerophos.), U.S.P.; the normal calcium salt of glycerophosphoric acid ($C_3H_5(OH)_2PO_4Ca$).—The most commonly used glycerophosphate. Fine, white powder; odorless and almost tasteless, somewhat hygroscopic. Sol. in water (1:50) insol. in alc. Solutions of glycerophosphates are decomposed on heating. *Dose*, 0.3 Gm., 5 gr., U.S.P.

Hypophosphites.—These were introduced by Churchill, 1855, against tuberculosis on the theory that phthisis is caused by lack of oxidation and that this would be stimulated by organic phosphorus; and that the hypophosphites would be converted into this "phosphatide element." On the basis of this fantastic theory, they have been used considerably as tonics in tuberculosis. The clinical evidence is too indefinite and the experimental evidence is generally negative (Marriott, 1916). (Report Counc. Pharm. Chem., 1916, J.A.M.A., 67, 760.)

The hypophosphites are excreted rapidly and almost completely unchanged (85 per cent.; Marriott, 1916) by the urine (Paquelin and Joly; Boddaert, 1895; Massol and Gamel, 1901; a trace may possibly be oxidized (Delaini, 1911). (Patto, 1910, claims that only a fraction is excreted unchanged.) They are not diuretic.

The unscientific status of the hypophosphites is reflected in the polypharmaceutical syrups in which they are generally prescribed, such as the *Syrupus Hypophosphitum*, *Compositus* (dose 10 c.c.), containing six hypophosphites besides quinine and strychnine; there is also an emulsion of cod liver oil with hypophosphites.

The hypophosphites are easily soluble in water; dose, 0.1 to 1 Gm.; 1 to 15 gr. The calcium salt is probably the most important.

Acidum Hypophosphorosum (Acid. Hypophos.), U.S.P.—About 30 per cent. of HPH_2O_2 . Colorless or slightly yellow, odorless liquid. Intensely acid taste. *Dose*, 0.2 c.c., 3 minims. U.S.P.

Calcii Hypophosphis (Calc. Hypophos.), B.P.; $Ca(PH_2O_2)_2$.—Colorless, transparent prisms, or small lustrous scales, or a white, crystalline powder; odorless, nauseous and bitter taste. Freely sol. in water (1:6.5); insol. in alc. *Dose*, 0.2 to 0.6 Gm., 3 to 10 gr., B.P.

Sod. Hypophos., B.P.; $NaPH_2O_2 \cdot H_2O$.—Saline taste. Freely sol. in water (1:1); sol. in alc.

Syrupus Hypophosphitum (Syr. Hypophos.),—Contains a mixture of calcium, potassium and sodium hypophosphites (total, 7.5 per cent.), acidulated with hypophosphorous acid. *Dose*, 10 c.c., 2½ drachms.

Syrupus Hypophosphitum Compositus, N.F.—Contains the above, also the hypophosphites of Fe and Mn, with quinine and strychnine. *Dose*, 10 c.c., 2 drachms; contains 11 mg. (⅓ gr.) quinine; 1.1 mg. (⅓ gr.) strychnine.

ELEMENTARY PHOSPHORUS

Yellow phosphorus (to which the discussion will refer, unless otherwise noted) is an active poison producing death by acute hepatitis, with alterations of nitrogen metabolism, and fatty changes of the liver and other organs. The continued administration of small doses modifies nutrition and bone-formation, and was formerly used against rickets, but has been displaced by safer measures. Phosphorus acts as such: its actions are not shared by any of its compounds, which are for the most part harmless.

Long continued exposure to the vapors of phosphorus may produce osteitis and necrosis of the jaw. This is generally attributed to the formation of acids by the oxidation of the phosphorus.

Amorphous or red phosphorus is non-volatile insoluble inabsorbable and therefore non-toxic when taken by mouth; but since it may contain

traces of ordinary phosphorus (to 0.6 per cent.—Blythe), large doses could become toxic. Intravenous injections (Nasse, 1885) produced the effects of ordinary phosphorus probably by conversion into this form.

Absorption, Fate and Excretion.—Yellow phosphorus is practically insoluble in water, but diffuses through this as vapor, and forms a dilute colloidal solution, the “phosphorus water.” It is soluble in fats and in bile (Hartmann, 1866), and is therefore absorbed from the intestines and from subcutaneous injections, especially if it is administered in finely divided form. The vapor may also be absorbed by inhalation. The absorption is always slow, and the systemic effects are therefore delayed several days. It is finally *excreted* in oxidized form (hypophosphoric acid, Poulet, 1872), but its *fate* is very imperfectly known. Although it oxidizes so readily in the air, its oxidation in the blood requires days (H. Meyer, 1881); perhaps it has an inhibitory action on oxidizing ferments similar to hydrocyanic acid (Schultzen and Riess, 1869). During its action it exists unchanged in the organs and in the expired air (Claude Bernard).

Etiology of Phosphorus Poisoning.—Phosphorus is quite accessible in the form of matches or phosphorus rat paste, so that poisoning, accidental or suicidal, is not uncommon. It also occurs, rather rarely, in the therapeutic use. Infusions of matches have been taken as abortifacient, with serious results. Chronic poisoning of somewhat different character is seen from its fumes, in chemical works and formerly in match factories. This, as well as the poisoning by matches, has been very greatly diminished since the introduction of amorphous (red) phosphorus. At present, yellow phosphorus is rarely used in the manufacture of matches.

Phosphorus Matches.—The first phosphorus friction matches were made by Derosne, in Paris, 1816, but they did not become practical until 1833, when processes for their manufacture were invented in several countries. These all employed yellow phosphorus; each match contains $\frac{1}{3}$ to 5 mg., so that 16 would be fatal for an adult.

The use of the dangerous yellow phosphorus in matches is now prohibited by law in practically all European countries. In the United States, a prohibitive tax has been placed on their manufacture. *Phosphorus sesquisulphide*, is now used in ordinary matches, which strike anywhere. This has a very low toxicity; guinea pigs are said to show no effects from doses of 0.3 Gm. per day (Brouardel). The “safety-matches” have no phosphorus on the sticks, which are usually headed with Sb_2SO_3 , KClO_3 and glue; the red phosphorus is here on the friction surface coating of the box.

The Symptoms of Poisoning.—These have the peculiarity that they occur in two well-defined stages: At first, there is local gastro-intestinal irritation; then more or less complete recovery; then, after two or three days, the phenomena of the systemic actions appear. These are distinguished by fatty enlargement of the liver, intense icterus, and metabolic changes pointing to diminished oxidation. They extend over several days and generally terminate in death by heart failure. Gastric, syncopal, or cerebral phenomena may predominate. About half the clinical cases end in death, usually in 4 or 5 days.

Acute Symptoms.—These generally start after some hours with gastric pain and burning, eructations with garlic odor, and finally vomiting, which may be luminous in the dark. Later there is often diarrhea. After 24 to 36 hours, there is more or less remission of the symptoms, usually of short duration, but which may last 2 or 3 days.

The Later Phenomena.—These begin with nausea; then gradually slight icterus; abdominal pain and tenderness; vomiting and soft stools, both often streaked with blood; coated tongue and fetor oris.

The symptoms become gradually more severe; and within two days the area of liver dulness has rapidly increased; the hepatic region is painful and very tender, and the icterus more intense. Icterus is noted in about half the cases; it appears generally on the second to the fourth day, but may be delayed till the 25th (Jaksch). If death occurs within the first two days of the second stage, there is usually no icterus (Magnus, 1914). All foods and liquids are vomited. The patient becomes profoundly prostrated with insomnia, anxiety, headache, muscle pains, spasm and feebleness. The temperature is normal, the skin dry, the respiration increased, the pulse soft but of normal rate. The urine is scanty, acid, dark brown from bile and blood, and contains albumin, casts and abnormal nitrogenous substances. Multiple hemorrhages may occur as petechiæ or in larger areas, in the skin, mucosæ, lungs and other viscera.

Agonal Stage.—The pulse becomes thready and intermittent; the heart dilated, with systolic murmurs; the respiration dyspneic or Cheyne-Stokes. Consciousness may be undisturbed, but generally there is somnolence, sometimes delirium and disturbances of temperature, finally coma.

Diagnostic Post-mortem Features.—These are: the icterus; phosphorus odor on opening abdomen; blood tarry and difficulty coagulable; multiple hemorrhages; fatty enlargement of the liver and other organs. Gastric lesions are slight or absent. *The mitochondria of the pancreatic cells*, according to W. J. M. Scott, 1916, are the first structures to show changes in phosphorus poisoning.

Course.—This runs from two to fifteen, averaging perhaps eight days. In the fatal cases, death occurs usually before the 8th day, most commonly in 4 to 5 days (Jaksch, Tardieu); it has occurred exceptionally in 4 to 8 hours.

Fatality.—This is high, about 55 per cent. (Falck); with larger quantities, such as are used for abortion, it may reach 95 per cent. (Kobert).

The Fatal Dose.—This may be as low as 50 mg., generally about 100 mg.; but 15 mg. may be severely toxic. It is much more dangerous in solution or when finely divided, than when larger lumps are taken. Monti administered as high as 7 mg. daily for three weeks against rickets, but this dosage proved toxic. A two-year-old child has been severely poisoned by therapeutic doses (1.2 mg. distributed over three days; Nebelthau). Magnus, 1914, states that no dangerous effects have ever occurred (in children up to eight years) from 0.5 mg. per day; although there may be some vomiting at first. He states the smallest dose that has exceptionally produced dangerous effects as 1 mg. per day.

Recovery.—This may occur gradually, even from advanced symptoms; but cerebral hemorrhages may leave paralytic *after-effects*.

Treatment of Acute Poisoning.—Any phosphorus remaining in the alimentary tract should be oxidized and removed. In view of the slow absorption of the phosphorus, gastric lavage may be successful even when started two hours after the ingestion. A large quantity of fluid should be used (5 to 10 gallons). The best antidote is copper sulphate, 0.1 to 0.2 Gm. in water, every ten minutes until emesis. This acts as a prompt emetic, and meanwhile oxidizes the phosphorus and envelops the globules with a coating of reduced copper which retards absorption (Woehler and Vogel, 1836; Straub, 1903). Gastric lavage with other oxidizing agents may be substituted: KMnO_4 , 0.1 per cent. (Bokai and Antal, 1889); or H_2O_2 , 2 per cent. of the official solution. These should be followed by a saline cathartic. Oils, fats and milk should be avoided while any phosphorus remains in the intestines, since they increase its solubility and absorption. Sodium bicarbonate may be given to prevent acidosis. When the systemic symptoms have set in, these measures are practically useless and the treatment must be mainly symptomatic. Transfusion of blood is said to have given good results.

In phosphorus poisoned animals, the *feeding of sugar* was found to replenish the hepatic glycogen, and to diminish the other toxic manifestations (Simonds, 1910).

Oil of Turpentine.—0.5 Gm. several times daily for a week may be tried (Andant, 1868; Koehler, 1872) but its benefits are doubtful, or at best inconstant. They seem to vary with different varieties of the turpentine, the fresh being often as effective as old ozonized samples. The action is not due to simple oxidation of the phosphorus,

but to the formation of complex compounds (Busch and Fischer); Kobert believes that it may be effective even after the phosphorus has been absorbed.

Special Phenomena of Phosphorus Poisoning.—*Action on Metabolism.*—This is the most interesting feature of phosphorus poisoning from a scientific standpoint. It occurs in chronic poisoning, or as a secondary process after a single larger dose. The phenomena consist in increased tissue destruction with disturbances of syntheses, oxidations and dissociations; increased but incomplete nitrogen metabolism; interference with glycogen deposition; increased lactic acid and ammonia excretion; inhibition of other synthetic processes; deposition of fat in the liver.

The Mechanism.—This is not understood. It appears to involve interference with certain ferment actions, primarily with some of those involved in carbohydrate metabolism.

Nitrogen Metabolism.—This is very greatly increased. The urinary nitrogen may rise by 300 per cent. (Storch, 1865). The excretion of phosphate and sulphur is also increased, while the chlorides are diminished by the inanition (Welsch, 1905). All the nitrogenous metabolites may participate in the increase (v. Jaksch, 1903); but not to the same extent (Muenzer, 1894). The urea is not nearly as much increased as the others and may even be diminished. It is to a large extent replaced by ammonia. This may be attributed to an increased production of sarcolactic and other organic acids. The uric acid excretion does not show characteristic changes; and the creatinine output is scarcely affected (Lusk). The hippuric synthesis of excised kidneys is checked (Hauser, 1895).

The blood of dogs poisoned with phosphorus shows increase of non-protein nitrogen, urea and amino-acids, partly through increased metabolism, and partly because of diminished excretion. There is generally a terminal acidosis (E. K. Marshall and Rowntree, 1915, 1918). The total N:urea ratio of the blood rises (Desqueyroux, 1922). The protein cleavage products may play a part in the production of the symptoms (Moriani, 1916).

A very important phenomenon is the appearance in the urine of *amino acids*, leucine, tyrosine, cystine; and peptone-like substances (Schultzen and Riess, 1869). Clinical cases may not show the tyrosine. The peptone-like substances are present especially in the early stages. Their nature is not known (Harnack, 1893).

Fatty Changes.—Extensive deposition of fat occurs particularly in the liver cells, whose fat-content may reach three or four times the normal; but it is seen also in practically all other cellular organs: muscle, skeletal, smooth and cardiac; kidneys; blood vessels; epithelium of stomach and intestine, etc. The fatty changes are preceded by "cloudy swelling," which is probably an intermediate stage. They are followed by proliferation of interstitial connective tissue (cirrhosis).

Similar fatty changes occur in poisoning by: Phlorhizin, arsenic, antimony, many volatile oils, the alcohol group, benzol, phallin, etc., in starvation, etc.

The Mechanism of the Fatty Degeneration.—This has been studied especially in the liver. It was originally assumed that the fat was formed *in situ*, by true degeneration of the protoplasm of the liver cells (Bauer, 1878). However, Lebedeff, 1883, disproved this, finding that fat is deposited in the liver only if the fat store of the body is ample; and that if some foreign fat is introduced into the subcutaneous tissue, the fat deposited in the phosphorus liver agrees in composition with this foreign fat. This suggests that the liver fat is merely transported from the fat depots. These observations have been confirmed by Rosenfeld, 1897; Pflueger, 1898; Foulerton, 1921; and others. (However, Salvioli and Sacchetto, 1922, claim that the phosphorus increased the visible fat in the liver, even in animals starved to the last degree; but the organ fat had not entirely disappeared). Similar observations were made in regard to the other poisons that cause "fatty degeneration" of the liver. The conclusion was strengthened by the observation of Athanasiu, 1898, that the total fat of the body is not increased by phosphorus. In fact it is rather diminished (Shibata, 1911). The increased fat of the liver must therefore have been drawn from other parts of the body so that the process is one of infiltration.

Lusk finds that the combustion of fat in phosphorus poisoning is not changed. Some of the "fat" consists partly of other lipoids (Dastre and Morat, 1879); Heffter, 1890, claims that the percentage of lecithin is decreased. The fat in the heart (studied by Rosenfeld, 1906) is also infiltrated (Leik and Winckler).

Leathes, 1909, showed that the liver effects certain changes in the depot-fats (desaturation, increasing the iodine-number). He believes that this is a necessary preliminary to the utilization of the fats in metabolism. Fatty infiltration of the liver would

therefore represent an excessive attempt at such conversion. Accordingly, it is found in all conditions in which there is a high need for fat (starvation, etc.). If such animals are freely fed, the fatty infiltration of the liver may disappear within a day (Mottram, 1915).

Carbohydrate Metabolism.—Phosphorus causes the disappearance of glycogen from the liver. This is not due to increased glycogenolysis, for the percentage of sugar in the blood is generally not increased, and in the later stages it is even decreased. Phosphorus must therefore inhibit glycogen synthesis, especially from non-carbohydrate sources (E. Franck and Isaak, 1911; Desqueroux, 1922). This would explain the prevention of epinephrine glycosuria by phosphorus; and the non-combustion of lactic acid. According to v. Fuerth, 1914, lactic acid appears in the urine only when the rabbits are fed on an excess of sugar. Dextrose also is not converted into glycogen (E. Neubauer, 1909); thus explaining the occurrence of glycosuria when carbohydrates are fed. Glycogen may be still formed from levulose. The tolerance for galactose and levulose is lowered (E. K. Marshall and Rowntree, 1915).

The increase of nitrogen excretion may be due to carbohydrate disturbance: Franck and Isaak, 1911, believe that this interference with glycogen synthesis is the primary action of phosphorus; they attribute the increased protein destruction to the necessity of making up for the lessened supply of energy material. The fat transportation to the liver could be similarly explained.

Accordingly Rettig, 1914, found that a diet rich in carbohydrates prevents the increased protein catabolism and the fatty changes. Ray, McDermott and Lusk 1899, also showed that with dogs rendered glycosuric by phlorhizin, phosphorus does not increase the nitrogen excretion; again indicating that the nitrogen excretion is not due to direct destruction of the protoplasm, but is in some way connected with the disturbed carbohydrate metabolism. Lusk, 1907, suggests that the primary action is to inhibit the ferment which burns lactic acid; and that the nitrogen changes are due to the resulting acidosis.

Oxygen Consumption.—The metabolic effects of phosphorus resemble those of oxygen deprivation (e.g., Porges and Pribram, 1908); and it has been suggested that phosphorus renders the cells less capable of utilizing oxygen. However, it is also possible that the metabolic changes in both cases are the secondary result of some other common factor. Indeed, Lusk, 1907, has shown that the oxygen consumption is not diminished but rather somewhat increased, partly by fever, and probably also by the toxic action of increased protein destruction.

Autolysis.—In advanced phosphorus poisoning, the postmortem autolysis of the liver is greatly accelerated (Jacoby, 1900; Porges and Pribram, 1908), probably by decreased resistance of the liver cells to the normal autolytic ferments (Wells). It is not clear what, if any, part this plays in the liver and metabolic changes during life.

Direct addition of phosphorus to excised normal liver does not hasten autolysis (Jacoby). The phenomena are probably analogous to those of late chloroform poisoning.

Bile and Icterus.—The swelling and subsequent cirrhosis of the liver obstruct the bile capillaries, so that the bile secretion is diminished or suppressed; and the gall-bladder contains only a little mucous fluid. The retention of the bile constituents produces the characteristic intense icterus. It was formerly believed that the formation of bile was also increased by the destruction of the blood; but there is no evidence for such destruction.

The Effects on the Liver.—These may therefore be summarized as: disappearance of glycogen; incomplete combustion of lactic acid; increased excretion of ammonia; increased protein destruction with incomplete desamidization of certain amino-acids; fatty infiltration; mechanical interference with bile formation; increased postmortem autolysis; decrease of fibrinogen.

The excretion of p-s-phthaleine is delayed (Whipple and Sperry, 1915). The liver, heart, ganglion and other nerve cells show degenerative changes similar to those of chloroform intoxication (Lissauer, 1914).

Changes in the Blood; Red Corpuscles.—It was formerly believed, on the basis of experiments on birds (Fraenkel and Rochmann), that these were rapidly destroyed;

in man and mammals (Taussig, 1892; v. Jacksch, 1893); however, no destruction occurs even in severe poisoning. In fact the corpuscles are often increased (Ragazzi, 1910; Leoncini, 1914) and this is the typical effect of therapeutic doses.

The hemoglobin is not altered (Leoncini). The viscosity and electrical resistance of the blood are increased by the polycythemia; and remain so until death approaches, when they suddenly decrease. The osmotic pressure of the blood was found increased by Bottazzi, 1896; unchanged by Ragazzi. The *alkalinity* is diminished. The catalase action is moderately decreased (Duncker and Jodlbauer, 1911). The statements as to the *leucocytes* are confused; Ragazzi describes increase of the polynuclear, and disappearance of eosinophiles. According to Leoncini, the leucocytes are at first diminished, then sometimes moderately increased.

The *coagulability of the blood* is diminished. This is probably due to the destruction of fibrinogen or of fibrin ferment; or possibly to the production of peptone bodies by the destruction of proteins (Cividalli, 1902). Denny and Minot, 1915, also find the antithrombin content of the blood diminished.

The *hemorrhagic tendency* is explained by the lessened coagulability of the blood and by the fatty changes in the capillary endothelium.

The *ecbolic action* which occurs with fatal doses may be referred to degeneration of the blood vessels. However, phosphorus also passes to the fetus in sufficient amount to produce fatty hepatic degeneration. Lewin records 27 cases in which phosphorus was used as abortifacient; it induced abortion in 23 of these, and death of the mother in over half of the cases.

Circulation.—Phosphorus appears to have direct toxic effects on the heart-muscle; for with intravenous injection this is paralyzed before anatomic degeneration has set in (Meyer, 1881). In the collapse, splanchnic stimulation is ineffective. In clinical poisoning, the syncopal cases may be due to this cardiac paralysis, but generally the circulation suffers but little until the agonal state.

Muscle and Nerve.—These are not directly affected.

The *Central Nervous System*.—This plays a subsidiary rôle, but is said to show histologic changes (Rossi, 1897).

Local Actions.—Irritation of the mucosæ is shown by the early acute symptoms, but phosphorus is not corrosive.

Chronic Phosphorus Poisoning.—This is seen especially in factories using yellow phosphorus. The most common manifestation is necrosis of the jaw; sometimes bronchitis, to which tolerance is acquired; and cachexia resembling mild acute poisoning.

Strict prophylaxis should be enforced. The manufacture of yellow phosphorus matches has been prohibited in most civilized countries. Exposed workers should attend to ventilation, cleanliness and strict oral hygiene (Ivy, 1911). Persons with defective teeth should not be subjected to the risks.

The *necrosis of the jaws* begins with salivation, suppurative ulceration of the gums, and ends in very profound periostitis, involving the whole jaw. It attacks about 2 or 3 per cent. of all exposed workers, and usually starts in carious teeth. The lower jaw is more often affected. The only treatment is excision of the diseased bone.

Identical necroses in the teeth and other bones have been produced experimentally (Wegner, 1872), by prolonged exposure of rabbits to phosphorus vapor, after laying bare the periosteum. The bone changes are probably allied to those seen in the therapeutic use, but intensified by the more direct contact and by secondary infections.

Phosphorus Burns.—These are no more dangerous than other burns of similar extent and do not produce any of the symptoms of phosphorus poisoning.

Bone Changes by Prolonged Administration of Small Doses.—These stimulate bone formation (Wegner, 1872); in growing animals, the epiphyses form compact instead of spongy bone; in adults, the Haversian and marrow canals are gradually filled with dense bone. This has the normal chemical composition and structure. Larger doses increase the vascularization of the bone (Kassowitz).

Therapeutic Use in Bone-diseases.—The stimulation of bone formation led to the use of phosphorus in rickets, osteomalacia, and delayed

healing of fractures (Kassowitz, 1884). The clinical evidence of its usefulness is contradictory; the best results are reported in rickets, in which it is said to improve not only the bone changes, but all the other symptoms. The improvement should be seen in about four weeks. It has now practically gone out of use, since the cod-liver oil vitamine is generally more effective and avoids the risks of toxicity.

Themister, 1918, found its clinical use to produce distinct stimulation of bone formation, provided that calcium deposition had not been markedly deranged by the disease. Phosphorus would therefore be useful mainly during the "healing stage," when improvement has already started.

The dose is usually about 1 mg. per day, with meals; best dissolved in olive or cod liver oil (0.01:100 c.c.). The solution should be freshly made. A pill (0.6 mg.) is also official. It is coated with Tolu to prevent oxidation.

The administration of phosphorus generally causes some gastrointestinal disturbance; sometimes the jaw necrosis; and rarely typical phosphorus poisoning. It must therefore be carefully watched and stopped if any gastric or intestinal effects appear.

Stability of Phosphorus Preparations.—Engelhardt and Winters, 1915, find the pills and spirit fairly stable, but not always. Compound elixirs are less stable.

Growth.—Phosphorus in doses proportional to those used clinically, administered to young rats with their food over long periods, produced marked and progressive retardation of growth. The animals remained stunted even when replaced on poison-free food. This suggests that the failure of growth may be due to premature solidification of bone, but no observations were made in this direction. With $\frac{1}{25}$ of the clinical dosage, there was first a doubtful retardation of growth; but after 4 months on this dosage, the weight increased markedly above the normal, especially in old animals; with young animals this increase occurred when they were replaced on the poison-free food. No observations were made as to the nature of the over-weight tissue, or of the metabolism (Sollmann, 1924).

Phosphorus in Nervous Diseases.—It has been advised as a tonic in alcoholism, neurasthenia, sexual exhaustion, neuralgia, tabes, cerebral degeneration, etc.; and in chlorosis and anemias. There is little scientific support, either experimental or clinical, for this use.

Zinc Phosphide.—This has been suggested as a therapeutic substitute (Vigier, 1876); there is very little scientific information about it.

Phosphoretted Hydrogen.—This gas (Phosphine— PH_3) is a violent poison; 0.025 per cent. in air is harmful after a time; and 0.2 per cent. is quickly fatal, producing dyspnea, fainting, lowered blood pressure, slowed heart; nausea and vomiting; convulsions and paralyzes; coma and asphyxia. Postmortem examination shows pulmonary congestion and exudation. Industrial poisoning occurs from its presence in acetylene and ferrosilicon.

Phosphorus Pentachloride.—Poisoning is described by Roch, 1914.

PREPARATIONS

Phosphorus (Phosphor.), U.S.P., B.P.—A translucent waxy substance of distinctive odor. Melts about 44°C . Oxidizes (ignites!) on exposure to air. Practically insol. in water, but slightly sol in alc. (1:400). Sparingly sol. in oils. Sol. in fat-solvents. *Dose*, 0.6 mg., $\frac{1}{100}$ gr.; U.S.P., 0.6 to 2.5 mg.; $\frac{1}{100}$ to $\frac{1}{25}$ gr., B.P., as pill or oily solution. These must be recently prepared. *Maximum dose*, 2.5 mg., $\frac{1}{25}$ gr.

Oleum Phosphoratum (Ol. Phosphor.), B.P.; 1 per cent. in olive oil.—*Dose*, 0.06 to 0.3 c.c., 1 to 5 minims, B.P., in almond or cod liver oil, or in capsules.

Pil. Phosphor., U.S.P.—0.6 mg., $\frac{1}{100}$ gr., coated with Tolu to retard oxidation. *Dose*, one pill (U.S.P.).

Pil. Phosphori, B.P.—1 per cent. (formerly 2 per cent.). *Dose*, 0.06 to 0.25 Gm., 1 to 4 gr., B.P.

WATER

The direct application of water to semipermeable cells produces osmotic changes. If the semipermeability is imperfect or impaired, there results a leaching-out of salts, and with this, a disturbance of the ion-ratio.

Instances of these deleterious actions are the water-laking of blood; the swelling and water-rigor of muscle, etc. The surfaces which are normally exposed to contact with water are protected against these actions, either by their impermeability, as the skin and bladder; or by the rapid passage of salts into the water, as in the alimentary tract. Even in these situations, however, the water causes more or less swelling, stimulation or irritation of the cells.

Water is, of course, an essential constituent of all protoplasm. It constitutes about two-thirds of the body-weight, 75 to 90 per cent. of the active tissues, 40 per cent. of bones. Since it is constantly lost to the body by the urine, lungs, perspiration and feces, this would lead to drying and concentration of the tissues; but before this reaches a demonstrable degree, the sensation of thirst prompts the replacement of the water. Any excess of water is promptly eliminated by the excretions, which are correspondingly increased and diluted. However, there is a temporary increase of the water content of the fluids and cells of the body; a removal of their salts; and alterations in the proportions of their ions. These changes in turn produce functional phenomena, characterized especially by increased secretions, and by changes in metabolism. The effects vary according to whether the quantity of water is normal or excessive; and according to the channel by which it is introduced. In addition to the water that is introduced as such, the alimentary canal reabsorbs the three to five liters of water that are secreted into it in the digestive juices.

Absorption from Alimentary Canal.—Water is rather slowly absorbed from the *stomach*, where it also delays the absorption of other substances. However, it passes rapidly into the duodenum, and is absorbed readily from the *intestine*, small and large; and in these it favors the absorption of dissolved substances. In health, the absorption occurs mainly in the upper portions of the small intestine (v. Mering, 1893; Moritz, 1893). The colon absorbs nearly two thirds of the water that enters the cecum; leaving about 75 per cent. of water in the normal, semi-solid feces.

Absorption by the Skin.—Water is not appreciably absorbed through the normal skin, although it is slowly absorbed into the epithelium, and produces swelling of the epidermis. Bathing in cold water contracts the cutaneous vessels, and diminishes the loss of water by perspiration; while hot water increases the loss favoring diaphoresis.

Digestion and Absorption of Food.—The ingestion of water with meals has decidedly beneficial effects upon all the digestive organs, even when the quantity of water is quite large (a liter with each meal); provided that the food is thoroughly masticated. It aids the digestive action of the saliva; increases the flow of gastric juice, its pepsin and acidity, and thus presumably the flow of pancreatic juice. It secures better absorption of the food, thus leaving less material for the intestinal bacteria, decreasing their number and the putrefactive processes. The same beneficial effects are secured with distilled water, which has no detrimental effects even in prolonged fasting experiments (Hawk, 1914).

These effects are utilized in the treatment of certain dyspepsias. Water is often useful in nausea. It is also valuable as a diluent for irritant drugs. Excessive water consumption would probably be harmful in gastric atony.

The secretion of *acid gastric juice* is increased (Heidenhain, 1879; Pawlow; Foster and Lambert, 1908; Sawitsch and Zeligony, 1913; and others).

Even 50 c.c. increases the acidity and peptic activity quite strongly. The degree of action is not influenced materially by the quantity, temperature, or by the presence of food (Bergheim, Rehfuß and Hawk, 1914).

The gastric stimulation does not occur in all cases. It is perhaps due to the washing of the hormone gastrin into the intestine (Ivy, 1918).

The flow of pancreatic juice and bile is also stimulated. The dilution would accelerate the action of the digestive enzymes. The diastatic efficiency of saliva is increased, the optimum being reached with 1:7 dilution (Bergheim and Hawk, 1913).

The *discharge of the gastric contents* is hastened (at least after a meal of meat, although not with potatoes; Hedbom and Cannon, 1909). The water does not actually mix with the gastric contents, but passes along a trough formed on the surface (Cohnheim).

The *rate of discharge* of water from the empty human stomach varies normally between 100 to 400 c.c. per minute. Older figures were higher, but misleading (Ivy, 1918). The *hunger contractions* are allayed by drinking water (Carlson, 1913). Hawk and his pupils (Howe, Mattill, and Hattrem, 1911 and 1912; Blatherwick and Hawk, 1913) found the *feces* reduced in weight and containing less nitrogen (both food and bacterial). The utilization of fats and carbohydrates is not affected (Blatherwick and Hawk, 1914). *Intestinal putrefaction* (as judged by indican) was lessened (Sherwin and Hawk, 1914); the acidity of the feces was increased. The effects are distinct, although they are naturally not very great in healthy subjects (Spiegler, 1901).

Hydremia.—The drinking of a large quantity of water, produces a slight but definite hydremia, as shown by a slight decrease in the electric conductivity of the serum (T. M. Wilson, 1905).

Haldane and Priestly, 1916, attribute this to the passage of salts into the intestines. Blix, 1916, found that the administration of water to well-fed rabbits could increase the water-content of their blood by a maximum of 11 per cent. Fasting and withholding water diminished it, also by a maximum of 11 per cent. on the second day. After that, it remained constant. Sublimate nephritis also produced hydremia.

Very intensive forcing of water by the administration of 500 c.c. every hour to a dog, by stomach tube, reduces the hemoglobin by about 15 per cent., the serum protein by somewhat more, and serum chloride by about 30 per cent. (C. H. Greene and Rowntree, 1924.)

Water in Traumatic Shock and Hemorrhage.—The oral or rectal administration of fluid appears to maintain the blood-volume better than the intravenous injection of saline or even of acacia solution; although it does not, of course, act as promptly (O. H. Robertson and Bock, 1919, Cannon, 1919).

The Excretion of Water.—This occurs by the kidneys, lungs, skin, and intestine. The relative importance of these channels varies with conditions. If, for instance, the water is taken hot (so as to favor dilation of the cutaneous vessels), it will act as a *diaphoretic*. If the conditions are not favorable to diaphoresis, it will be excreted mainly by the kidneys. Excessive quantities of water may also be excreted by the *intestine*, if the conditions are favorable, and may thus lead to diarrhea.

The Diuretic Effect of Water.—When the water is absorbed from the alimentary tract, the diuresis is prompt, strong, and certain so long as the kidneys are normal.

Three to 5, and even 10 liters may be taken and absorbed in the day, in man, without altering the consistence of the feces. If a large quantity is ingested, a half to three-fourths may be excreted by the urine within forty-five to ninety minutes (Mattill and Hawk, 1911). The excretion may be forced above 10 liters per day, and continued for several weeks, apparently without deleterious effects to the kidneys or otherwise; this does not even create salt-hunger (Sollmann and Hoffmann, 1905). The diuretic action of moderate quantities of water can be greatly enhanced by the addition of other diuretics, but if very large quantities of water are given, the addition of diuretics has no further effect.

Haldane and Priestly, 1916, found no definite relation between the diuretic response to water and hydremia, as judged by the hemoglobin concentration of the blood.

Hypodermic and intravenous injection of water produce little or no diuresis. Hashimoto, 1914, attributes this to deficiency of salts, and not to the production of any diuretic substance in the alimentary canal, as was believed by Cow, 1914.

Composition of the Urine.—The urine in water-diuresis becomes very dilute, although the total or daily excretion of the dissolved constituents is generally increased. However, there is no simple relation between the increase of the different constituents, for instance N and Cl (Heilner, 1906).

Therapeutic Use of the Diuretic Effect.—This is especially useful for diluting the urine, to lessen its irritation in inflammations of the urinary passages; and to prevent the precipitation of its constituents in urinary calculi.

Diuresis for Removal of Poisons.—This has only a very limited efficiency.

Very energetic diuresis, by water or by intravenous saline or glucose, is able to save animals from *slightly* superfatal doses of strychnine (Eggleston and Hatcher, 1917; Kleiner and Meltzer, 1917); but is quite inefficient against diphtheria toxin (Sansum, 1918).

Use in Fever.—Cushing (1905) found the administration of very large quantities of cold water (4 ounces every fifteen minutes while awake) of marked benefit in *typhoid fever*. It serves to keep the mouth clean; it must have a distinct antipyretic effect; and it may aid by eliminating toxins and waste products.

The water would act as an antipyretic by its own temperature, and by facilitating perspiration and heat loss (see the work of Barbour, under Heat Regulation). It also serves to keep the mouth clean. Balcar et al., 1919, found that "salt-fever" can be prevented by giving plenty of water. The effect of water in fever has also been investigated by Schwenkenbecher and Inagaki, 1906.

Blood-Pressure.—The increased ingestion of water (for man, 3 liters beyond the normal) is said to produce a material lowering of the systolic and diastolic pressure, normally and in hypertension (J. B. Orr and Innes, 1922).

Metabolism.—Increased ingestion of water flushes salts and metabolites from the tissues and tends to increase protein metabolism and oxidative changes.

Increased Nitrogen Excretion.—The administration of large quantities of water causes a very considerable temporary increase in the *urinary nitrogen*, as much as 34 per cent. (Neumann, 1899). The excess is excreted mainly as urea; the uric acid being often unchanged. Firahall and Hawk, 1912, found the *uric acid output* in man decreased, while the allantoin was increased. The excretion of the phosphates and sulphates is also increased. The removal of chlorides is so extensive that their percentage in the urine soon falls to a very low figure.

Other Urinary Constituents.—Wilson and Hawk, 1914, report that the ingestion of additional water, moderate or abundant, causes a temporary decrease in the daily output of *chloride*; presumably through the need of equalizing the osmotic pressure of the retained water. The *ammonium* is increased (presumably as a consequence of the heightened gastric acidity), the *phosphate* unchanged, the acidity variable.

Increased Metabolism.—The excessive excretion of metabolites is mainly due, beyond doubt, to the "flushing out" of the tissues by the diuresis (Haas, 1908). But if this were the only cause, the continued excessive administration of water would soon exhaust the stored waste products, and their excretion would fall rather below the normal figure. Actual results show that this holds for the chlorides, but not for N, P or S; their excretion remains permanently increased, although it does not remain at the original high figure (Edsall, 1900). There must therefore be an *increased production of these metabolites*.

Metabolism in Animals.—This conclusion is supported by the results on *animals*, although these are somewhat different from those obtained on man. Dogs in nitrogen equilibrium do not show any permanent changes in their nitrogen excretion when four times the normal quantity of water is administered, notwithstanding the increased diuresis. In starving dogs, however, it may be increased by 80 per cent. The explanation of these discordant results is probably that the removal of the water by diuresis keeps step with the absorption in the fed animals; so that it never comes to any considerable increase in the water content of the body, and the metabolism is therefore not increased.

Nitrogen Retention in Nephritis.—The increased N elimination following liberal water administration lowers the abnormally high N figures of the blood. However, to reduce these to the normal level, it is necessary to employ both water administration and limitation of N intake (N. B. Foster and Davies, 1916).

"Alterative Effect" and Use in Obesity.—Water, especially in the form of mineral waters, is employed for its metabolic effects in a variety of obscure conditions, particularly in obesity, but the results are uncertain.

It is difficult to predict whether the breaking down of protein molecules will increase or diminish the body fat. If it is only partial, it may result in the formation of fat from the proteins; if carried further, it may lead to the destruction of fat as well.

Local Actions.—Water is mildly stimulant and irritant to sensitive surfaces.

The growth of artificial cultures of frog's tissues is hastened by diluting the serum of the culture fluid (Ruth, 1911).

The effects of baths and similar hydrotherapeutic measures depend upon reflexes due to the physical action of temperature, etc.

Distilled Water.—This is more injurious than ordinary water to the lower animals and to excised tissues; partly because of the total absence of salts (especially of calcium, thus probably altering the permeability of the plasma membrane; R. H. True, 1914); and partly because it often contains traces of copper and ammonium compounds. *This toxic action can not occur by the drinking of distilled water by higher animals*, which obtain their salts from food rather than from water: The salts of the food would in all ordinary cases be more than sufficient to cover the deficiency of salts in the water. The statements, which are occasionally made, that the drinking of distilled water leads to toxic effects, are therefore entirely groundless: Distilled water is often drunk exclusively on ships, without any bad results. Nor is distilled water detrimental in nephritis (Marcus, 1907).

Effects of Water by Intravenous Injection.—The immediate effects of small amounts, slowly introduced (and especially of *hypodermic injections*) bear a general resemblance to those following the injection of isotonic salt solutions. The changes in metabolism and urine are probably similar to those which occur on taking water by mouth. Larger doses and rapid injection introduce important modifications. Hemoglobin appears in the urine, from the laking of the blood corpuscles. The respiration is slowed and the blood pressure is lowered. The central nervous system shows rather late paralysis and convulsions. The diuresis is quite small, since the hypoisotonic condition of the blood slows the renal circulation by the swelling of the kidney cells. The excretion of water occurs mainly by other channels, so that there is usually a serous diarrhea, increased salivation, etc. The fatal dose of water (by intravenous injection) is somewhat smaller than that of normal saline solution; distilled water is again somewhat more toxic than well water.

The Withholding of Water.—This affects the metabolism in much the same way as the administration of salts in hyperisotonic solution: The excretion of metabolites is at first lowered, by the lessened diuresis; but as the destruction of proteins is at the same time increased, the excretion of metabolites is also increased after a time. When water is given, the stored metabolites are washed out, leading to a very greatly increased excretion (Landauer, 1895; Straub, 1899; Spiegler, 1901).

Thirst.—This is a very delicate reaction to concentration of the tissues. Cannon, 1919 conceives the mechanism as drying of the mucosa of the mouth and pharynx, attributable to diminished output of saliva; this is turn, being conditioned on the limitation of water in the system. However, further investigation is needed.

PREPARATIONS

Aqua, U.S.P.—The purest natural potable water obtainable.

Aqua Destillata (Aq. Dest.), U.S.P., B.P.; Distilled water.

Aqua Destillata Sterilisata (Aq. Dest. Steril.), U.S.P.—Sterilized Distilled Water for injections should, if possible, be used within forty-eight hours after its preparation; for old distilled water is seriously contaminated with bacterial products.

MINERAL WATERS

These will be discussed more in detail in other places, according to their ingredients, but the whole subject may be very briefly summarized in the following compilation:

The action of natural mineral waters has been known empirically since remote times. Their use came about probably by accidental observation and also through the marked taste which they possess.

Spring and Artificial Mineral Waters.—A very striking observation was early made, namely, that these mineral waters, when used at their source, appear to be more effective than artificial compounds of practically the same composition, or even than the same water when used at a distance.

The most diverse explanations for this have been advanced. Especially in the case of thermal waters, so-called tellurial forces, some mysterious property imparted to them by the earth, have been invoked. Since the discovery of radium, it has been found that some mineral waters are slightly radioactive, and this has been used to explain their action. Others, again, have laid great stress upon the presence of minimal traces of rare elements, somewhat upon the homeopathic principle. Still others believe that the artificial waters—even if they contain the same elements in the same proportion—do not contain them in the same state of combination; for instance, that the artificial water would contain NaCl and MgSO₄, the natural water MgCl₂ and Na₂SO₄. This is, of course, contrary to the demonstrated facts; all solutions containing the same proportions of the same ions, will have these ions present in the same state of combination, no matter what particular salts were used to introduce these ions. There is nothing in any of these theories. Mineral waters are simply solutions of the ingredients of the soil, and possess only the action of those ingredients which are present in notable amount.

The difference between the water of natural sources and the artificial solutions rests upon other causes, which are sufficiently easy to appreciate, but difficult to reproduce.

These factors refer largely to hygiene and climate. A large proportion of the effects must be attributed to the rest, the freedom from care and business pursuits, the exhilarating effect of improved hygienic, atmospheric, and scenic conditions, better regulation of all the habits, of diet, exercise, etc. The mere drinking of large quantities of fluid is also something which it is difficult to enforce at home, but which the patient does regularly in watering-places. Added to these comes finally the specific action of the dissolved salts.

The effect of mineral *baths* is purely local and reflex. There is practically *no absorption* of the dissolved salts through the skin. The effects are in general the same as with hydrotherapy, excepting that they are somewhat stronger.

The waters of mineral springs vary in **temperature**; those below 25°C. are called cold; 25 to 37.5°, warm; above this, hot.

The **molecular concentration** of mineral waters varies considerably; the depression of freezing-point is 1.0150 for Hunyadi and Apenta; 0.320 for Vichy; 0.275 for Carlsbad; 0.240 for Apollinaris, etc. (Kostkewicz, 1899).

Classification.—These waters are usually classified according to the contained **salts**. Various classifications are current. The following will be used here:

1. Plain Saline (NaCl).
2. Carbonated: $\left\{ \begin{array}{l} (a) \text{ Plain.} \\ (b) \text{ Alkaline (NaHCO}_3\text{).} \\ (c) \text{ Saline (Na}_2\text{SO}_4\text{).} \end{array} \right.$
3. Magnesia.
4. Sulphur.
5. Chalybeate.

Occasional constituents of small importance are Ca, I, Br, Li, and As.

The physiologic effects of the majority of these constituents will be discussed under their respective headings, and will only be very briefly alluded to in this place. It will also be impossible to take up the composition and special indications of the different mineral waters, in anything like an exhaustive manner. It will be necessary to illustrate these classes on only a few well-known waters. It need scarcely be mentioned that the above classification is not an absolutely sharp one, but that many mineral waters belong partly to several classes.

The composition of American Mineral Waters may be ascertained from the publications of the U. S. Bureau of Chemistry.

1. Plain Saline Waters.—These are used mainly externally for baths. The most typical is sea-water (see Index).

Artificial sea-baths may be made by dissolving 4 per cent. of sea or rock salt in water.

Some of the important saline sources are the following:

European:

	Per 1,000: Fixed salts	NaCl	Temperature (C.)
Kissingen.....	15	11	18.5°
Baden-Baden.....	28	21	18.5°
Nauheim.....	30	25	33.0°

American: Saratoga Congress, New York, approaches Kissingen.

2. Carbonated Waters.—(a) **Plain.**—In these the CO₂ is the main constituent. This aids digestion, and these waters are used mainly as plain table waters. The most used is the artificial soda-water.

An example of natural carbonated water is Apollinaris:

Per 1,000 Gm.:

NaCHO ₃	NaCl	Na ₂ SO ₄	CO ₂	Temp.
1.2	0.4	0.3	1.5	21°

(b) **Alkaline.**—These contain a notable amount of NaHCO₃. They have the alkaline effects and are therefore useful in gastric catarrh, hyperacidity, hypersecretion of mucus, and as diuretics, in obesity, gout, urate stones, and diabetes. They are most useful when taken hot and drunk very slowly, since in this way they cause the least irritation in the stomach.

(c) **Alkaline Saline Waters.**—These waters usually contain in addition some Na₂SO₄. The indications for use are the same as for the preceding. The cold waters contain more CO₂ (Marienbad and Franzenbad). The hot alkaline waters are very numerous.

The following may be taken as examples:

European Carbonated Alkaline Waters, per 1,000:

	NaHCO ₃	Free CO ₂	NaCl	Na ₂ SO ₄	Temp.
Vichy.....	5.0	500	...	0.2	40°
Ems.....	2.0	500	1.0	...	40°
Selters.....	1.2	1,200	2.3	...	cold
Spa, Pyrmont, Wiesbaden.					

American: Saratoga Selters, Saratoga Vichy, Sweet Springs of Virginia, Gettysburg, etc.

(d) **Of the carbonated saline waters** the most representative is the *Carlsbad*. The formula for the artificial salt is:

K ₂ SO ₄	0.12
Na ₂ SO ₄	2.64
NaHCO ₃	2.16
NaCl.....	1.08
	6.00 Gm.

This quantity (a teaspoonful) is the proper amount for a liter (quart) of water.

3. Magnesia Waters.—These contain MgSO₄, Na₂SO₄, CaSO₄, MgCl₂, but no CO₂. They are useful as cathartics.

European, in 1,000 Gm.:

	MgSO ₄	Na ₂ SO ₄	CaSO ₄	NaCl	MgCl ₂
Hunyadi János.....	22.3	22.5	...	1.3	...
Seidlitz.....	13.5	...	1.4	...	0.4

Epsom and Friedrichshall belong to the same class.

American: Crab Orchard, Kentucky; and Bedford Springs, Pennsylvania.

4. Sulphur Waters.—These contain free H₂S and sulphides. Externally they stimulate the skin and soften the epidermis; internally they act as cathartics. They have considerable reputation in the treatment of chronic rheumatism. Some examples are: Aix-la-Chapelle, Harrogate, Virginia Sulphur Springs. The following will give an idea of their composition.

In 1,000 Gm.:

	Free H ₂ S	Na ₂ SO ₄	NaCl	Temp.
Aix-les-Bains.....	0.003	0.092	0.030	44°

5. Chalybeate Waters.—These contain Fe, usually as bicarbonate, also NaCl and Na₂SO₄. The amount of iron is from 0.01 to 0.12 of FeO per liter. The most famous springs are: Tunbridge and Brighton in England; Pyrmont, Wiesbaden, and Spa on the Continent; Bedford, Pittsburg, Brandywine, and several Virginia springs, in the United States.

SODIUM CHLORIDE

Sodium chloride constitutes the greater part of the electrolytes of the tissues (with certain exceptions), and especially of the fluids, of vertebrates. Its ions are essential for the functioning of most cells. Since the ions are constantly excreted, especially by the urine, they must be constantly replenished, leading to the instinctive use of salt in food. Its administration to mammals, even by intravenous injection, produces practically only osmotic effects; but marked ion-actions may be observed by exposing excised tissues to solutions with or without the sodium and chloride ions.

The therapeutic uses of salt depend mainly on its osmotic effects. These result in stimulation of the gastric mucous membrane, leading to its use as condiment and in some indigestions; under suitable conditions, a laxative action; irritation of the skin, with attending reflex stimulation, utilized as salt-water baths. After absorption, it leads to diuresis and slight metabolic changes. Isotonic solution is used as vehicle or for cleansing sensitive mucous membranes, *f.i.*, the nose; and for hypodermic and intravenous injections. These saline infusions are employed in hemorrhage, collapse, and for the dilution or removal of systemic poisons.

The intravenous injection of strongly hypertonic solutions is fatal, with stimulation and paralysis of the central nervous system.

Retention of chloride occurs in certain pathologic conditions, especially pneumonia and other fevers, nephritis, cancer, etc. Its mechanism is not explained. It may favor the formation of edemas, against which salt-poor diet is sometimes efficient.

NaCl Income.—With ordinary diets, this ranges between 10 and 15 Gm. per day; but its reduction to 5 Gm., or even 1 to 2 Gm., causes no disturbance. Carnivorous animals obtain a sufficient supply in their food. But since K predominates over Na in the ash of plants, herbivora and animals feeding on a mixed diet require additional NaCl. This need has led to the *instinctive use of this salt*: in regions remote from deposits of this salt, ashes of plants which are rich in Na have been used by peoples as ignorant as the negroes of the interior of Africa. A table of the salt content of food is given by Leva, Arch. f. Verd. Krankh. 16: 267.

Distribution of NaCl in the Body.—The most exact and comprehensive determinations are those of Wahlgren, 1909, and Padtberg, 1920, on dogs. Similar relations probably hold for man and other animals: The entire body contains about 0.17 per cent., expressed as Cl (0.11 per cent., Rosemann, 1910). Of this, about a third is in the skin, the remainder chiefly in the blood muscles, bones and intestines. The highest percentage of Cl exists in the skin (0.38 per cent.); then the blood (0.31 per cent.); kidneys (0.26 per cent.); and lungs (0.24 per cent.). The brain, bones and intestines contain 0.17 to 0.18 per cent.; the liver, 0.13 per cent.; the muscles only 0.07 per cent. According to other determinations, blood serum contains 0.36 to 0.42 per cent. (equivalent to 0.60 to 0.64 per cent. NaCl); saliva, 0.16 to 0.24 per cent. Cl; the human intestinal juice 0.38 to 0.67 per cent. NaCl; sweat, 0.285 per cent. (Kovesi); human gastric "appetite" juice 0.49 to 0.56 per cent. Cl (Carlson, 1915). The red blood corpuscles contain 0.12 to 0.18 per cent. of Cl, and 0.21 to 0.28 per cent. of Na₂O; except in some animals (horse, pig and rabbit), whose corpuscles contain practically no Na (see Potassium). The chloride content of the entire human body is estimated at 60 to 133 Gm., equivalent to 150 to 300 Gm. of NaCl (Magnus-Levy, 1906).

Artificial Variations of Chloride Content.—Padtberg studied the changes following the intravenous injection of NaCl. Here, also, the skin maintains the highest percentage; but because of their greater mass, the muscles and intestines take up the greater absolute amount. With Cl-poor food, the total Cl content sinks to 0.137 per cent., the loss being greatest from the skin. The skin therefore acts as a chloride depot, storing and giving off most of the excessive or deficient Cl. Rosemann, 1911, found the entire Cl content increased by 100 per cent. when dogs were given highly salted food. With the return to normal diet, the Cl content returned to one and one-half times the ordinary level within five days; the further fall to normal occurred much more slowly.

Austin and Jonas, 1918, confirm that the *chloride content of the blood* is not materially and persistently altered even by prolonged diets of either high or low chloride content.

Chloride Content in Disease.—Biernacki, 1894, found the Cl of the blood constant in numerous diseases. Javal and Adler, 1906, determined the percentage of Cl and water in the organs after death from various diseases, with a special reference to edema; but the results were not decisive.

Leva, 1915, states that human organs in renal, cardiac and vascular disease may contain twice, the skin even three times, the normal amount of Cl, without material increase of their fluid. Similar results were obtained on uranium rabbits.

F. C. McLean, 1915, found the chloride of the plasma increased, clinically, in cardiac and renal disturbances, and in pneumonia; diminished in diabetes and with diuretics. The chloride and urea content of the plasma do not go parallel. In uremia, the diminution of blood-chloride is concomitant with increased hydrogen ion concentration (McLean 1916).

Microchemic Distribution.—A. B. Macallum, 1905 and 1908, found the chloride most abundant in the inactive tissues, especially in the intercellular spaces and in degenerating cells. It is absent from the nuclei (as also PO_4 and K, and probably all other inorganic ions); but it occurs abundantly in the cytoplasm. Nerve fibers are rich in Cl, especially the axons; but the myeline sheaths are free from it, and nerve cells contain very little (Macallum and Menten, 1906).

Excretion of Chloride.—This occurs mainly by the urine, chiefly as KCl; only a small part being lost by the feces and perspiration. The excretion varies quantitatively with the salt income, but generally lags somewhat behind in time. The administration of salt therefore produces a temporary accumulation in the tissues. With a steady income of salt and water, equilibrium is reached, in normal man, in three or four days (Borelli and Girardi, 1915). If the supply of salt is stopped, the excretion falls to a very low level within three days, the tissues retaining their normal salt content with very great avidity. A small excretion (0.6 to 0.9 Gm. daily in man) continues, however, so that the tissues finally lose salt. This leads to the phenomena of "*salt-hunger*." A normal kidney can excrete 15 to 20 Gm. of NaCl per day.

Feces.—The fecal chloride excretion is normally insignificant, but in nephritis it may reach 3 to 5 Gm. NaCl per day (Javal, 1903; Halpern, 1905).

Diurnal Variations.—In man, the urinary chloride excretion is always greater in the forenoon than in the night, independently of meals. The midday meal has an influence, the excretion being decreased half an hour after eating, due to the gastric excretion of HCl. This lasts an hour, and is followed by marked increase (Herrmannsdorfer 1912).

Time of Excretion.—Giving 10 Gm. by mouth, the additional chloride should be excreted within twenty-four to forty-eight hours, either by diuresis, or by increased salt concentration. A longer delay indicates impaired permeability of the kidney.

The observations of Vallery-Radot, 1918, may be taken as an example of the normal course; An individual of a so-called "*salt-free*" diet, which actually corresponded to 1.5 Gm. of NaCl per day, was excreting 2.0 Gm. per day. When changed to a normal diet, containing 11.5 Gm. of NaCl per day, and kept on this, he excreted, on the first day, 3 Gm.; second day, 5 Gm.; third day 11 Gm.; fourth day to the 9th day, 11.5 Gm. daily. On changing to a salt-free diet, the reduction of the excretion followed a similar (inverted) course. Schlayer and Takayasu, 1913, consider the salt and iodide excretion as an index of tubular activity; whereas water and lactose excretion indicate the renal vascular function. This classification is based on rather ill-established assumptions.

Influence of Other Salts and Diuretics.—The excretion of Cl can be hastened by the administration of related salts (bromides, iodides, nitrates, thiocyanates). Conversely, the administration of Cl hastens the elimination of these salts, and may be useful against iodism and bromism. Diuret-

ics have little effect; the drinking of large quantities of water reduces the percentage of Cl in the urine; the absolute quantity may be unchanged or moderately increased (Rulon and Hawk, 1911).

With dogs, theobromine and caffeine diminish the Cl, both absolute and percentage, independently of any diuretic effect (Saccone, 1911). In rabbits, however, these and other diuretics tend to increase the Cl excretion proportional to the diuresis (Bonnamour and Imbert, 1912).

Chloride Retention.—The chloride excretion is greatly diminished in some cases of nephritis; in fevers, particularly in pneumonia (where much salt is retained in the effusion); and during the rapid development of new tissue (cancer).

Retention in Fever.—This was first described by Redtenbacher, 1850, and has been extensively investigated, especially by Rochmann, 1889. The low Cl excretion is partly due to the low Cl income; but even when this is taken into account, there is a considerable deficit in the output, *i.e.*, a true retention (Garratt, 1904). This is especially marked in pneumonia; and the Cl in the exudate is not sufficient to account for the difference. The retained Cl seems to be distributed indiscriminately through all tissues. The Na and Ca are also retained, while K and Mg are excreted normally or in excess (Peabody, 1913). Medigreceanu, 1911, found a comparatively slight Cl retention in turpentine pleurisy, and none in pneumococcus septicemia in rabbits. This indicates that the retention is connected with the pulmonary changes. Snapper, 1913, attributed the retention to altered cell permeability; for he claims that the addition of sodium sulphate to blood causes the passage of NaCl into the corpuscles in fever; whereas normally it causes the passage of Cl out of the corpuscles. McLean, 1915, found the diminished excretion in pneumonia associated with lowered Cl content of the plasma. At the crisis, the Cl increases both in the plasma and in the urine.

The whole subject is still very obscure; but from the work of Barbour and others, it appears that fever is associated with increased fluid affinity of the tissues; and this would bring with it a corresponding retention of chloride.

Retention in Cancer.—The diminished excretion is probably explainable entirely by the deficient Cl income, and its need for the formation of new tissues and transudations (Gaertig, 1890; Laudenheimer, 1892).

Retention in Nephritis.—This was mentioned in connection with edema. It is most apt to occur in acute glomerular nephritis (Borchardt, 1912). However, in chronic parenchymatous nephritis the ability to excrete chloride is generally impaired before the nitrogen excretion (O'Hare, 1916), and, the impairment keeps step with the severity of the lesion. Chronic interstitial nephritis is not generally characterized by defective chloride excretion.

The Cl excretion is increased in the early diuretic stage of uranium and cantharides nephritis; it is usually diminished with large doses of uranium or chromate. The Cl excretion bears no simple relation to the anatomic changes (Austin and Eisenbrey, 1911).

Salt Test for Nephritis.—Schlayer, 1911, keeps the patient on a constant diet for several days, then adds 10 Gm. of NaCl in one dose. This excess is normally excreted within twenty-four or at most forty-eight hours. A delay beyond this indicates diminished permeability of the kidneys to chlorides. Frothingham, 1915, classifies the excess excretion within forty-eight hours, of 8.5 Gm. as no retention; 4.5 Gm. as slight retention; less than 4.5 Gm. as considerable retention. Hedinger and Schlayer, 1912, now employ a "nephritic test meal." A strictly similar test may be made with urea, 10 Gm. of which should also be excreted within forty-eight hours. The urea excretion is impaired particularly in chronic interstitial and not in chronic parenchymatous nephritis; *i.e.*, just the reverse of chloride retention (v. Monakow, 1914).

Diabetes.—The literature contains contradictory statements as to the chloride metabolism in human diabetes (Lebensohn, 1915). The "chloride threshold" of the blood is either unchanged or lowered (McLean, 1915).

In pancreatectomized dogs, Lebensohn found the chloride metabolism quite normal, but Rabens, 1915, claimed that such dogs excrete only $\frac{1}{10}$ to $\frac{1}{4}$ of the chloride of normal dogs on the same diet.

Beard and Rowntree, 1917, report that diabetic patients when permitted, often consume large quantities of sodium chloride with their diet, and develop retention edema. They are also subject to "salt edema" from sodium bicarbonate administration.

Mechanism of Chloride Regulation.—The blood maintains its chloride concentration remarkably constant, and even the tissues undergo only temporary changes. The regulation is accomplished through the adjustment of the urinary excretion; but the mechanism by which this is controlled is not understood, notwithstanding extensive investigations. The problem is possibly analogous to that of the regulation of the sugar content of blood.

Colloid-chloride Combination.—One theory (Forster, 1873) assumes that the greater quantity of the salt exists in the body in a form (perhaps as a *combination with the proteins*) in which it can not pass through the living kidneys. This salt would therefore be retained with great tenacity. Any excess, over this, such as is normally present, is free and filters very readily into the urine. This theory agrees with the observation of Sollmann (1902) that the injection of those ions which are closely related to chloride (viz., Br, I, NO₃, SCN) increases the chloride percentage in the urine, while other ions do not have this effect: it could be assumed that the related ions can displace the chloride from its protein compound. However, all attempts to prove by chemical or physical methods the existence of such compounds in the blood have failed. Rona, 1910, *f.i.*, showed by "compensated osmosis" that the Cl of the blood diffuses exactly as if it were in the ordinary ionic condition. M. Fischer, 1915, believes that retention of salt and water are both due to imbibition of body colloids, which is increased by acids, and therefore he thinks by acidosis.

Cushny (1902), attributes the chloride regulation to the absorbing mechanism of the tubules.

Chloride Threshold.—Ambard and Weil assert that there is a certain threshold of the NaCl concentration of the plasma—normally 5.62 Gm. per liter. If the concentration falls below this, no chloride is excreted; if it rises above, the excretion varies as the square of the excess (McLean, 1915).

Limited Salt Income.—The maintenance of a certain salt content is indispensable to the body, sodium chloride being especially important. Animal food appears to contain a sufficiency of this salt; while a herbivorous and omnivorous diet is insufficient in this respect. Under ordinary conditions, the excretion of salt keeps perfectly parallel with the salt income (Falk, 1848), so that a moderate excess of salt income is practically without effect, except on the urine. A very limited salt income (as by an exclusive milk diet) can also be borne for a considerable time, being met by a corresponding decrease of chloride excretion, so that the percentage of the salt in the blood is scarcely altered, and no general symptoms whatever result. Dogs on a Cl-poor diet retain Cl or I more efficiently than an ordinary food (Sarvonat and Cremien, 1911). The diminished income of salt in fever seems to have no deleterious effect. Even when the excretion is further increased by liberal water-diuresis, the patients show no particular craving for salt. Complete abstention from food also does not produce any effects referable to the absence of salt. After a ten-day fast, the total quantity of Cl in the body is reduced by only 2 per cent.; and the percentage of Cl is even above the normal, because the tissues disappear more rapidly in starvation than does the Cl (Rosemann, 1912). D'Er-rico, 1910, found no change in the freezing-point or conductivity of the blood in inanition. The inorganic metabolism in starvation has also been studied by Cathcart and Fawsitt, 1907.

Salt Starvation.—This may be produced by feeding food deprived of all its salts (J. Forster, 1873), or by "deceptive feeding," abstracting the gastric juice through a fistula (Rosemann, 1912). Forster found that pigeons died in thirteen to twenty-nine days; dogs in twenty-six to thirty-six days. In man, an abstinence of nine days is serious, but not dangerous. The subject does not return to normal for a week or two after resuming the consumption of salt (E. Taylor, 1904).

The process of removing of salt from food is also bound to result in deficiency, of vitamins, unless these are added artificially. This was not done by the experimenters since the existence of vitamins had not been recognized at that time. The following phenomena may therefore have been due in part to vitamin deficiency:

The animals emaciate rapidly, [through anorexia and other interference with digestion and absorption. Great muscular weakness and tremors, with occasional convulsions, are very prominent. The mental faculties are dulled. The urine and breath contain acetone. The loss of the mineral constituents of the body is relatively small. The N excretion is fairly equal to the income. A conspicuous change is the decrease in the excretion of *gastric HCl* (Cahn, 1886). This stops completely when the chloride stock of the body has fallen by 20 per cent. (Rosemann, 1912). It is not known how far

the other changes are due to mere Cl loss; and how much the absence of the other ions contribute to the result.

Salt-poor Diet.—The use of NaCl poor food in edemas, etc., was discussed previously. Javal, 1912, suggests the addition of sodium iodide or bromide to improve the taste of the unsalted bread. Cl-poor diet has also been employed to enhance the retention of the bromide ion in *epilepsy* (Toulouse and Richet, 1900). Indeed, the efficiency of the bromide treatment has been referred to de-chloruration; but this is probably erroneous (see Bromides; Januschke, 1913). Tables of the content of the various salts in foods are given by Albu and Neuberg, *Mineralstoffwechsel*.

Effects of Excessive Consumption of Salt.—By means of the regulating mechanisms, an excess of the Na or Cl ions is eliminated very promptly, and could not produce any very large effect. But even when they are retained, these ions *produce only very small actions*, for the amounts normally present are so large that the artificial introduction of ordinary amounts will not increase their ratio to a considerable extent. Na and Cl are therefore the most indifferent of the ions, and their salts are used when the effects of other ions are to be tested. It is important to remember, however, that they are really very essential to the protoplasm, and that the absence of effects is due only to the fact that the variations which are introduced are relatively small.

Local Actions of Salts.—Salts in isotonic or hypotonic solutions have little local action; in substance or in hyperisotonic solutions they act as rather mild irritants, without destroying the tissues.

Action on the Skin; Salt-baths.—Sodium chloride and other neutral salts, e.g., in the form of sea baths, produce a mild but extensive stimulation of the skin, and thereby reflex tonic effects. The mechanical irritation of the dried salt crystals contributes to the result. They possess an advantage over most other irritants in that they do not injure the epidermis.

Alimentary Canal.—Salt produces a similar stimulation of the mucosa of the alimentary canal, especially in the stomach, *i.e.*, before the salt is diluted. Hypertonic solutions produce emesis; if they reach the duodenum, they tend to evoke a "peristaltic rush" that sweeps them onward; if they remain for any time they depress peristalsis (Baur, 1926; v. Oettingen and Sollmann, 1926).

The action is deep since the salt stimulates all the cells with which it comes into contact in the course of its absorption. Since the salt is quickly removed by further absorption, it does not cause any permanent change. In this way, it differs from the majority of gastric irritants, which produce a superficial but persistent action. The stimulation by salts may therefore be continued for a considerable time, and is frequently very useful in the treatment of certain cases of "atonic" *dyspepsia*. Salt also often aids the digestion of otherwise difficultly digestible articles. On the other hand, the action would be undesirable in hyperchlorhydria and especially in gastric ulcer, and the salt income should be limited in these conditions. Rosenblat, 1907, observed markedly increased secretion in the Pawlow miniature stomach, depending on the concentration; 1 per cent. was indifferent; greater dilutions were slightly stimulant. The increase of gastric secretion occurs also if chloride (Na, Ca or Mg) is injected intravenously; this enjoins caution in the surgical use of saline injections, in conditions in which gastric rest is desirable (Frouin, 1922).

Pepsin.—W. W. Hamburger, 1915, found that neutral solutions of NaCl, even in the concentration of serum, rapidly destroy pepsin. The inhibition is complete with 2.5 per cent. NaCl; scarcely perceptible with 0.25 per cent. Other inorganic salts act similarly, probably by liberation of OH ions (Hamburger and Halpern, 1915). The destruction does not occur in the presence of free acid; but once destroyed, the ferment can not be re-activated by acidulation. This reaction is probably the explanation of the "antipepsin" of the serum. Neutralization of gastric juice likewise destroys its pepsin, since NaCl is formed. This would contribute to the action of alkalies, for instance in gastric ulcer.

Laxative Action.—A teaspoon of salt in a pint of water, taken before breakfast, is often laxative.

Saline Diuresis on Milk Flow.—In lactating goats, with limited water income, diuretic doses of salt or urea decrease the yield of milk and increase its fat-content,

presumably by diminishing the available amount of water. The nitrogen of the milk is not increased (Steenbock, 1915).

Toxic Action.—If salt is given in large amounts and concentrated form, the irritation may lead to a strong inflammation—to severe *gastroenteritis*, which may be fatal. *Poisoning by enema* was reported by Brooks, 1910. A pint of saturated solution had been injected, and repeated twice at hour intervals. The symptoms were restlessness, thirst, rapid pulse, coma, fever (109°F.), frequent micturition, dyspnea. Death occurred eight hours after the first injection, preceded by convulsions and bloody discharge from the rectum.

Action after Absorption.—The ingestion of salts, without sufficient water to render them isotonic, must tend to *increase the salt concentration of the body*. This increase affects mainly the tissues, the molecular concentration of the blood remaining practically unaltered. This increased salt concentration is counteracted by the stimulation of two mechanisms: a desire for water (*thirst*); and the elimination of highly *hypertonic urine*. If water is given freely, the salts are powerfully *diuretic*. This leads to an *increased excretion of metabolites*, partly by the flushing out of stored waste products, but also by *direct stimulation of metabolism*. If the water income is restricted, the poor urine flow decreases the N excretion temporarily (Desgrez and Guende, 1912).

The effect upon the metabolism is uncertain in its outcome, as is the case with all alternatives. It may be useful especially in *obesity*.

Saline Diuresis.—When extra salt is administered by mouth, it may increase the urine flow, or the percentage of urinary chloride, or both. This probably depends on the state of the tissues more than on the kidneys.

Respiratory Metabolism.—This is increased by saline injections, especially if hypertonic (Raeder, 1915).

Salt Glycosuria.—Bock and Hoffmann, 1871, observed that intravenous injection of NaCl solution into rabbits produces glycosuria. This was confirmed by Kuelz, 1872 (who also found that it does not seem to occur in dogs); and later by M. Fischer, O. H. Brown and others. The glycosuria is greater with rapid injection or higher concentrations, and may be abolished by the addition of Ca ions.

The *mechanism* of the salt glycosuria is in dispute. Underhill and Closson, 1906, claim that it is accompanied by hypoglycemia, and therefore attribute it to increased permeability of the kidneys. E. Franck, 1913, failed to find the hypoglycemia, and attributes it to polyuria. Willenko, 1911, states that it does not occur after section of the splanchnics and refers it to stimulation of the central nervous system. Further work is evidently needed.

E. Hirsch, 1915, reports hyperglycemia from intravenous injection of 10 per cent. NaCl. The action is central, presumably on the glycosuric center. Solutions of 2.5 per cent. or more dilute, even in large quantities, do not increase the blood-sugar; nor does sodium carbonate or acetate, nor calcium chloride. Sodium sulphate also does not produce hyperglycemia (Kleiner and Meltzer, 1916). Magnesium sulphate, however, does so.

It is interesting that diabetic puncture and puncture of the funiculus teres in rabbits increases the urine and the percentage of chloride ("*Salt puncture*"). The urinary effect is independent of the glycemia, but depends on nervous impulses carried by the splanchnics (Jungmann, 1914).

Salt Fever.—Finkelstein, 1908, and Schaps, observed that the administration of salt to infants by mouth or hypodermically, may produce fever. A slight rise of temperature is also observed in adults, if at least a liter of 0.9 per cent. NaCl is injected hypodermically (Bingl, 1910); but is prevented if Ca is added, as in Ringer's solution (Meyer and Rietschel; Bock, 1912; Burnett and Martin, 1916). The rise is accompanied by an increased N metabolism and heat production (Freund and Grafe, 1911). Hypertonic salt solution (3 per cent. NaCl) is much more effective (Rolly and Christjansen, 1914). A similar rise is produced by the injection of isotonic dextrose or lactose, and by indifferent particles (paraffin, colloid metals, etc., Bock); but these may have a different origin. The salt fever is not due to infection, for it occurs with absolutely sterile solutions and with oral administration (Bingl; Freund, 1913). It is therefore quite distinct from the "water infection," the "wasserfehler" or Wechselmann, 1911; *i.e.*, the fever that occurs after the injection of solutions made with stale distilled water. This is caused by the filterable and thermostable toxins of a peculiar bacterium (F. Seibert, 1924). Finkelstein and Bingl assumed that the salt fever is produced by irritation of the heat centers by the chemic products resulting from the action of the Na ions on the tissues.

An apparently different type of salt fever is produced by the injection of hypertonic solutions of salt, glucose etc. This can be prevented by the administration of water

and is attributed by Balcar et al., 1919, to the dryness of the tissues, limiting perspiration and therefore reducing heat dissipation.

Wright's Surgical Solution.—A. Wright, 1917, recommends the saturation of wounds with a hypertonic saline solution, aiming to keep the surface irrigated with lymph. He employs 4 per cent. of sodium chloride and 1 per cent. of sodium citrate in distilled water, sterilized by boiling for half an hour.

Fackenheim, 1915, uses the same principle by dressing the wound daily with granulated sugar.

PREPARATIONS

* *Sodii Chloridum* (Sod. Chlorid.), U.S.P.; (*Sod. Chlor.*), B.P.; (Common Salt), NaCl. White, crystalline powder of purely saline taste. Freely sol. in water (1:2.8); nearly insol. in alc.; sol. in glyc. (1:10). Chlorides are incompatible with salts of silver and lead. Dose, 15 Gm., ½ ounce, U.S.P.

* *Liquor Sodii Chloridi Physiologicus* (Liq. Sod. Chlor. Physio.), U.S.P. (Normal Saline Solution).—0.85 per cent.

SALINE INFUSIONS AND TRANSFUSION

The injection of saline solutions, of blood serum, washed corpuscles, non-coagulable blood, or direct transfusion of blood produce very similar results and are merely modifications of the same general procedure.

General Effects of Saline Infusions.—The general effects of hypodermic or intravenous injections of saline solutions on the quantity of blood, lymph and urine, and the fate of these solutions were discussed under "Salt Action." It may be recalled that the quantity of fluid in the blood is temporarily increased. This produces a very moderate rise of blood pressure; and this, perhaps with some direct salt action, results in an increased excitability of the respiratory, vagus (H. C. Jackson and Ewing, 1914) and vasomotor centers. With *normal animals*, the rise of capillary pressure is large and persistent; while the rise of arterial pressure and the medullary stimulations pass off quickly, but without noticeable fatigue. In *animals whose blood pressure is low*—particularly if this is due to hemorrhage, saline infusions bring the pressure toward normal, and maintain it much better. Excessive injections of saline solutions may cause death from *pulmonary edema*, or from overdilatation of the heart. Even therapeutic injections may produce glycosuria, slight fever, and rarely albuminuria.

Vasomotor Center.—In normal animals, injections of 10 to 40 c.c. per kilogram produce only slight stimulation or no change. Occasionally, *i.e.*, when there is maintained rise of blood pressure, the vasoconstriction is quite marked (Pilcher and Sollmann, 1914).

Quantitative Relations.—These effects are produced by all salts whose ions are not specifically toxic, *e.g.*, by most sodium salts. To have any effect, these must be used in rather large amounts, *i.e.*, from 25 to 50 c.c. of the eighth-molecular solution per kilogram of bodyweight. Solutions which contain *all* the salts of the serum in the proper proportions (*e.g.*, Locke's Fluid) are somewhat better than the normal (0.9 per cent.) sodium chloride solution, but the latter suffices for all practical purposes.

Even small doses of isotonic NaCl may produce changes in blood pressure, while Ringer's solution or glucose has much less effect (Selig, 1911); so that the action is probably not wholly osmotic. Frogs' vessels are dilated by perfusion with NaCl (Hooker, 1911).

Factors Involved.—The effects produced by injections of sodium salts depend on the interaction of a number of factors, especially:

Hydremic plethora. Osmotic changes. Changes in the alkali reserve, by selective retention of the cation. Altered ion ratio in the blood. The nature of the anion. This, however, probably acts mainly by altering the permeability of the cells to sodium (Gruenwald, 1918).

Toxic Doses of Different Cations.—Joseph and Meltzer, 1907, found that MgCl₂ was fatal for mammals with 0.223 Gm. per kilogram (1 c.c. m/5 per kilogram per minute); Ca and K required about double, Na twenty times as much.

Hypoisotonic Solutions.—These act very much like isotonic solutions, but are somewhat more injurious and may lake the blood.

Hyperisotonic Solutions.—These, by abstracting water from the tissues, produce a much more violent stimulation of the central nervous system, passing on to convulsions, but always followed by depression. Small intravenous injections raise the blood pressure partly by direct stimulation of the heart (Retzlaff, 1915). With larger injections, the blood pressure shows a progressive fall, with temporary rise during the spasms. The respiration is at first quickened, but becomes slow and shallow as the blood pressure falls. The heart is quickened, feeble, and arrhythmic. In the later stages it may be slowed by stimulation of the vagus center. The temperature rises. The diuretic effect and the local irritation are also much greater.

It is probable that some of the phenomena of *uremia* are due to a hyperisotonic condition of the blood, which may reach almost double the normal concentration in this condition.

Dehydration by Hypertonic Glucose or Saccharose Injections.—In dogs, the diuresis produced by prolonged intravenous injections may diminish the body weight by 10 to 11 per cent., the plasma volume by 20 per cent., in 2 hours. The chloride concentration of the blood rises proportionately to the concentration of the plasma; the urea concentration of the blood also increases, although the excretion of urea is increased by the diuresis (Keith, 1924).

Restoration of Normal Blood Volume.—The circulation rapidly disposes of injected solutions by exchange with the tissues. As has been explained more fully under *General Salt Action*, the total molecular concentration, the ratio of ions, and the total volume of blood are restored to nearly normal within half an hour.

Conditions Delaying the Restoration of the Blood Volume.—In normal dogs and rabbits, the blood-volume returns to normal within half an hour after the intravenous injection of warm Ringer's fluid equivalent to the total blood-volume. This is delayed by morphine, and by nephritis (uranium, chromate or tartrate), but not by ligation of the kidney vessels. The restoration is not affected by the addition of 0.4 per cent. sodium carbonate, either in normal or in nephritic animals (Bogert, Underhill and Mendel, 1916). The restoration of the blood volume is also delayed by choline and by pilocarpine, but with the latter, the permeability is at first increased. Atropine has no effect. In peptone shock, the saline leaves the blood volume rapidly, but not completely (Underhill and Eppstein, 1923). With isotonic solutions of sodium bromide, nitrate, acetate and thiocyanate the restoration occurs at about the same rate as with chloride; with sodium sulphate, the return of the old volume is less complete (A. H. Smith and Mendel, 1920). Gelatin solutions (2 per cent.) may leave the blood as rapidly as plain saline, although more commonly from 11 to 27 per cent., are still present in the blood after half an hour. The gelatin leaves the blood in the same ratio as the fluid (Boycott, 1914) and is partly excreted in the urine.

Balanced Solutions.—It has been pointed out that even isotonic sodium chloride solutions are injurious to isolated tissues; that the function of isolated tissues requires exactly "balanced," solutions, of the type of Ringer's or Locke's solution; but that this is not necessary in the intact animals, because the regulating mechanisms of the body rapidly restore the normal concentration and ion-ratio of the blood. Solutions of sodium chloride of 0.6 to 1 per cent. may therefore be used for hypodermic, and even for intravenous injections, although Locke's fluid is more desirable. The chief difficulty with Locke's solution is the precipitation of calcium carbonate, if the finished solution is heated for sterilization. This may be remedied by passing CO₂ through the sterilized solution until the pH of 7.35 is reached (neutrality to phenol-red); or it may be prevented by the sealing of the flask during sterilization; or the solution may be heated without the bicarbonate, which is added when the solution has cooled. It would probably be advantageous to allow for the osmotic pressure of the glucose, and to reduce the sodium chloride concentration.

A variety of minor modifications and special formulas have been proposed but it is not clear that these deserve preference.

Special Ingredients.—Saline infusions are used mainly for the mechanical result of increasing the quantity of circulating fluid. Any indifferent solute could therefore be substituted for isosmotic quantities of sodium chloride. Most substitutes, however, are too toxic for large intravenous injections.

The only substitutes for, or additions to, salt that have reached some practical importance are: glucose, sodium bicarbonate, acacia and gelatin.

Glucose.—This may have advantages, especially in impending acidosis, and in cardiac collapse, where it acts as a nutrient (1 Gm. of glucose yields about 4 calories); in nephritis, when diminished salt-permeability of the kidneys may render saline injection inadvisable; or in fever, because the oxidation of the sugar leaves the water at the disposal of the tissues. It is often used in strongly hypertonic solutions, although it is probable that approximately isotonic solutions (5 per cent.) should be preferred. It is also injected with acacia, especially in shock. In any case, it should be aimed to graduate the injections, so as to avoid persistent and marked hyperglycemia.

Enriquez, 1914, recommends a 30 per cent. solution, injected at the rate of 250 to 300 c.c. per hour, to a total of one liter.

Erlanger and Woodyatt, 1917, claimed fair results with dogs in shock.

H. J. John, 1920, used it with good results in pneumonia (250 c.c. of 10 per cent., by vein, 2 or 3 times daily).

Antipyretic Effect.—Barbour, 1919, observed in man under suitable conditions a very slight lowering of temperature by increased heat dissipation, after oral administration of 30 to 100 grams of glucose in 250 c.c. of water.

Acacia and Other Colloids.—Colloids leave the vessels very slowly; and by their imbibition affinity, they tend to retain the injected fluid, and so to diminish diuresis, lymph filtration and edemas. They therefore maintain the blood volume materially longer than do non-colloid saline injections, and so are more effective in maintaining the blood pressure in hemorrhage and shock. The addition of gelatin (0.15 per cent.) was introduced by Hogan, 1913, and 1915; later acacia (6 to 7 per cent. in 0.9 per cent. NaCl; Bayliss, 1916, 1920) was substituted as being more effective and more practical. The immediate response is undoubtedly better and more lasting than with plain saline, and this may turn the scale in a few critical cases; but the improvement in the ultimate mortality rate, or in the amount of blood that may be safely withdrawn, is so small that it falls almost within the statistical error. Acacia infusion was tried extensively during the war, at first with much enthusiasm; but this gradually diminished, so that they have nearly gone out of use. The benefits are much less than with blood, which should be used in desperate cases of hemorrhage if it is practicable; while in non-fatal hemorrhage and in shock, the superiority of acacia over saline does not appear sufficient to justify the risk of the occasional severe and even fatal reactions. These may be due in part to faulty technic; but some at least are probably due to special susceptibility to the acacia itself. This produces alterations in colloidal equilibrium of the blood, which tend to agglutination of the corpuscles and to other anaphylactoid phenomena, (Kruse, 1919; Hanzlik and Karsner, 1919; Hanzlik, 1924). The susceptibility to these varies in different animals, and recognizable reactions are exceptional in man; but as with all anaphylactoid reactions, there are likely to be marked varia-

tions. There appears also to be considerable differences in different specimens of acacia (De Kruijff, 1919).

Colloids on Diuresis.—Knowlton observed that 5 per cent. of gelatin or of acacia, added to Ringer's fluid, practically prevented a diuretic response; whereas soluble starch, which is at least equally viscid, did not inhibit diuresis. The effect of gelatin is probably due to its water-affinity.

In the experiments of Bogert, Underhill and Mendel, 1916, the urine-flow was as great with 2 per cent. gelatin as with plain saline. The gelatin solution generally left the circulation somewhat more slowly than plain saline; but not always. The gelatin was eliminated from the blood at the same rate as the fluid, being partly excreted by the kidneys (Boycott, 1914).

In rabbits, J. Clark, 1918, found that the gelatin begins to leave the blood immediately after injection, its elimination being completed in 6 to 24 hours.

Alkali.—The addition of 0.05 to 0.5 per cent. sodium bicarbonate to the physiologic saline solution (Howell, 1900; Dawson, 1904) serves to maintain the alkaline buffer-value of the blood and to counteract the tendency to acidosis that exists with low blood-pressure (Milroy, 1917). However, for the limited volumes that are used in moderate hemorrhage or mild collapse, it appears a needless complication. Definite acidosis, as in diabetic coma, requires alkali injections of higher concentration (to 500 c.c. of 5 per cent., injected in half an hour).

Therapeutic Uses of Saline Injections.—These are employed to tide the patient over acute anemia from hemorrhage; in collapse; or in alternation with bleeding for the removal of poisons (uremia, CO, etc.). Direct transfusion of blood is more efficient, but more inconvenient and often inadvisable.

Use in Hemorrhage.—Saline injections are made with the object of restoring the fluid needed for effective work of the heart. The restoration of the blood pressure succeeds temporarily unless the hemorrhage has reduced the pressure to the level of shock (Pilcher and Sollmann, 1914; Downs, 1916). Short of this, the temporary benefits are often striking; but since the solution does not stay long in the vessels, the final fatality is not greatly influenced.

Influence of Saline Infusion on Hemorrhage Fatality.—Kwan, 1913, *f.i.*, found that rabbits die from acute hemorrhage when 26.7 to 32 c.c. of blood are lost per kilogram. When the blood was replaced at once by simple saline, the fatal limit was 33.5 to 37.5; when replaced by Ringer's solution 33.6 to 37.3 c.c. per kilogram.

Efficiency of Modifications.—This was investigated by Penfield, 1918. By repeated hemorrhage, he kept the blood pressure of dogs about 40 mm. Hg for 1 to 1½ hour. Then a saline injection was made, equal in volume to the blood withdrawn. Survived animals were observed for a week:

About half of the animals survived, the ratio being the same for plain 0.9 per cent. sodium chloride, for the Bayliss gum-bicarbonate solution and for the Erlanger gum-dextrose solution.

Extremes of Hemorrhage.—Richet, 1918, found that the minimum of blood compatible with survival (in dogs) is 4 per cent. of the normal number of corpuscles, and 27 per cent. of the normal blood mass. This means that considerable blood may be replaced by saline. For instance, with simple gradual hemorrhage, death occurs when 77 per cent. of the blood corpuscles have been lost; but if saline is injected, life persists until the blood corpuscles loss has reached 87 to 96 per cent.

Traumatic Shock.—The low blood pressure that is characteristic for shock, early suggested the use of saline solution. The results, however,

have been uniformly disappointing. Normal saline solution does not raise the pressure materially. Excessive injection easily produces fatal dilation of the heart. If acacia or epinephrine are added, the blood pressure can be maintained longer, but only at the expense of overloading the heart. The ultimate mortality is practically the same as in untreated animals.

Saline Infusion in Collapse.—This may hasten recovery in temporary collapse, as with phenol and other poisons. It is of little use in the lasting collapse of fever or severe shock.

Use in Uremia and Other Intoxications.—Saline solutions were extensively employed as diuretics; but it is now recognized that simple injection does not increase the elimination of the toxic substances sufficiently to be of much value. (Their influence has been studied by Lenhartz, 1899.)

A limited disintoxication occurs with strychnine (Hatcher and Smith, 1917; Kleiner and Meltzer, 1917). The recognition of the impermeability of the kidney to chloride in some nephritides enjoins special caution. Mosenthal and Schlayer, 1913, claim that the kidneys of experimental nephritis do not respond well to NaCl. In any case, saline injections must be used cautiously in anuria, and must not be persisted in if a moderate injection does not cause diuresis.

Plasmapheresis.—This term was introduced by Abel to designate the replacement of the plasma with saline solution. The blood is withdrawn, the corpuscles separated and washed by centrifugation, suspended in 0.6 per cent. NaCl, and reinjected. In this way much larger amounts of plasma may be withdrawn without damage, especially if the process is several times repeated. The number of red corpuscles rises at first (*i.e.*, the volume of liquid in the vessels is reduced); but ultimately they decline slowly. The plasma proteins may be reduced to a third. The urea and non-protein nitrogen of the blood are increased. The temperature rises slightly (Abel, Rowntree and Turner, 1914; Turner, Marshall and Lamson, 1915).

Hepatic degeneration (phosphorus or chloroform) delays regeneration of the blood proteins after plasmapheresis (Herr et. al., 1918).

Transfusion of Blood.—This was tried clinically in very early times, but with disastrous results, since foreign species were generally used. Worms-Mueller, 1875, investigated the acute and late effects of the transfusion of the blood of the same species, the fate of the blood, the therapeutic field, etc., and practically stated our modern knowledge of the subject, except some technical details (Sollmann, 1915). He showed that changes of the blood volume between 25 per cent. below the normal, to 30 or 50 per cent. above normal do not materially alter the normal blood pressure; attributing the adjustment to vasomotor changes. The pressure remains practically unaltered even with extreme plethora; but other acute central symptoms supervene.

Fate of the Transfused Blood.—As to the further fate of the animals, Mueller showed that increasing the normal quantity of blood by 80 per cent., by slow transfusion, does no damage. Of the injected plasma, about half the water has disappeared from the blood within two hours; the remainder leaves more slowly, requiring several days. The plasma protein also disappears promptly; and increased urea excretion indicates that it has been metabolized. The injected corpuscles persist much longer, the normal ratio being restored in three to four weeks. He therefore concluded that the usefulness of transfusion is due solely to the injected corpuscles. No differences were found between fresh or defibrinated blood and blood that had been kept on ice for a day.

These observations have been confirmed by the modern investigators. For instance, Weinberger, 1908, found in dogs that the water leaves the blood vessels very rapidly, causing diuresis, but not nearly as great as with NaCl solution. The red corpuscles can thus be raised temporarily to over 13,000,000; but they gradually decline during the succeeding days. The specific gravity rises still more. Animals invariably die after four or five transfusions, with hemoglobinuria and nephritis. The injected blood probably has no nutritive value, the nitrogen being rapidly eliminated.

The transferred corpuscles persist over 30 days, as judged by the agglutination reaction (Ashby, 1919).

Transfusion by Citrated Blood.—This is discussed under Sodium Citrate.

Indications for Transfusion.—These were stated by Mueller: excessive hemorrhage; carbon monoxide poisoning; and some chronic amenias, for instance, leukemia. These are practically the modern indications, (*i.f.* Ottenberg and Libman, 1915).

Transfusion is also used to overcome the hemorrhagic tendencies of purpura and similar diseases.

UREA

Urea, $\text{CO}(\text{NH}_2)_2$ is an effective diuretic, acting probably by simple osmosis. It is little if at all toxic.

Hewlett *et. al.*, 1916, find that the administration of 100 Gm. of urea by mouth to man increases in a few hours the blood urea to 160 to 245 mg. per 100 c.c.; and that this is accompanied by prostration, apathy and somnolence. These symptoms resemble those occurring in pure retention-uremia, when the blood urea rises to 100 to 200 mg. per 100 c.c. However, nephritis may not show any uremic symptoms with 255 mg.; McLean, 1917.

Urea is not utilized in nutrition (Henriquez and Anderson, 1914). When additional urea is administered, it is excreted promptly and completely, mainly by the kidneys. The excretion is impaired in chronic interstitial nephritis (v. Monakow); but not in chronic parenchymatous nephritis; so that urea has been recommended as a diuretic in the latter condition (McLean). The sweat also excretes a small amount of urea, (0.21 per cent., Kovesi). The urea content of the milk is not increased by urea administration (Steenbock, 1915). The beneficial effects of urea on perfusions were discussed previously.

Urea occurs as colorless crystals of cooling, saline taste, freely soluble in water (1:1); soluble in alcohol (1:7). The effective diuretic dose would be 20 to 40 Gm. per day.

POTASSIUM SALTS

General Statement.—Potassium is widely distributed through the body and is essential to the vital functions. It depresses the functions of the nerves, nerve-endings, heart muscle, and skeletal muscle, and is mutually antagonistic with Na and Ca ions. Smooth muscle, on the other hand, is stimulated by potassium.

With intravenous or hypodermic injections, the ion-actions manifest themselves by depression of the heart and other muscles, and of the central nervous system. These effects may also be secured from toxic doses by mouth; but not by ordinary doses, since the rapid excretion prevents the accumulation of excessive potassium in the tissues. The therapeutic use of potassium as cardiac and nervous depressant was a faulty deduction from the laboratory experiments. The oral administration of moderate quantities of potassium has practically only osmotic effects—diuresis, slight changes in metabolism, etc. The therapeutic actions of potassium salts are therefore attributable to their anions, and are practically equivalent to the corresponding sodium salts. The potassium salts perhaps produce somewhat more local irritation. They are contraindicated in renal insufficiency, since the deficient excretion could lead to the development of toxic potassium effects.

Income of Potassium.—The daily diet of man contains about 3 to 4 Gm. of K_2O and 5 to 8 Gm. of Na_2O ; but there are great variations. A vegetable diet contains relatively more K.

Distribution of Potassium.—This is in many respects converse to that of sodium. The K is generally more abundant within the cells; the Na in the extracellular juices, serum and lymph. The serum of all mammals contains about 0.025 per cent. of K_2O as against 0.44 per cent. of Na_2O . The percentage in the *blood corpuscles* differs markedly in different species, being generally inverse to the percentage of Na. The corpuscles of the horse, pig and rabbit contain 0.33 to 0.52 per cent. if K_2O and no Na_2O ; in man, the ratio of $\text{K}_2\text{O}:\text{Na}_2\text{O}$ is 0.4:0.075; in the beef, sheep and goat, it is 0.07:0.23; in dogs and cats, 0.3:0.28. In the K-rich animals, the dissolution of a fith of the corpuscles would liberate a fatal quantity of potassium. Muscle fibers also contain K without Na (Fahr, 1912). Macleod, 1907, found that the juice expressed from the heart or skeletal muscle produces a typical potassium effect on the heart.

The distribution of K within the cells has been investigated by A. B. Macallum, 1907. It is absent from the nuclei and from the nerve cells; but is present in the cytoplasm of most vegetable and animal cells, including the muscles, the nerve fibers, the granula of the pancreatic cells, etc.

Excretion.—A considerable part of the potassium, 15 to 25 per cent., is reëxcreted in the feces. The urine contains generally Na:K::2:1 to 5:3. In starvation, the ratio is reversed to 1:3.

The excretion of K seems to be hastened by the addition of Na (Biernacki, 1911). A few experiments by Blumenfeldt, 1913, indicate that the excretion of administered potassium is delayed by aortic insufficiency, arteriosclerosis, and interstitial nephritis.

Influence of Excretion on Effect.—The effect of potassium, as of other cathions, varies greatly according to the channel of introduction, because the excretory capacity for these ions is usually much greater than the rate of their absorption from the alimentary canal. Oral administration is therefore effective only if very large doses are given; if the mucous membranes are corroded; or if the excretion is checked, as by ligation of the kidneys.

The influence of excretion is well illustrated by *magnesium*: after excision of the kidneys, the toxicity is increased 50 per cent., and the action is more lasting and cumulative. On the other hand, some vicarious channel of excretion becomes established, so that the toxicity is less eighteen hours after operating than it is immediately (Meltzer and Lucas, 1907).

The toxicity of intravenous KCl is diminished by NaCl (Amberg and Helmholz, 1916).

A summary of the *excretion of salts* is given by Heffter, 1903.

Systemic Actions.—The *central nervous system* is paralyzed by K in its whole extent. The reflexes suffer, then the medulla. Depression of the respiratory center leads to asphyxial convulsions. Absence or increase of K are both depressant to the perfused respiratory center of the frog (Hooker, 1913). With intravenous injection, the most important effect is the cardiac paralysis.

Cardiac Actions.—Small concentration of potassium depress and high concentrations paralyze the heart, the contractility being considerably more resistant than the rhythmicity, so that the arrested heart may contract strongly to electric stimulation. The resistance of the rhythm varies widely for the different portions of the heart, in the direction of the gradient; *i.e.* it requires much higher concentrations to arrest the rhythm of the sinus than that of the sinus-free ventricle, and this is more resistant than the sinus-free auricle. The normal plasma concentration of potassium is distinctly detrimental to the rhythm (not to the contractility) of the ventricle and auricle, and this aids to subject these to the pace-making rhythm of the nodal tissue, which is not depressed by these concentrations (Kolm and Pick, 1920; Chu and Sollmann; Sollmann and Chu, 1926). The tonus-waves of the turtle's auricle are increased. The rhythmic depression of moderate concentrations of potassium may be more or less antagonized by calcium. Absence of potassium from the perfusion fluid abolishes the inhibitory power of the vagus on the heart (Howell, 1906).

The depressant action of potassium occurs in the nerve-free heart of the chick's embryo, and is therefore muscular. In Langendorff perfusions of the *excised mammalian heart*, increase of K produces inhibition, followed by fibrillation. Paralysis occurs when the concentration in the blood reaches 0.08 per cent. (Hald, 1905). Howell and Duke, 1908, found that stimulation of the vagus causes an increased output of K in the perfused heart, especially the auricles. They attribute the vagus stoppage to the K which the stimulation of the nerve is assumed to convert from a non-diffusible into a diffusible form.

In intact mammals, the effects are somewhat different for intravenous and arterial injections (Mathison, 1911); *by the vein*, there is a primary fall of blood pressure, with a slight secondary rise. The fall is due to cardiac disturbance, decreased output, heart-block, slowed pulse, tonus changes, sudden systolic standstill, usually before the respiration stops. Slow continuous injections into dogs produce slowing and weakening of the heart by central vagus stimulation; for if the vagi are divided, the heart is quickened and strengthened, and often shows extrasystoles. Larger doses depress the heart muscle directly, even when the vagi are divided. Fatal doses produce ventricular and eventually auricular fibrillation (Hering, 1915). *Arterial injection* causes an immediate

rise of blood pressure, by stimulation of the vasomotor center, and of the vessels directly (it occurs even when the central nervous system is destroyed).

Smooth Muscle.—The tone and contractions of the intestines, uterus bronchi and arterioles are stimulated by excess of potassium (Mathison, 1912). However, the vessels of frogs are dilated by perfusion with potassium (Hooker, 1911).

Skeletal Muscles.—K weakens the muscles; diminishes the height of contraction; lengthens the latent period; and decreases the conductivity and excitability (Fahr, 1910). In this way, potassium counteracts the effects of veratrine.

Deficiency of Potassium has no effect upon the contraction range of a toad gastrocnemius muscle nor upon its ability to pass into a state of tetanus; but the ability of the muscle to maintain a condition of tonus is impaired (Neuschlosz, 1923).

Nerve.—Injection of K suspends the conductivity of nerve and potentiates the anesthetic effect of cocaine. Na, NH_4 and Mg do not have this effect (Zorn, 1913). Injury, and the local application of lipolytic anesthetics increases the concentration of K ions in medullated nerve fibers. This may play a part in the anesthetic effect (Menten, 1912).

Use as Local Anesthetic.—Under clinical conditions the local anesthetic action of potassium salts is almost insignificant, since the potassium is very rapidly absorbed or "neutralized" by other ions in the tissues (Sollmann, 1917). However, 1 per cent. potassium chloride may be used in place of normal saline for the dilution of the more active anesthetics.

Mechanism of Potassium Action.—Excised tissues respond to potassium excess, deficiency and restoration much more rapidly than the ion can pass into or out of the muscle-cells (Urano, Fahr). It must therefore act on the cell surface or membrane. It has been suggested that the high migration-speed of the K ions would upset the surface potential.

Potassium Poisoning in Nephritis.—The administration of 5 to 10 Gm. of KCl (diluted) usually produces no symptoms, even when the permeability to NaCl is impaired, as in chronic nephritis. Occasionally, however, a nephritic patient may develop severe potassium poisoning, as in a case described by Smillie, 1915. The symptoms started after seven hours and reached their maximum in twenty-one hours. They consisted of cyanosis, weak pulse, and vomiting. Rabbits with their kidneys rendered less permeable by uranium nephritis also showed markedly increased susceptibility to potassium. However, with the ordinary potassium income, v. Limbeck, 1892, did not find increase of K in the blood of uremic dogs.

Potassium in the Toxicity of Urine and in Uremia.—The toxic action which urine possesses when injected intravenously has been variously attributed to the leucomaines; to toxins, etc., and at one time even to the urea. Various theories and methods of diagnosis were built upon the variations in this toxicity. It has, however, been shown that about 85 per cent. of the toxicity of the urine is due simply to its potassium salts. The symptoms are also precisely those of the latter. What causes the other 15 per cent. of the toxicity is at the present not known. Hartman, 1915, claims to have isolated from normal urine a cyclic ketone, "Urinod," which is quite toxic, and produces headache in small doses—perhaps through its disagreeable odor.

If the undiluted urine is injected, its osmotic pressure also contributes to the toxicity. The acidity, volatile products, pigments, and urea have no effect. It is quite probable that the urine contains true toxins and other toxic products in disease, but no method has so far been devised for estimating the importance of these.

The conditions are still more complicated in *uremia*: it is very probable that the retention of potassium and ammonium salts and the increased osmotic pressure of the blood contribute to the effects, but there seem to be other factors which are not understood. Foster, 1915, has isolated some unidentified crystallizable toxic substances from the blood of uremic patients, which he failed to find in normal blood. Further investigation is needed.

Hatcher and Smith, 1916, found that the intravenous injection of urine is practically non-toxic to cats.

Potassii Chloridum, KCl.—Readily sol. in water. *Dose*, 1 to 2 Gm. (15 to 30 gr.). Not to be confused with the toxic chlorate!

LITHIUM SALTS

Lithium urate is relatively soluble. By a misinterpretation of this chemical fact, the lithium salts were introduced as solvents for uric acid:

and hence as remedies against gout, rheumatic conditions, etc. Since the soluble urate can not be formed in the presence of sodium or potassium ions, it can not exist in the body or in the urine. The uses of lithium salts therefore have no rational foundation, and they may be considered inefficient, and in larger doses somewhat dangerous.

The action of this cation resembles potassium quite closely, but it is somewhat less toxic to the heart, and causes a vagus stimulation. These effects are seen only on intravenous injection. A most important difference from potassium consists in a *specific gastroenteritis* which is produced even when the salts are given subcutaneously, or if the administration of small doses is continued for some time (1 Gm. of the carbonate in man). The action is local, the lithium being largely excreted by this channel. It is also excreted by the kidneys, but does not cause nephritis (Krumholf, 1884; Good, 1902). It is also excreted in the milk (Koldewijn, 1910).

Acute poisoning from larger doses in man (four doses of 2 Gm. of LiCl) is described by Cleveland, 1913. There were no gastro-intestinal symptoms; but marked muscular and general prostration; vertigo; and eye and ear symptoms resembling cinchonism.

Action on Urates.—Lipowitz, 1841, found that lithium carbonate is a better solvent for uric acid (about four times) than sodium carbonate. He suggested its therapeutic use, and this was introduced by Ure, 1844, and Binswanger, 1847. Garrod, 1861, found that gouty tophi were dissolved in lithium solution. However, the solvent action occurs only when strong solutions of lithium carbonate act on uric acid. In the presence of NH_4 , Na or K, the less soluble urates of these cations are formed. The solution can therefore not occur under the conditions of the body or urine (see Index, Urate Solvents). Lithium salts have diuretic actions (Husemann), but no greater than the Na salts. The popular "Lithia waters" have been shown to be practically devoid of lithium. The best contain only 0.01 to 0.02 per cent. "Buffalo Lithia Water" contains only a fifth as much lithium as Potomac River water; 200,000 gallons would be needed to supply the ordinary therapeutic dose of lithium.

PREPARATIONS

Lithii Carbonas (Lith. Carb.), B.P., Li_2CO_3 .—Light, white powder; odorless; alkaline taste. Sol. in water (1:78); almost insol. in alc. Dose, 0.12 to 0.3 Gm., 2 to 5 gr., B.P.

Lithii Citras (Lith. Cit.), B.P., $\text{Li}_3\text{C}_6\text{H}_5\text{O}_7 \cdot 4\text{H}_2\text{O}$.—A white powder, or in granular form; odorless; cooling, faintly alkaline taste. Deliquescent. Freely sol. in water (1:1.4); very slightly sol. in alc. Dose, 0.3 to 0.6 Gm., 5 to 10 gr., B.P.

Lith. Cit. Eff., B.P.—5 per cent. Dose, 4 to 8 Gm., 1 to 2 drachms, B.P.

RUBIDIUM AND CESIUM

These also resemble potassium. Rubidium iodide and bromide were introduced into therapeutics, with the improbable claim that they produce less iodism and bromism. The doses are the same as those of the potassium salts.

Cesium or rubidium may replace potassium in the excised frog heart (Zwaardemaker, 1918).

AMMONIUM COMPOUNDS

The ammonium ion produces rather strong stimulation and subsequent paralysis of the central nervous system, especially the medulla. The systemic effects are seen only with intravenous administration, because the ammonium ion is rapidly converted into urea and excreted. On excised muscles, it has a weak curare action.

In intact animals, the effects of the ammonium compounds are strictly local. They diffuse rather rapidly, and thus exert considerable salt action, especially irritation. These local actions increase the flow of mucus, which is also rendered more fluid. Ammonium chloride is therefore used

as an expectorant in the first (dry) stage of acute bronchitis and in dry chronic bronchitis. It is also somewhat diaphoretic (nauseant action?). Large doses are emetic. Ammonium acetate has been employed as a weak diaphoretic and diuretic in fevers, but is probably useless.

Ammonium hydroxide and carbonate act also as alkalies; and by the liberation of the volatile and diffusible NH_3 , their action extends deeply. Their vapor is used to produce reflex stimulation of the medullary centers (trigeminal reflex), in collapse, fainting, etc. When too concentrated, they produce laryngitis, bronchitis and pneumonia.

Applied to the skin, ammonia produces rubefaction, and if concentrated and confined, vesication, usually without corrosion. It is used in combination with oil (ammonia liniment) for counterirritation in rheumatism, etc. Ammonia is also applied to insect bites.

Expectorant Action.—Ammonium chloride makes the sputum subjectively "looser," easier to raise, and perhaps more abundant. The increased secretion of mucus and saliva is mainly a reflex from the local irritant action, although there may be some direct central stimulation (V. E. Henderson, 1910). The liquefaction of the mucus may be due partly to the ammonium ion, partly to the excretion of the alkaline ammonium carbonate by the saliva. This excretion, however, is quite small, since most of the ammonium is destroyed in the body. Ammonium chloride is also said to have a primary astringent effect on the mucous membrane.

Administration.—Ammonium chloride is used in acute and chronic bronchitis in the dose of 0.3 Gm., 5 gr., repeated as needed; either as troches (0.1 Gm., 1½ gr.), or in solution. Its disagreeable taste is less noticeable in acid mixtures (*syrup of citric acid*). Ammonium carbonate (same dose) is more solvent for mucus, but rather nauseant.

When it is desired to extend the direct action to the trachea and bronchi, the ammonium may be administered in the form of inhalation of ammonium chloride, produced in a finely divided state by bringing together the vapors of ammonia and hydrochloric acid.

Bronchial Secretion.—Ammonium salts, like other emetics, increase the bronchial mucus, even when they are placed in the intestines; but by this method, the dose must be much larger than therapeutic. Ammonium salts produce moderate dilation of excised bronchial muscle (Trendelenburg, 1912).

Absorption and Excretion by the Lungs.—Magnus, 1902, and Brucini, 1907, found that ammonia is neither absorbed nor excreted by the lungs; but Hoeber, 1912, and McGuigan, 1913, claim that the inhalation increases the percentage of ammonium in the blood. However, this insignificant absorption occurs from the trachea and bronchi, and also from injured alveoli (Magnus, Sorgdrager and Leuwen, 1914).

W. Coleman, 1916, states that traces of ammonium can be discerned in the sputum (not in the saliva) twelve hours after discontinuing small doses of the salts (½ grain every two hours).

Disintoxication of Ammonium.—Ammonium is partly excreted as such by the urine; but the greater proportion is rapidly converted into urea, according to the formula:

Two molecules of water are split off from the ammonium carbonate and urea remains. This liberates the acid ion with which the NH_4 was combined: this will seize upon the free fixed alkali of the body, and lead to a

diminished alkali stock of the tissues. In this way any excess of ammonium introduced into the body is very soon eliminated, or at least ceases to act as ammonium.

The transformation of ammonium into urea is much more complete when the ammonium is given combined with organic acids, than in the case of its inorganic salts, for with the latter, a part of the ammonium is needed to help in the neutralization of the anions (Underhill; Caldwell and Clotworthy, 1916).

There is similarly a fairly definite relation between the ammonium excretion, the reaction of the urine, and acidosis conditions (Hasselbalch, 1906).

Ingested ammonium disappears very rapidly from the circulation, even if the kidneys are ligated (Jacobson, 1914). The conversion of ammonium carbonate into urea is practically complete in all mammals. Ammonium chloride is destroyed more efficiently by herbivorous animals than by carnivora or man.

In man, after the administration of 5 Gm. of ammonium chloride, 52.5 per cent. were recovered from the urine in 2 days (Wolf and Osterberg, 1912).

Ammonium in Metabolism.—Arterial blood contains normally about 1.5 mg. of NH_4 per 100 c.c. Portal blood contains from 3.5 to 8.5 mg. (Carlson and Jacobson, 1910). Folin and Denis, 1912, believe that the excess in the portal blood comes mainly from bacterial changes in the large intestines. The ammonium is probably a normal forerunner of urea. This is formed from ammonium carbonate by the subtraction of H_2O :

Place of Urea Formation.—The transformation of ammonium into urea occurs in perfused liver (v. Schroeder, 1892; Fiske and Karsner, 1913); the urea may also be considerably higher in the hepatic than in the portal blood (Van Slyke, Cullen and McLean, 1915). The liver must therefore play a prominent part in urea formation. However, probably all organs participate, especially in its formation from amino-acids (Folin, 1914). For instance, the amount of urea in the tissues or blood, after the intravenous injection of amino-acids, is smaller in animals with the liver and intestines excluded from the circulation (Fiske and Sumner, 1914). Jansen, 1915, also presents evidence that the liver has a considerable role in the formation of urea from amino-acids.

Function of Ammonium in Neutrality Regulation.—The transformation of ammonium into urea is utilized for the control of the reaction of the body: when there is an excessive formation of acid (acidosis), the transformation is less complete, the acid being neutralized by the ammonium and excreted in the urine. If alkalies are administered, the ammonium is displaced from its salts, and converted more completely, so that none may appear in the urine (Janney, 1912). The ammonium-urea relation of the urine is thus an index of the acid production or alkali income.

The ammonium excretion is therefore high in diabetes (Boussignault, 1850), where a tendency to acidosis is frequently present.

Ammonium Chloride Acidosis.—When ammonium chloride is administered, the conversion of part of *this* ammonium into urea leaves an excess of chloride anions, which neutralize a corresponding part of the alkali-reserve of the body (Haldane, 1920). This is used therapeutically especially in pediatric practice to render urine more acid, and to counteract alkalosis.

Utilization of Ammonium Nitrogen.—Grafe and Schupfer, 1912, claimed that ammonium may replace the protein in food. This was confirmed by Knoop, 1913; Grafe 1914, and others. However, it does not prove that ammonium is converted into tissue nitrogen. It is more probable that it is utilized by the intestinal bacteria, and that these are then digested and their nitrogen absorbed. Accordingly, Henriquez and Anderson, 1914, found no retention of nitrogen after the intravenous injection of ammonium or urea. Taylor and Ringer, 1913, did observe considerable N retention after oral administration of ammonium carbonate. However, the associated changes in metabolism

indicate that the retention is due to a toxic action of the ammonium, rather than to its utilization (Underhill and Goldschmidt, 1913).

Autointoxication by Ammonia.—The symptoms of uremia, tetany and other convulsive diseases resemble somewhat the picture of ammonium poisoning. It has therefore been suggested that these conditions are due to failure of the liver to transform the ammonium. This appears unfounded. There is no evidence that the ability to form urea is impaired, except perhaps in extreme cases of liver degeneration. Fiske and Karsner, 1914, found the ammonia conversion by perfused livers unimpaired after acute hepatic injury by chloroform, phosphorus, etc. Even if the ammonium were not destroyed, the excretory mechanism of the kidneys could be expected to remove the excess.

In fact, the ammonium content of the blood has not been found increased in uremia or in acute yellow atrophy of the liver. An increase of 50 per cent. above the normal has been reported after complete excision of the thyroids and parathyroids (MacCallum and Voegtlin, 1909; Berkeley and Beebe, 1909); and the ammonium production is increased (Underhill and Saiki, 1908), or its destruction diminished (Carlson and Jacobson, 1910). A similar increase was reported in clinical tetany (Musser and Goodman, 1909). There is also a close resemblance between the symptoms of tetany; those of animals with Eck's fistula on a meat diet (Pawlow, 1892); and ammonium poisoning. Even the concentration of NH_4 in the blood required to produce true ammonium tetany, (0.008 per cent., Magnus, et al., 1914) seemed very similar (Jacobson, 1910). However the later work of Carlson and Jacobson, 1911, with improved methods, showed that the increase of ammonium is not constant and falls within the variation of normal animals, so that even these conditions can not yet be classed as ammonium intoxications.

McNeil and Levy, 1917, conclude that increase of blood ammonium above 1 mg. per 100 c.c. which occurs in various diseases, is not connected with acidosis, but rather with hepatic disturbance, especially of the acute functional type.

Intravenous Injection of Ammonium Chloride.—The effects vary with the dose and the rate of injection. Marfori, 1893, described immediate tremors and twitchings, advancing to tetany, violent convulsions and opisthotonus; irregular respiration; salivation and emesis; somnolence and lassitude. The respiration shows a momentary convulsive inspiratory standstill, followed by increased rate. This stimulation occurs even with small doses. Blood-pressure tracings show a temporary fall then a slow but more lasting rise; with slowed rate and "vagus pulse." The rate may be quickened during the convulsions. These effects indicate stimulation of the respiratory, vasomotor, and vagus centers. If the injection is not promptly fatal the functions recover rapidly (Meneguizzi, 1912).

Curare Action.—This is much weaker than with the organic ammonium bases (see Muscarin).

Plant Tumors.—The injection of ammonium salts and a number of other substances produce tumor-like cell proliferations in plants (E. F. Smith, 1917). They are probably due to removal of growth restraining factors by lowering of surface tension, etc.

Reflexes from the Inhalation of Ammonia Vapors.—Through irritation of the sensory trigeminal endings, these produce momentary standstill, then increase of respiration; stimulation of the vasomotor center (rise of blood pressure); and vagus slowing of the pulse (in rabbits, vagus standstill).

Use for Medullary Stimulation.—Ammonia is one of the most effective means for stimulating the medulla reflexly. It may be used as the *aromatic spirit of ammonia*—15 to 30 drops in a tumbler of water; or as ammonium carbonate—smelling salts; in headache, fainting, collapse, excessive anesthesia, etc. Care must be used so that the unconscious patient is not made to inhale too concentrated a vapor.

Toxicology.—The neutral ammonium salts may produce gastritis. This would be treated by dilution and evacuation. Ammonia and the carbonate produce more violent irritation, and also inflammation of the respiratory passages. The mortality of ammonia poisoning is therefore high. If the patient recovers from the acute effects, pneumonia may set in; or the hoarseness or aphonia may last for months. The treatment consists in artificial respiration, weak acids and oils.

PREPARATIONS—AMMONIUM

Liq. Ammon. Acet., U.S.P., B.P. (Spirit of Mindererus).—7 per cent. of $\text{NH}_4\text{C}_2\text{H}_3\text{O}_2$, with small amounts of acetic and carbonic acids. Should be slightly acid. Must be recently prepared. *Dose*, 15 c.c., 4 drachms, U.S.P.; 8 to 24 c.c., 2 to 6 drachms, B.P.

Ammonii Carbonas (Ammon. Carb.), U.S.P., B.P. (Sal Volatile, Hartshorn, Baker's Ammonia).—Consists of a mixture of varying proportions of acid ammonium carbonate (NH_4HCO_3) and ammonium carbamate ($\text{NH}_4\text{NH}_2\text{CO}_2$). For medicinal purposes, only the translucent portions are used. On exposure to air, it becomes a powder, losing NH_3 and CO_2 ; and changing to ammonium bicarbonate, NH_4HCO_3 . White, hard, translucent, striated masses; strong odor of ammonium, without empyreuma; sharp, saline taste. It is slowly but freely sol. in water (1:4); the carbamate changing to normal ammonium carbonate. It is decomposed by hot water. Alcohol dissolves the carbamate and leaves the carbonates. *Incompatible* with acids and the salts of most metals and alkaloids. *Dose*, 0.3 Gm., 5 gr., U.S.P.; 0.2 to 0.6 Gm., 3 to 10 gr., B.P.; diluted.

**Spiritus Ammoniaë Aromaticus* (Sp. Ammon. Arom.), U.S.P., B.P. (Aromatic Ammonia).—A solution of ammonium carbonate (3.4 per cent.), ammonia water (9 per cent.), and aromatic oils (lemon, lavender and nutmeg) in alcohol of about 65 per cent. (U.S.P.). The composition of the B.P. is similar. A nearly colorless liquid when freshly prepared, but gradually acquiring a yellowish color. *Dose*, 2 c.c., 30 minims, U.S.P.; 1.2 to 2.5 c.c., 20 to 40 minims, repeated; single, 4 to 6 c.c., 60 to 90 minims, B.P.; largely diluted.

**Ammon. Chlor.*, U.S.P., B.P. (Sal Ammoniac; Salmiac), NH_4Cl .—White crystalline powder, without odor, of cooling saline taste. Freely sol. in water (1:2.6); sol. in alc. (1:100); freely sol. in glyc. (1:8). Neutral or slightly acid to litmus. *Incompatible* with alkaline hydroxides or carbonates (liberation of ammonia); precipitates with Ag and Pb salts. *Dose*, 0.3 Gm., 5 gr., U.S.P.; 0.3 to 1.2 Gm., 5 to 20 gr., B.P.

Troch. Ammon. Chlor., U.S.P.—0.1 Gm., flavored with Licorice and Tolu.

**Aqua Ammoniaë* (Aq. Ammon.), U.S.P.; *Liq. Ammon.*, B.P.; Ammonia Water.—Contains about 10 per cent. (by weight) of ammonia (NH_3). It loses strength on standing. Colorless liquid of pungent ammonia odor and caustic soapy taste. Freely miscible with water and alcohol. *Incompatible* with most metals and alkaloids. *Dose*, 1 c.c., 15 minims, U.S.P.; largely diluted.

Aq. Ammon. Fortior, U.S.P.; contains about 28 per cent. of ammonia; *Liq. Ammon. Fortis*, B.P., about 32.5 per cent.

**Linimentum Ammoniaë* (Lin. Ammon.), B.P.—A mixture of 1 part ammonia water, 1 part almond oil and 2 parts olive oil.

Lin. Camph. Ammon., B.P. (Compound Liniment of Camphor).—12.5 per cent. of Camphor; 25 per cent. of Stronger Ammonia in alcoholic solution of Lavender.

CLASSIFICATION OF EXPECTORANTS

These are the remedies that modify expectoration and are therefore employed in the treatment of coughs. The successive stages of bronchitis present different indications, which are met by the various classes of expectorants.

The act of coughing is a coördinated reflex involving the respiratory center, and resulting in the sudden and violent expulsion of air from the lungs. It has a physiologic function in the removal of irritant substances or of accumulation of mucus from the respiratory passages. Like other reflexes, however, it tends to persist after its cause has ceased to be active; or it may become excessive. In either case it requires treatment. It must be borne in mind that cough is merely a symptom, and while it may be treated directly, as such, no treatment can be of permanent benefit unless it is also directed against the original cause, if this is still in operation. This cause lies most commonly in the respiratory passages, but there appear to be other conditions which may give rise to cough, or which at least may help in its production. The changes produced in the general circulation by drugs like *digitalis*, *strychnine*, or the *nitrites* are sometimes beneficial. When signs of disease are present in other organs (dyspepsia, etc.), these should receive direct treatment. General measures, such as laxatives, diaphoretics, antipyretics, analgesics, etc., must be used as the indications arise. Removal to a

more suitable climate is often advisable, and sometimes necessary in chronic bronchitis. A dry climate is chosen if the secretion is profuse, and *vice versa*.

SEDATIVE EXPECTORANTS

These are used, especially in the early stage of bronchitis, to soothe the acute inflammation, mainly by stimulating the secretion of the protective mucus. They comprise the **nauseant expectorants**, especially ipecac and antimony; more rarely apomorphine, pilocarpine, lobelia, etc. (Senega, although a nauseant, is generally classed as a stimulant expectorant.) With the sedative expectorants may also be classed the **demulcent expectorants**, acacia, syrup, glycerin, glycyrrhiza, demulcent herbs (species pectorales, breast-tea); the **saline expectorants**, ammonium chloride and potassium iodide; and the **alkaline expectorants**, ammonium carbonate, sodium bicarbonate or borate.

These saline and alkaline expectorants are also used in the other stages of bronchitis, whenever the mucus requires thinning. The demulcents are useful throughout.

IRRITANT (STIMULANT) EXPECTORANTS

These are employed in subacute and chronic bronchitis, to irritate the mucous membrane in such a way as to stimulate repair. They tend to diminish the excessive secretion usually present in these later stages. They are represented especially by the **aromatic expectorants**. The volatile oils, balsams and phenols, especially *terpene hydrate*, terebene, cubeba, santal, balsam of Peru, tolu, and styrax, *creosote* and guaiacol, tar, benzoates. The irritant *senega* and *squill* are also classed as irritant expectorants. **Astringents** are used when the inflammation involves the larynx or pharynx.

ANODYNE EXPECTORANTS

These are represented mainly by the opiates, paregoric, morphine, and especially codeine, all in small doses. These are used to depress the excessive cough reflex, especially if the secretion is scanty, and should not be employed when the mucus is excessive. They appear to diminish the secretion, presumably because the delay in its expulsion permits drying. *Hydrocyanic acid* was used in coughs to stimulate the respiratory center and perhaps for a local anodyne action. It is ineffective and obsolete. Small doses of *chloroform* are also employed.

SIMPLIFICATION OF EXPECTORANTS

The great number of expectorants is not generally needed. The following suffice to meet the conditions in the most effective manner:

Against dry congestion: Syrup Ipecac, 1 c.c.; or Tartar Emetic, 5 mg.

Against thick secretion: Ammon. Chloride, 0.3 Gm.; K₁, 0.25 Gm.

Against excessive thin secretion: Terpene Hydrate, 0.15 Gm. in capsules.

Against irritation: Codeine, 5 mg.; Alkaline gargles.

EXPECTORANT VEHICLES

The syrups of tolu, of tar, and of wild cherry contain expectorant constituents, but their quantity is so small that they act merely as flavoring vehicles. The syrups of glycyrrhiza and of acacia are also used.

COUGH MIXTURES

These polypharmaceutical preparations usually contain morphine and therefore give relief; but since they can not meet the special indications of the different stages, they

should be avoided. The "Brown Mixture," whose activity depends on antimony and opium, is one of the best. This, and a few others, may be mentioned as illustrations.

PREPARATIONS—COUGH MIXTURES

(*Mist. Glycyrr. Co.*—See Index).

(*Syr. Scil. Co.*—See Index).

Species Pectorales, N.F.—Altha, Coltsfoot, Glycyrrhiza, Anise, Mullein, and Orris. Used as infusion 1:10 ad libitum.

Syrupus Pini Strobi Compositus, Compound Syrup of White Pine, N.F.—White Pine Bark, Wild Cherry, Aralia, Gilead, Sanguinaria, Sassafras, Chloroform. Dose, 4 c.c., r drachm.

CALCIUM SALTS

The insoluble calcium phosphate and carbonate serve to give hardness to the bones and teeth. Their deficiency is one of the important phenomena of rickets and osteomalacia. Pathologic calcifications of arteries and other tissues are phenomena of degeneration; their mechanism is not understood.

The soluble Ca ions have equally important functions. They are present in all tissues, and appear to be essential to the proper permeability of the plasma membrane. Excess of Ca is depressant to most nervous and muscular functions, and is antagonistic to Mg and Na. These systemic actions are produced only on excised tissue or with intravenous injection, since the absorption of Ca is quite slow. It has been tried, with only partial success, in various spasmodic conditions.

Acute deficiency of Ca produces stimulation of these structures, most conspicuously of the central nervous system. This is seen in poisoning by oxalates, which precipitate Ca. It may also be produced by the intravenous injection of citrates or tartrates which decrease the ionization of Ca.

Calcium is also necessary for the coagulation of blood and for the typical clotting of milk. Calcium salts have therefore been administered in hemorrhagic conditions; but since these are not due to deficiency of Ca, the additional Ca has no effect.

Calcium seems to decrease the permeability of blood and lymph vessels, and thereby to lessen exudation. It has been used against serum rashes, urticaria, etc. with variable success. Calcium carbonate (chalk) is employed in diarrheas, mainly as antacid and protective; but it may also decrease the exudation directly. Lime-water (solution of calcium hydroxide) is added to milk to increase its alkalinity. Calcium oxide, quicklime, is a slowly acting caustic, and is used, as also the hydroxide or slaked lime, as disinfectant. Calcium sulphate, plaster of Paris, is important for its mechanical properties.

The calcium salts are also used for the actions of their anions (bromide etc.).

Distribution of Ca in Cells.—Calcium is present in practically all cells and tissues. Only a few of the lower fungi are able to live without it. O. Loew, 1899, claimed that it occurred only in the nuclei and not in the cytoplasm of the cells. In support of this, Hoerhammer, 1912, found it absent from the non-nucleated red blood cells (beef), but present in the nucleated corpuscles of chickens. However, Macallum has adduced direct microchemical evidence that it is not in the nuclei proper, but in the nuclear membrane and cytoplasm.

Calcium Income.—The daily requirement for man has been estimated as 0.7 to 1.5 Gm. of CaO (7 parts of CaO = 5 parts of Ca). Ordinary diets contain 0.3 to 4.2 Gm. (according to Sherman and co-workers, 1910 and 1918, American diets yield only 0.08 to 1.69, mean; 0.85 Gm.). It is therefore conceivable that the income may sometimes be deficient, *f.i.*, in pregnancy. It is easily increased by drinking milk; or by diluting the table-salt with an equal amount of chalk (McCollum, 1919).

Only a part of the calcium is absorbed; Forster, 1885, estimates the absorption as about 60 per cent. It is stated that its utilization is better from meats than from vegetables. However, the calcium of carrots and spinach is said not to be as well utilized as that of milk, and probably has no advantage over inorganic calcium salts (McClugage and Mendel, 1918). In fact, the inorganic calcium salts supply the needs as well as natural foods (Osborne and Mendel, 1918).

Calcium in Milk.—Adults require about 0.45 gram of calcium per day. This is supplied by a pint of milk, but would need pounds of meat or cereals. It is not generally realized that milk usually contains more calcium than does lime water (Sherman et al., 1918).

The calcium of milk seems to be more favorably retained than calcium lactate (Givens and Mendel, 1917).

Calcium Excretion.—This is adjusted to the income; but the minimum quantity required to maintain equilibrium varies with the diet (Kochmann, 1910).

Nelson and Williams, 1916, found the average daily excretion by urine and feces in man to total 0.43 to 1.02 Gm. of CaO (all ages, unrestricted diet). 0.15 to 0.5 Gm. per day are excreted by the urine, mainly as phosphate; the remainder leaves by the feces. It is believed (E. Voit, 1880) that a part of the fecal Ca is absorbed by the small intestines and re-excreted by the large. The administration of soluble Mg salts increases the urinary excretion of Ca, but not if phosphates are present in the alimentary canal (Hart and Steenbock, 1912).

In human urine, either Ca or Mg may predominate, this being fairly constant for the individual, and largely independent of the food (Nelson and Burns, 1916).

With *hypodermic injection* of calcium, a large part is excreted promptly by the urine, a small proportion being temporarily retained. The intestines do not always participate in the excretion. The output of Mg is also increased (Mendel and Benedict, 1909).

Calcium Retention and Deficiency.—The administration of Ca (chloride or lactate, several grams per day) increases the Ca stock of the tissues and blood, even in well-fed adults (Voorhoeve, 1911 and 1913).

Lactation depletes the Ca stock, in cows, even when Ca is added to the food (Forbes et al., 1917).

Acidosis on Ca Excretion.—The Ca excretion is said to be increased in acidosis, and in epinephrine glycosuria (Underhill, 1916).

The oral administration of hydrochloric acid was said to increase the urinary excretion of Ca and Mg (Stehle, 1917). However, Givens, 1918, found that the Ca and Mg balance is not materially altered. Alkalies do not decrease the urinary Ca output in human diabetes (Givens and Mendel, 1917).

Calcium Content of Blood.—The corpuscles contain very little calcium; so that there is a marked difference between the calcium content of the whole blood and that of the serum. The calcium content of the whole blood therefore does not permit any conclusions as to calcium metabolism. The calcium content of the serum or plasma, on the other hand, is remarkably uniform (between 9 and 11 mg. of Ca per 100 c.c.; Halverson and Bergstein, 1917), even in most pathological conditions (Halverson et al., 1917). In cows, Meigs and Blatherwick, 1917, found the plasma calcium between 0.0086 and 0.0114 per cent.; practically unaffected by pregnancy, lactation, or considerable changes of diet (in very young calves, however, it is higher, up to 0.11 per cent.).

In *rickets* there is a slight but distinct decrease (Howland and Marriott, 1917). In *tetany*, the plasma calcium falls to 3–5 mg. per 100 c.c. This is counteracted by measures that increase the acid-alkali balance of the body; *i.e.* by the administration of acids, ammonium chloride or calcium chloride. The calcium level of the blood may be very materially raised by the injection of the parathyroid hormone; and the level falls if the parathyroids are excised.

The condition of calcium in the plasma is not adequately understood. A part (60 to 70 per cent.) diffuses readily through colloidal membranes and is presumably ionized; a part is indiffusible, probably in the form of colloidal phosphates and carbonates; and a part is perhaps bound into proteins. The soluble and diffusible calcium exists mainly as calcium bicarbonate (Halverson et al., 1917); and as the solubility of this is limited, the blood-calcium cannot rise materially above the normal limit, unless the acid-base balance is shifted toward the acid side; or conceivably by conditions that favor the existence of colloidal solution. On the other hand, losses of calcium which would tend to reduce the calcium below the level of solubility, would be made good by solution of calcium from the bones, unless associated conditions changed the solvent capacity of the plasma. The marked increase of plasma calcium by administration of the parathyroid hormone, and the decrease in parathyroid deficiency, are presumably due to changes in the conditions that determine the solubility. During the adjustment of the new level, the diffusible plasma calcium changes twice as rapidly as the non-diffusible; but the normal ratio is restored in one or two days (Moritz, 1926).

Calcium Administration on the Urine.—The effects are inconstant (Porges and Pribram, 1908) evidently depending on uncontrolled conditions and probably largely secondary to other actions. The oral administration of large doses of *calcium chloride* increases the acidity of the urine; for a large part of the calcium is converted into the carbonate and escapes absorption; whilst the liberated chloride ion is absorbed and so increases the proportion of fixed acid in the body (Haldane et al., 1923).

This acidity tends to dissolve and mobilize the bone-calcium, so that the prolonged administration of large doses of calcium chloride to animals may actually produce rarefaction of bony tissue (Etienne, 1912).

The urine-flow tends to be increased, in normal individuals, presumably mainly by the acidosis. In perfusion of excised kidney, calcium decreases the vein and ureter-flow (Sollmann), but this involves unphysiological concentrations.

In nephritis (particularly glomerular), large doses of calcium chloride by mouth sometimes causes marked diuresis, but may be ineffective (Keith and Barrier, 1924). The diuresis may outlast the administration (Blum), so that it may be due to absorption of the nephritic edema, rather than to a renal action. The direct effect of the increased acid excretion would presumably be detrimental to inflamed kidneys. Duenner, 1916, found that intravenous injection of calcium into rabbits converted subacute uranium nephritis into the acute form. In human nephritis, Jacoby and Eisner, 1913, found that calcium administration decreased the excretion of chloride, iodide and nitrogen. Abe, 1913, claimed that it prevents the increase of urate excretion by cinchophen. Hamburger found that the sugar retention of frog kidneys was conditioned on a narrow zone of calcium concentration.

Calcium in Bone Diseases.—Rachitis and osteomalacia show deficient Ca content of the bone. Somewhat similar, but not strictly analogous changes, are produced by deficient Ca income in young animals. This suggested the treatment of these conditions by the administration of lime salts, particularly calcium phosphate. The results were disappointing; doubtless because the deficiency is not in the income, but in the assimilation of the Ca by the bone-forming tissues.

Calcium-poor Diet.—If young animals are fed on such a diet, their bone formation is defective. The bones contain about the normal percentage of lime; but very little bone is laid down, and this is thin, pliable, deformed and fragile (E. Voit, 1889). It contains more water, Na and K, while the Mg is not materially increased. However, the percentages vary in different parts of the skeleton. The animals are undersized, with poor appetite and defective nutrition (Weiser, 1914).

Mendel and Osborne, 1917, found that rats require considerable calcium and phosphate for growth.

In rabbits, the Ca content of the bones is increased by green food, diminished by exclusive oat diet (Luithlen, 1912). The difference might be explained by the vitamine content of the green food. The administration of sodium oxalate for a week diminishes the Ca content of the soft tissues before it affects the bones (Sarvonat and Roubier, 1911). If this diet is rich in magnesium, the bones may accumulate double the normal Mg content, but without improving the skeletal development.

Rachitis.—The percentage of mineral substances, and particularly the calcium phosphate in the abnormal proliferating bony tissue is materially reduced, sometimes to half of the normal. This is due to disturbance of the phosphate (see Index) metabolism, and not of the calcium. The calcium income may be abundant (Stoelzner, 1899); the absorption and excretion of calcium are practically normal (Ruedel, 1893); the calcium level of the blood is but little decreased (Howland and Marriott, 1917). The condition is prevented and cured by the antirachitic vitamine, by sunlight, and by ultraviolet lights. The administration of calcium salts could have little effect (M. Klotz, 1915).

Physical Chemistry of Ossification.—Blood plasma is practically saturated with calcium bicarbonate and dicalcium phosphate (H. G. Wells, 1906). Serum dissolves 475 per cent. more CaCO_3 than does water, and 90 per cent. more $\text{Ca}_3(\text{PO}_4)_2$. This relatively high solvent power is due partly to the CO_2 tension, partly to the proteins, which act as protective colloids. Both may be readily altered, for instance by local changes of reaction, or by local autolysis of the proteins. The latter decreases the solubility of the phosphate more than that of the carbonate, so that the phosphate would be precipitated more readily. This agrees with the fact that bone contains about nine times as much of the phosphate than of the carbonate of calcium (Pauli and Samec, 1909). The precipitation of calcium in the presence of colloids was investigated by Sabbatani and Salvioli, 1912.

Osteomalacia.—In this disease, the bone contains but 20 to 40 per cent., instead of the normal 56 to 60 per cent. of inorganic salts, their place being taken by new formed osteoid tissue. The condition is also not ascribable to deficient Ca income, but to excessive destruction of bone tissue. Limbeck, 1894, found the excretion of Ca, especially by the intestines, to exceed the income. Neumann, 1896, also found the excretion high, especially in the early stages, when the Ca of the bones is still high. The later stages may show retention.

Infantile Scurvy.—There is a decided decrease of blood calcium, although not as much as in rickets. This is associated with slight acidosis. There is no tendency to tetany (A. F. Hess, 1919).

Pernicious Anemia.—Moraczewski, 1900, claims considerable loss of Ca.

Diabetes.—Kahn and Kahn, 1915 and 1916, find that diabetic patients have a negative calcium balance. They claim that the intravenous injection of calcium, in diabetic patients, produces marked decrease of glucose excretion, gradual decline of the glycemia, diminished urine output, and relief of symptoms; and that it appears to prevent the development of acidosis. They inject cautiously an m/8 solution of CaCl_2 in normal saline, from 15 c.c. upward. These observations require confirmation. Other investigators found no effect, for instance from the administration of calcium phosphate, even in the mildest cases (Bruning, 1898). Calcium chloride injections prevent the glycosuria and fever of NaCl injections; but large doses of CaCl_2 may themselves produce glycosuria (Underhill and Kleiner, 1908). In *phlorhizin glycosuria*, Jacoby and Rosenbloom, 1915, found that large doses of calcium diminish the excretion of sugar, nitrogen and acetone. The blood-sugar is also lowered, so that presumably the production of sugar is diminished.

Calcium Therapy in Phthisis.—This was recommended by Fourcroy, 1783. It has been tried repeatedly, on the assumption that phthisis is accompanied by excessive excretion of calcium. This has been affirmed by some competent observers, but does not appear to be an invariable phenomenon (Kahn, 1914). Mohler and Bergeim, 1917, found no characteristic changes.

The clinical reports are too discordant to justify faith in this treatment.

Intestinal Tuberculosis.—The intravenous injection of 5 c.c. of 5 per cent. calcium chloride was introduced by Saxtorph, 1918. According to Fishberg, 1919, it relieves

the diarrhea and pain in minor grades. It is ineffective in the severer grades, and is at best only palliative.

Reproduction.—Emmerich and Loew, 1915, observed that administration of calcium to female mice, guinea pigs and rabbits was followed by increased number of pregnancies and higher average of the feti. The addition of solid calcium salts to the ordinary feed of pigeons does not materially influence the amount of calcium in the *egg-shells* (Riddle and King, 1921).

Degenerative Calcification.—This is a common pathologic process, especially in connective tissue.

The calcified areas are generally dead (except those that have the structure of bone). The lime deposits in the dead tissue have usually the same proportion of lime salts as bone, about 87 per cent. of phosphate, and 10 to 15 per cent. of carbonate.

The mechanism of calcification is not understood. Klotz, 1905, believed that it starts with fatty degeneration, the fats and proteins forming soaps, and these passing into Ca soaps, and finally into inorganic Ca compounds. Klotz and Bothwell, 1915, describe fatty changes and deposition of calcium salts, especially in the capillary endothelium of the lungs of rabbits injected intravenously with olive oil or cholesterol. However, this theory seems disproved by the experiments of Wells, 1906, and especially of Baldauf, 1907.

Wells found that certain substances, including dead cartilage, when introduced into the tissue of rabbits, accumulated rather large quantities of calcium, indicating a direct physical or chemical affinity. He believes that the calcium exists in the blood, as a nearly saturated solution of an unstable double salt of calcium bicarbonate and dicalcium phosphate; and that is precipitated from this solution if the CO_2 tension is reduced.

Calcified Arteries.—MacCordick, 1913, finds the rigidity of calcified arteries different during life than after death, and therefore suggests that the Ca is in solution during life, and deposits in the plaques after death.

Systemic Actions.—In general, excess of calcium ions tends to depress, their deficiency to increase excitability. The details, however, vary in different tissues, and presumably according to conditions, especially the ratio of K, Na and H ions. Intact animals also are depressed by excessive Ca concentration of the plasma, whether it is induced acutely by injecting CaCl_2 , or more slowly and persistently by parathyroid hormone; conversely, decrease of the Ca ion concentration of the plasma, by parathyroid deficiency, or by the injection of the anions (oxalate, etc.) that dis-ionize calcium, produce tetany, and increased excitability of the autonomic system (vagus, depressor etc.). Acute hemorrhage does not have this effect (Schafir, 1915), since it does not lower the calcium concentration of the plasma.

Physical-mechanism of Calcium Action.—Hoeber, 1914, suggested that the fact that calcium ions generally favor the consolidation of colloidal systems whilst the alkali metals favor liquefaction may furnish the key to the biologic effects.

Toxic Effects of Calcium Salts.—Large *intravenous injections* produce acute lowering of the blood pressure; paralysis of the heart and respiration; arrest of urine-flow and peristalsis. *Smaller injections*, 0.06–0.09 Gm. of the chloride or acetate per Kg., in cats or dogs, are followed by characteristic impairment of the equilibrium tonus and postural reflexes of the skeletal muscles. The intravenous reactions may be in part colloidal, due to the formation of colloidal $\text{Ca}_3(\text{PO}_4)_2$ (Heubner, 1924).

Hypodermic injections have similar, but much slower actions. Animals die of central paralysis a few days after the hypodermic injection of 0.3 to 0.4 Gm. CaCl_2 per kilogram. Oral administration does not produce these systemic effects.

Respiration of Mammals.—Schlick, 1911, described apparent stimulation in anesthetized animals. Hafner, 1913, finds that this is indirect, due to failure of circulation from cardiac depression. The direct action is respiratory depression, which may be the cause of death.

Perfused Respiratory Center of Frogs.—This was depressed by decrease of Ca, stimulated by absence or excess of Ca (Hooker, 1913).

Circulation.—Small doses, intravenously, sometimes increase the blood pressure and heart rate slightly, by brief depression of the vagi; larger doses paralyze the vagi, but diminish the heart rate and blood pressure, by a mixed effect on the cardiac muscles and nerves (Cazzola, 1913). The small doses may considerably increase the output of

the heart without changing the rate, *i.e.*, by increasing the amplitude (Rothberger and Winterberg, 1912).

Calcium on Heart Muscle.—On excised heart Ca antagonizes both the toxic action of Na and the inhibitory action of K. Calcium free Ringer's solution, therefore, tends to arrest the excised heart because of the predominance of K ions. Complete absence of Ca rapidly abolishes rhythmic contractility. Absence of Ca also removes the rhythmic activity of other striped and unstriped muscle; and these reappear when Ca is added (Buglia, 1911). The effects are so rapid as to suggest that they must be exerted on the plasma membrane.

Other Earthy Metals.—Ba, Sr, Ca and radium emanations act identically on the isolated frog heart, the activity decreasing from barium in the above order. Low concentrations increase the diastole, to diastolic standstill. Higher concentrations increase the systole to systolic standstill (Kionka, 1914).

Cardiac Vagus.—The presence of Ca is necessary for the inhibitory activity of the vagus (Schiff; Busquet and Pachon, 1909); but apparently not for muscarine (O. Loewi, 1912).

However, contradictory results are often obtained, the effects evidently being influenced by conditions. Thus, Brine, 1917 finds, contrary to the former workers, that calcium free solutions, or those poor in calcium, do not interfere with the vagus excitability (inhibition in the perfused turtle heart).

A somewhat smaller concentration of Ca suffices in the presence of K (Hagan and Ormond, 1912). A moderate decrease of Ca increases the excitability of the vagus; excess of Ca diminishes the excitability (Cazzola, 1913). Similar phenomena are observed with the pelvic and chorda tympani nerves (O. Loewi, 1912). Increase of Ca also restores the irritability of the vagus when this has been depressed by Mg (Auer and Meltzer, 1909).

In complete heart-block injections of calcium (or barium) produce attacks of temporary arrhythmia and ventricular tachycardia, increasing to fibrillation. These attacks may be preceded by groups of powerful and rapid beats. The auricles are affected in the same sense, but not as greatly. The blood pressure rises (Van Egmond, 1913).

Calcium Deficiency on Cardiac Drugs.—In perfused frog hearts, absence of calcium from the perfusing fluid does not appear to interfere with the typical action of epinephrine, agaricin, saponin, strophanthin or veratrine.

Blood Vessels.—Hooker, 1911, found that Ca perfusion dilates the vessels of the frog. R. G. Pearce, 1913, found Ca necessary to the vasoconstrictor action of epinephrine in perfused frogs; epinephrine in NaCl producing vasodilation. Ca was not necessary to the vascular effects of curare, ergot, or barium. The conditions seem to be reversed in mammals, for Cow, 1911, found that the sensitiveness of arterial rings to epinephrine and pituitary was increased by absence of Ca; the reaction to barium was again unaffected. With perfused frogs, deficiency of Ca in the fluid causes the production of edema, excess of Ca produces capillary constriction and arrests the flow (H. J. Hamburger, 1922). Hamburger advised a solution containing NaCl 0.6 + CaCl₂ (anhydrous) 0.0035 per cent.

Striped and Smooth Muscle.—The rhythmic contractions, which are started in skeletal muscle when immersed in NaCl solution are abolished by Ca (Sidney Ringer, 1883). Calcium also has a *curare action* (Joseph and Meltzer, 1911). Excised bronchial muscle is constricted by Ca or Sr, though less than by Ba (Trendelenburg, 1912). Calcium arrests pituitary asthma (Kayser, 1914).

Pupil.—Auer and Meltzer, 1909, observed that the intravenous injection of Ca produces a maximal miosis, in which the pupil is irresponsive to sympathetic stimulation. The simultaneous exhibition of other drugs shows interesting complex phenomena. The miotic action appears to be due mainly to direct stimulation of the sphincter muscle fibers, and probably also of their nerve-endings, supported by diminished irritability of the peripheral sympathetic mechanism.

Antagonism of Ca and Mg.—This has been discussed (see Index). It should be remembered that the actions of Ca are conditioned on the ratio of other ions. Thus, the intravenous injection of Ca which is depressant to normal animals, causes recovery of an animal anesthetized with Mg. Strontium does not have this effect (Meltzer, 1909).

The Nature of Calcium Action and Antagonism.—(See Index.)

Inactivation of Calcium.—The Ca in the body-fluids, and presumably in the cells, can be rendered inactive by the introduction of precipitant anions, such as the oxalates or fluorides; or by decreasing its ionization with citrates or tartrates (Sabbatani, 1901 and 1902). In the isolated heart, the toxicity is greatest for citrate, then oxalate, then tartrate (Salant and Hecht, 1914). In either case, the inactivation produces the oppo-

site effects from Ca, viz., excessive stimulation, convulsions, hypersensitiveness of the autonomic nerves, and rhythmic contractions. Similar effects are seen in intoxications by acids, As, Hg or chlorates, which probably all diminish the Ca content (Chiari and Froehlich, 1911). These effects may be promptly removed by the addition of Ca and less efficiently by Sr and Mg (Starkenstein, 1914); but not by other cations, not even by those (Ba, etc.) which precipitate the oxalate. The stimulation is therefore not due to the oxalate, etc., as such, but to the inactivation of the Ca. This is confirmed by the observation that equimolecular solutions of the different inactivators have practically equivalent effects (Starkenstein).

Salant and Hecht, 1914, describe some observations which they consider to contradict this explanation. They find in perfusion of the isolated heart that calcium citrate or tartrate solutions act practically the same as equimolecular calcium chloride. This, however, need only mean that the citrate, when already bound to calcium, does not disturb the ionization of the calcium in the tissues.

Calcium Precipitants on Brain.—Direct application of calcium precipitants to the cerebrum stimulates the white matter, and increases the excitability of the gray matter to electric stimulation (Maxwell, 1906).

Use of Calcium in Convulsions.—The depressant action of calcium suggests its use in *strychnine poisoning*, but Fischer (1904) found it ineffective. Zanda (1902) obtained better results by dural injection; but the effective dose was so large as to be itself dangerous. Januschke and Masslow, 1914, conclude that even large doses of calcium have no direct inhibitory effect on experimental convulsions, whether cerebral, medullary or spinal. The apparently successful results of Januschke, 1913, and presumably those of Yogi, 1912, and other workers, are attributed to delayed absorption of the hypodermic injections of the convulsants, which results from previous calcium treatment.

Calcium chloride administration also controls the *tetany* arising from *parathyroid deficiency* or other causes (Netter, 1907; W. G. McCallum and Voegtlin, 1908; Kinnicutt, 1909). Geopfert advised 8 to 14 Gm. of calcium chloride daily, in doses of 1.5 to 2 Gm. The administration must be continuous, for spasms reappear if it is discontinued for twelve hours (M. Klotz, 1915). Gruenfelder, 1913, reports that *laryngospasm* and tetany are controlled more promptly by calcium bromide (2 Gm. per day) than by sodium bromide.

Control of Inflammations and Edemas.—The administration of calcium salts sometimes diminishes inflammatory phenomena and especially the formation of effusions. This may be ascribed to decreased permeability of the capillary endothelium somewhat analogous to the effects of calcium on other cells; but the effects are uncertain, depending on unknown conditions.

Effect of Calcium on Effusions.—R. Chiari and Januschke, 1910 and 1911, found that the hypodermic injection of Ca prevents the pleural effusion which ordinarily occurs after fatal doses of NaI, diphtheria toxin, thiosinamine, etc. It also prevented the inflammatory edema of the conjunctiva after oil of mustard or abrin; and the irritation of the skin by croton oil (Luithlen, 1913). It has been found similarly useful in various skin rashes. Some of these results were contradicted by Levy, 1911 and 1914, but confirmed by Leo, 1911. The effect of a dose lasts about a day. Fleisher, Hoyt and L. Loeb, 1909, also found that CaCl_2 intravenously, decreases the elimination of injected saline fluids, not only by the kidneys, but to a lesser extent also by the intestines. It also causes some depression of intestinal absorption. On the other hand, it increases the tendency to peritoneal and pulmonary transudation. This is only partly due to interference with the kidney function, for the ascitic tendency is exaggerated by Ca even after nephrectomy. Calcium has also been found unsuccessful in clinical serous effusions. Velden, 1913, suggests that it lessens the absorption of the ascites more than its formation.

Yanagawa, 1916, did not obtain any effect on the *lymph-flow*; but his observations were restricted to very acute changes.

Mechanism of the Antiedemic Action.—Luff, 1909, attributed the effect of Ca to increased coagulability of the blood. However, Chiari and Januschke found it effective even when the blood was kept non-coagulable by hirudin. They suggest that the Ca has a precipitant effect on the cement substance of the endothelium; but more probably, the permeability of all the cells is decreased. Deltjen (1904) has observed that small traces of calcium, strontium, barium, and magnesium lessen the solvent action of distilled water on cells. Herbst found that sea-urchin ova swell when Ca is removed,

and shrink when it is added. Osterhout, 1911 and 1912, showed that CaCl_2 prevents the entrance of NaCl into spirogyra filaments, and that it renders the plasma membrane of kelp (*laminaria*) impermeable. Pfeffer, 1877, stated that calcium phosphate forms semipermeable membranes. These have been investigated in further detail by Meigs, 1915. The changes in the appearance of fluorescein in the anterior chamber of the eye also indicate decreased permeability (G. Rosenow, 1916).

The emulsion experiments of Clowes, 1916, offer a possible explanation of the diminished permeability (see Emulsions, Index).

Phagocytosis may also play a part. H. J. Hamburger, 1910, found that therapeutic quantities, hypodermically or by mouth, increase the ameboid movements of the leucocytes, and therefore chemotaxis and phagocytosis.

This holds true for the leucocytes of rabbits as well as horses (de Haan, 1918); for bacteria as well as carbon. It requires the presence of serum, and the favorable concentration has a narrow range, which varies with conditions and for different organisms (Redden, 1918).

On the other hand, Ikeda, 1916, reports the migration of leucocytes from inflamed frog's mesentery, as inhibited by calcium chloride.

Use of Calcium in Skin Rashes, Catarrhs, Etc.—Wright, 1896, claimed that the administration of calcium chloride tends to prevent the occurrence of serum rashes. Netter, 1907, also believed it useful in urticaria, acute edema, frost bite, and pruritus. Other similar conditions said to be relieved by Ca are boils, erythema, lichen planus, hemoglobinuria, etc. (Luff, 1909); hay fever and iodide coryza (Chiari and Januschke, 1911, Emmerich and Loew, 1915); asthma (Kayser, 1912, 1914). Large doses must be administered for some time (see below), and even then the clinical benefits are uncertain. The susceptibility to experimental wheals (codeine) does not appear to be influenced by the Ca-level of the plasma (Pilcher).

Strong solution of CaCl_2 (10 per cent.) applied to the scarified skin, raises an urticarial wheal (Pilcher and Sollmann, 1916).

Effects of Various Conditions on Skin Reactions.—Luithlen, 1911 to 1913, studying the reaction of the skin of cats to croton oil, found that this may be modified by Ca and oxalates; by different diets (suggesting that eczema may be a constitutional exaggeration of the reaction of the skin to normal irritation); and by the injection of serum, soluble starch and even mineral colloids, *i.e.*, silica. Serum injections have been used clinically against certain skin diseases (A. Mayer and Linser); but are only efficient in those diseases which are based on exudation or transudation.

Calcium on Intestines.—Calcium carbonate, and to a smaller extent the phosphate, have long been used in *diarrhea*. Their action is generally explained as antacid and protective, but it is possible that the depressant ion-action comes into play.

Saline Cathartics.—Chiari, 1910, calls attention to the fact that all the cathartics are antagonistic to Ca; and that this may explain their action, at least partly.

Excised Intestine.—Vanysek, 1914, states that calcium chloride stimulates the circular and relaxes the longitudinal muscle of cat's intestine.

Calcium in Hemorrhage.—Ca is necessary for the action of thrombokinase on thrombogen (or for the conversion of prothrombin in thrombin—Howell, 1914) and hence for the coagulation of the blood. The coagulation of shed blood is prevented by the addition of 0.1 per cent. of a soluble oxalate, or 0.4 per cent. of a citrate or fluoride. The latter, however, acts also otherwise than on the calcium. Strontium and barium have the same effect as calcium, in a less degree (Ringer and Sainsbury, 1890). It has been thought that the administration of Ca would be useful when it is desired to increase the coagulability of the blood, as in persistent hemorrhages, aneurism, hemophilia, purpura, etc. However, the normal content of Ca in the blood is more than is required for coagulation; further increase of Ca does not increase the coagulability. The addition of calcium to hemophilic blood *in vitro* delays rather than hastens its coagulation (Hess, 1915). Nor has it been shown that Ca is deficient in any of these conditions.

Estimations of the coagulation time after administration of Ca have given contradictory results, due partly to differences of technic, partly to the time when the observations were made. The experiments of Velden, 1913, indicate that the coagulability is indeed increased for a short time. This increase is also produced by equal quantities of NaCl, and is probably due to a local action on the alimentary canal. It does not last beyond twenty or thirty minutes, and would therefore be useless. However, since the administration of Ca does no harm, its use may be permissible. Any benefits in purpura (Russel, 1907) could perhaps be explained by its action on the permeability of the vessels.

Historical.—The influence of calcium on coagulation was not recognized till 1879 (Hammersten and others); and its indispensability was first shown by Arthus and Pagès, 1890. The inhibition of coagulation by plant juices, which is due to the disionization of calcium, was discovered by Archibald Pitcairn, 1717 (Sollmann and von Oettingen, 1926).

Clinical Data.—The use of Ca in hemophilia was started by Wright, 1893, who claimed a reduction of the coagulation time to 60 to 70 per cent. Colemann, 1907, found no effect on oral administration, but shortened coagulation time from hypodermic injection. Purely negative results were obtained by Robertson, Illmen and Duncan, 1907; Addis, 1909; Rudolph, 1910; Dale and Laidlaw, 1912; and Hess, 1915. In obstructive jaundice, when blood coagulation is delayed by excess of bile in the blood, Lee and Vincent, 1915, report restoration of the coagulability by calcium lactate (7 Gm. per day).

The theories of hemophilia are reviewed by Hurwitz and Lucas, 1916. Kahn, 1916, reports one case with deficient calcium content of the blood.

With *hirudin plasma* the coagulation is further delayed by the addition of calcium (Hess, 1915).

Other Substances Increasing the Coagulability of the Blood.—Gelatin, kephalin and serum are discussed elsewhere (see Index). Velden, 1911, also found increased coagulability after the digitalis group, suprarenal extract, and amyl nitrite.

Coagulation of Milk.—Ca is necessary for the precipitation of the caseinogen as casein. Its place may be taken by Sr and Ba (Harris, 1896).

Rigor Mortis.—This is hastened by the systemic administration of Ca, delayed by Mg (Meltzer and Auer, 1907).

Oral Administration for Systemic Action.—Calcium carbonate and phosphate are absorbed almost as well as any of the calcium salts, since they are largely converted into soluble salts in the digestive tract (O. Loew, 1914). They should therefore serve quite as well for oral administration, as the water-soluble salts, viz. the chloride, lactate or acetate; but as these happened to form the starting point of the modern calcium therapy, they are still generally prescribed. The chloride is less costly, but its taste is rather more disagreeable than that of the lactate or acetate.

The single *oral dose* of the chloride is 0.5 to 1 Gm., 8 to 15 gr., in solution, with meals. The daily dose against serum rash is 0.75 to 1 Gm., beginning on the day of the antitoxin injection, and continuing for three days after the last injection (Netter, 1909). Against hay fever, hemorrhage, etc., 1 to 3 Gm. are given daily, commencing as early as possible and continuing for several weeks. This continued use does not seem to cause harm (Emmerich and Loew, 1913, 1915). The lactate may be given in double this dosage. Hypodermic and especially intravenous administration appear inadvisable.

Hypodermic Administration.—This has no material advantage. The lactate is preferred to the more irritant chloride; at least, the chloride should not be used in concentrations above 1 or 2 per cent. or there will be indurations or sloughing (Wright, 1896; Seelig, 1925). The local injection of calcium chloride also breaks down the local resistance against bacterial infection, at the site of injection ("Kataphylaxis"). This has

been used to produce experimental injections (Bullock and Cramer, 1919; abscesses, Rossides, 1926).

The concentration of the lactate should not exceed 5 per cent. since stronger solutions solidify (Hugenholtz, 1915). The *hypodermic dose* of the lactate is 0.5 to 2 Gm. in 20 to 50 c.c. of water.

Intravenous injections have been employed in spasmodic conditions; 2 to 4 Gm. of the chloride or lactate in a liter of normal saline, injected very slowly. The chloride should not be injected intravenously in concentrations above 1 per cent. (Seelig, 1925) lest the escape of the solution around the needle cause sloughing.

PREPARATIONS

* *Calcii Carbonas Præcipitatus* (Calc. Carb. Præc.), U.S.P., B.P. (Precipitated Chalk), CaCO_3 .—Fine white powder, without odor or taste. Practically insol. in water; decomposed by acids. *Dose*, 1 Gm., 15 gr., U.S.P., as powder. This will neutralize 0.730 Gm. absolute HCl. Larger doses are harmless. *Dose*, B.P., 1 to 4 Gm., 15 to 60 gr.

* *Creta Præparata* (Cret. Præp.), U.S.P., B.P.; Prepared Chalk (Drop Chalk).—Native Calcium Carbonate freed from most of its impurities by elutriation. A white to grayish-white, very fine, amorphous powder, often formed into conical drops; odorless and tasteless. Almost insol. in water; insol. in alc. *Dose*, 1 Gm., 15 gr., U.S.P.; 1 to 4 Gm., 15 to 60 gr., B.P. Used extensively in tooth-powders.

Mist. Cret., U.S.P., B.P., Chalk Mixture.—The average dose, 15 c.c., 4 drachms, contains about 1 Gm. of Prepared Chalk suspended in Cinnamon Water, U.S.P.; 3 per cent. of chalk, B.P. *Dose*, 15 c.c., 4 drachms, U.S.P.; 15 to 30 c.c., $\frac{1}{2}$ to 1 ounce, B.P.

Pulv. Cret. Co., U.S.P.; Compound Chalk Powder.—A mixture of 30 per cent. of Cret. Præp.; 20 per cent. of Acacia; 50 per cent. of Sugar. *Dose*, 2 Gm., 30 gr., U.S.P.

Pulv. Cret. Arom., B.P.—25 per cent. of Chalk; 50 per cent. of Sugar; with Aromatics. *Dose*, 0.6 to 4 Gm., 10 to 60 gr., B.P.

Calcii Chloridum (Calc. Chlor.), U.S.P., B.P.; Calcium Chloride (Not to Be Confused with Chlorinated Lime, Miscalled "Chloride of Lime"), CaCl_2 .—White, translucent, hard fragments, or granular; odorless, of sharp saline taste. Very deliquescent, and should therefore not be dispensed in powders, but as solution. Freely sol. in water (1:1.2) also in alc. (1:10). *Incompatible* with carbonates, phosphates and sulphates. *Dose*, 1 Gm., 15 gr., U.S.P.; 0.3 to 1 Gm., 5 to 15 gr., B.P., diluted.

It may be made non-hygroscopic by the addition of lactose. (Yearbook, American Pharmaceutical Association, v. 5, p. 268.)

Calcium chloride occurs with varying quantities of water. The U.S.P. specifies a minimum of 75 per cent. of CaCl_2 ; the B.P. is dried at 200°C.

Calcii Lactas (Calc. Lact.), U.S.P., B.P., $\text{Ca}(\text{C}_3\text{H}_5\text{O}_3)_2 + 5\text{H}_2\text{O}$.—White, granular masses of powder, without odor or taste. Sol. in water (1:20), but very slightly sol. in alc. *Dose*, 1 Gm., 15 gr., U.S.P.; 0.6 to 2 Gm., 10 to 30 gr., B.P.

Syr. Calc. Lactophos., B.P.—7.5 per cent. of Calc. Lact. with phosphoric acid; orange-flower flavor. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Calcii Phosphas, B.P., $\text{Ca}_2(\text{PO}_4)_2$.—White powder, insol. in water, sol. in acids. *Dose*, 0.3 to 1 Gm., 5 to 15 gr., B.P.

(*Liq. Calc.*, *Syr. Calc.*, *Calx*.—See Index.)

PARATHYROID HORMONE AND TETANY

The functions of the parathyroid glands are quite distinct from those of the adjacent thyroid; for instance, the parathyroids are usually normal in cretins (Rousay and Clunet, 1910). The glands were discovered by Sandstroem, 1880, and their physiological importance pointed out by Gley, 1892. The literature to 1921 is reviewed by Boothby, 1921.

Experimental Tetany.—Excision of the parathyroid glands of dogs produces tetany; and this is responsible for the convulsions and early fatality of thyro-parathyroidectomy. The symptoms may be temporarily controlled by the injection of parathyroid extracts (Beebe, 1907), and also by the administration of calcium. This suggested that the glands are concerned with calcium metabolism, for instance, that they control the retention of calcium (MacCallum and Voegtlin, 1909). However, it

was noted that parathyroidectomy is also followed by other metabolic changes, which might favor convulsions, although these are really quantitatively unimportant.

The *ammonium content* of the blood is increased by depressed functioning of the liver (Carlson and Jacobson, 1910). *Guanidine*, histamine and similar *toxic bases* appear in the urine (W. F. Koch, 1913). D. M. Paton et al., 1917, suggested that the parathyroids regulate guanidine metabolism and so control muscular tone.

The *carbohydrate tolerance* is lowered by excision of the parathyroids (Underhill and Hilsditch, 1909). Injection of the nucleo-protein produces polyuria and dilation of the pupils (Ott and Scott, 1909 and 1910).

Destruction of the parathyroids also increases the *vaso constrictor response* to nicotine, epinephrin and pituitary, involving therefore the most peripheral vasomotor mechanism. This effect is also counteracted by calcium (Hoskins and Wheelon, 1914).

Interrelation with Thymus.—Uhlenhuth, 1918, found that mammalian thymus produces convulsions when fed to the larvæ of salamanders. This occurs only before their parathyroids have developed. Apparently, thymus contains tetanic poisons, which are antagonized by the parathyroids. Calcium and magnesium also check the thymus convulsions, but much less perfectly.

Calcium Content of the Blood.—The actions of the parathyroid hormone were placed on a definite and quantitative basis by the discovery of Collip, 1925, that the calcium content of blood-plasma can be very markedly raised by the intravenous injection of purified acidulated aqueous extracts of the parathyroid gland (similar to the extracts prepared by A. M. Hanson, 1923). The removal of the parathyroids from dogs lowers the plasma calcium from the normal (about 10 mg. per 100 c.c.) to 5 to 7 mg. or less, when the tetany develops. A single injection of the parathyroid extract restores the calcium level to the normal, and as this is approached, the spasmodic phenomena disappear. The calcium level reaches a maximum in 9 to 18 hours, and then declines to the previous level, in 12 to 36 hours. By repeating the injections daily, the calcium can be maintained at the normal level, and the tetany kept completely suppressed. Injection of the extract in the normal animals raises the plasma calcium in an entirely similar manner; the rise merely starts from a higher level and therefore passes at once into hypercalcemia. A single dose may raise the calcium to 18 mg.

The increase involves first the more diffusible calcium; but the rise of the less diffusible is more prolonged, so that the normal ratio is eventually restored (Moritz, 1926). Presumably this is due to an increase of the plasma phosphate, which seems to follow a curve similar to that of the less diffusible calcium. The plasma chloride is markedly decreased. The *blood pressure* also falls temporarily during the intravenous injection, as with organ extracts.

Phenomena of Overdosage.—When the calcium level of the plasma rises above 15 mg., the phenomena of calcium poisoning develop. Their severity depends not only on the extent, but also on the duration of the calcium rise; a single injection is therefore rarely fatal even if the level reaches 20 or 23 mg.; whilst continued administration would invariably be fatal, even at lower levels. The fatality sets 18 to 23 mg. as a limit for the level to which calcium can be raised. Unskillful administration of parathyroid hormone would therefore be very dangerous; but there is no danger under proper conditions; *i.e.*, careful dosage, surveillance of the patient, and immediate discontinuance when warning symptoms of overdosage appear, namely vomiting and diarrhea. The more severe grades pass through apathy, lethargy and coma to death. The plasma

volume diminishes greatly, and the viscosity of the blood rises correspondingly and hinders the circulation (Collip and Clark, 1925). The picture differs considerably from that of calcium chloride injection, since this does not produce a sufficiently lasting rise of blood calcium; but similar effects follow if sodium biphosphate is injected with the calcium (Collip, 1926).

Clinical Tetany.—Excision of the parathyroid glands in man is followed by the same phenomena as in animals. *Infantile tetany* also presents an identical picture, and the spasmodic symptoms are paralleled by a corresponding fall of the plasma calcium to a mean of about 5 mg. per 100 c.c. (Howland and Marriott, 1917). The concentration of the phosphate in the plasma is approximately normal, but the excretion of phosphate in the urine is diminished. Changes in the guanidine content of the urine have also been claimed, but these are probably due to unreliable methods (Greenwald).

Clinical tetany may be suppressed by the oral administration of large doses of calcium chloride (Netter, 1907; Kinnientt, 1909; Howland and Marriott, 1917). The significance of this was somewhat obscured by the observation that similar improvement is secured by the administration of acid or ammonium chloride which tend like calcium chloride to increase the acid balance. This suggested that the significant feature of tetany consists in "alkalosis" and this may be true in an indirect sense, for it is quite likely that the acid-balance determines the concentration to which the plasma can hold calcium in solution.

The control of tetany by these agents requires inconveniently large doses, and is slow and indefinite. The response to parathyroid administration is more direct and much more prompt. It is somewhat effective by mouth but the absorption is uncertain and difficult to control, and the hypodermic, intramuscular or intravenous injections of the purified extracts are vastly superior. This is effective also in *gastric tetany*.

Other Spasmodic Conditions.—Parathyroid administration and injections have been tried against paralysis agitans (Berkeley, 1909), chorea and eclampsia; apparently without success, for these conditions do not show calcium deficiency. The spasms could probably be allayed by increasing the calcium above the normal, but this would also develop the dangerous effects of hypercalcemia.

Marine, 1914, found that the parathyroid hyperplasia, which is produced in fowl by a diet of maize and wheat, is retarded by feeding calcium, accelerated by sulphuric acid or neutral sulphur.

In *guanidine tetany*, Watanabe, 1918, claims that the blood serum contains about the normal amount of calcium; but that the phosphate content is markedly increased.

Failure against Inflammations and Effusions.—The attempt to treat urticaria, coryza, asthma, edemas, etc., by parathyroid administration, analogous to the administration of calcium chloride, has not given promising results.

Standardisation of Parathyroid Hormone.—The Collip extract ("parathormone") is standardized on dogs, the unit being $\frac{1}{100}$ of the quantity required to raise the plasma calcium of a normal 20 Kg. dog by 5 mg.

Dosage.—This should be adjusted according to the effects. The usual range is 10 to 25 units per day, or on alternate days; 10 mg. in infantile tetany; injected hypodermically, intramuscularly or intravenously, often in fractionated doses. As much as 100 mg. has been injected in an hour, but this is not advisable, and could not be continued.

The desiccated gland was formerly used by mouth, 6 mg. four times daily. This is not recommended.

Toxic Actions.—Morris, 1915, described mental symptoms in a patient which he is inclined to attribute to the prolonged administration of large doses of parathyroid gland.

OXALIC ACID AND OXALATES

Oxalic acid and the oxalates possess a strong acid action, resulting in local irritation and corrosion. In addition, they produce violent stimulation, and later paralysis, by depriving the tissues of their calcium through precipitation. These actions are completely antagonized by the addition of Ca. The oxalates have some toxicologic importance but no therapeutic interest. The small quantities which occur in many vegetables (rhubarb, etc.) are ineffective; at least if these are consumed in the ordinary amounts.

Lower Organisms.—Oxalates are toxic to all life except to a few lower fungi which do not contain calcium. They are toxic to most plants, but certain species contain soluble oxalates. In algae the main histologic changes are seen in the portions richest in calcium—nucleus and chlorophyll (O. Loew, 1912). Oxalic acid is probably a constant product of metabolism, and possibly one of the functions of calcium is to render it harmless.

Actions on Peripheral Autonomic Nervous System.—The oxalates act like deprivation of Ca; *i.e.*, they increase the sensitiveness to epinephrine and pilocarpine; but they diminish the excitability to electric vagus stimulation (Chiari and Froelich, 1911).

Skeletal Muscle.—If dilute solutions of oxalates are applied directly to skeletal muscle, they cause rhythmic contractions. Lessening the proportion of Ca by any other means has the same effect. Larger doses of oxalates depress the excitability and force of the skeletal and cardiac muscles.

Frog's Heart.—Injections of oxalates produce slowing and weakening; with stronger concentrations prompt diastolic arrest, first of the ventricle, then of the auricles. This can be removed completely by rinsing with Ca solution (Januschke, 1909). Washing with NaCl alone gives much poorer recovery (Gros, 1913). Similar effects are seen with perfused mammalian hearts (Salant and Hecht, 1915).

Intact Frogs.—These show progressive and descending loss of reflexes; fibrillary twitchings; central paralysis; finally cardiac arrest. This is also promptly removed by Ca and Sr.

Intravenous Injections in Mammals.—The oxalates affect first the *central nervous system* in its whole extent, from mental functions to reflexes, producing at first stimulation, with convulsions, and then *paralysis*, the latter being the more conspicuous with large doses.

The medullary centers are especially affected. In consequence of the *asphyxia* produced in this manner they cause glycosuria, and possibly through the same cause indicanuria. The temperature rises. *Death* occurs from respiratory paralysis, excepting when the poison is injected directly into the circulation, in which case it may paralyze the cardiac muscle (slowed heart and fall of blood pressure, v. Vietinghoff-Scheel, 1901; Starkenstein, 1914). In *excised intestines*, the calcium precipitants increase the tone and the pendulum movements (Starkenstein).

Oxalates, injected with Mg, increase the anesthetic effect, presumably by inactivating the antagonistic Ca (Gates and Meltzer, 1914).

Blood Coagulation.—This is prevented *in vitro* by the addition of 0.1 per cent. of ammonium, potassium or sodium oxalate. This is due entirely to calcium precipitation, so that the addition of calcium chloride restores the coagulability (Arthus and Pagès).

Fate and Excretion.—Oxalates are very resistant to oxidation in the animal body. Indeed, there has been some question whether any is burned; but it seems certain that a limited amount is oxidized. The excretion (92 to 95 per cent. after hypodermic injections) occurs almost completely by the kidneys. The fresh urine contains mainly oxaluric acid, $\text{CO} \cdot \text{NH} \cdot \text{CONH}_2$, but on standing, this decomposes into urea and oxalic

acid; and this forms calcium oxalate. This is almost insoluble and occurs as envelope-shaped crystals, which are diagnostic of oxalate poisoning. The crystals may be excreted in such great amounts as to block the urinary tubules, and may thereby possibly lead to *nephritis*, or retention of urine and uremia. Calcium oxalate, in rod-shaped crystals, may be found in all the organs, but it may be absent from these in very acute poisoning (Mürset, 1885).

Oxalate Poisoning. When taken by mouth, the oxalates are *readily absorbed*, and poisoning is not at all infrequent from confusion with other salts.

The *symptoms* are: first, those of a local caustic, especially when the acid was used; then those of collapse, the latter possibly preceded by convulsions. The pulse is very small and weak.

Death by oxalic acid and oxalates usually occurs very rapidly, much more quickly than by other caustic substances. This is of diagnostic importance. (In one case death took place in ten minutes.) Sometimes fatal collapse may occur after hours of relatively slight symptoms (O. H. Brown and Scott, 1912). (A study of seventeen human cases of oxalic acid poisoning is reported by Wichern, 1912.) The *fatal dose* varies with the concentration. The smallest recorded amount is 5 Gm. *Metabolism* is markedly depressed in oxalate poisoning, especially the production of carbonic acid. The respiratory quotient falls (Corley, 1902). The urines in Wichern's cases were scanty, with traces of albumin, and rarely calcium oxalate crystals. Polyuria developed later. Hemorrhagic nephritis was not observed.

Treatment of Oxalate Poisoning.—The chemic *antidote* would be calcium in any shape, calcium chloride and lactate, chalk, lime-water, etc. (Husemann). Liberal quantities of water should be given to prevent the deposition of crystals in the kidneys. Calcium lactate could also be given by vein; magnesium sulphate as cathartic; digitalis against collapse.

Experimentally, magnesium injection has proven of some value by quieting the stimulation (Gates and Meltzer, 1917; Gates, 1918).

Cumulative Action.—This is observed after continued feeding of rabbits with oxalates or citrates (Salant and Swanson, 1918).

Rhubarb Leaf Poisoning.—Serious and even fatal poisoning has been attributed to the eating of boiled rhubarb leaf "greens." The leaves contain about 10 grains of oxalate per pound, and this has been held responsible for the poisoning (J. A. M. A. 1917, 68:1928, 1919, 73:926). The connection appears rather doubtful.

Oxalate Content of Vegetables.—Data are given by Arbenz, 1917.

FLUORIDES

Sodium fluoride is a general protoplasmic poison. It has a strong *local irritant action*, a 2 per cent. solution being corrosive to mucous membranes. The *systemic action* resembles that of the oxalates and is probably produced in the same manner, by the formation of insoluble calcium salts.

In the *frog*, it produces fibrillary contraction of the muscles. These disappear on section of the nerve. Larger doses produce rigor. The systemic effects are dyspnea, loss of reflexes, stoppage of respiration, cardiac standstill. In *mammals* it causes salivation, gastroenteritis, dyspnea, muscular weakness and tremors, epileptic convulsions, fall of arterial pressure, and stoppage of respiration and heart. Rigor sets in quickly (Tappeiner, 1889). The abdominal organs are congested. The intestinal epithelium is destroyed (even when the poison is introduced by other channels), while the cilia of the respiratory epithelium may still be moving (Siegfried, 1901). Small doses poison the blood vessels, first increasing their permeability (Asher, 1910).

Blood Coagulation.—The addition of 0.4 per cent. of sodium fluoride renders the blood non-coagulable. This is not due merely to the precipitation of calcium, for the coagulability is not restored if the calcium is restored, but only if thrombin is also added. It has been suggested that the fluoride prevents the breaking up of the platelets and leucocytes; but this requires confirmation.

Acutely Fatal Dose.—For mammals, this averages about 0.5 Gm. per Kg. of body-weight, by mouth; about 0.15 Gm. per Kg. hypodermically or by vein (Tappeiner 1889).

Continued Administration.—When sodium fluoride is administered to rats over prolonged periods (Goldemberg, 1917, 1919; Sollmann, 1921) in daily doses of 15 to 150 mg. per Kg. of body weight, it produces progressive impairment of growth and food consumption, but with little mortality; and without any histologic lesions.

The damage is proportional to the dose. It tends to outlast the administration of the drug; so that the growth of animals that have been poisoned with fluoride remains permanently below that of unpoisoned animals.

The diminished food consumption is not due to distaste of the fluoride food; for the animals do not prefer unpoisoned food (except with the highest concentrations). The effects are not due to "general salt action" for corresponding doses of NaCl are not harmful.

Calcium fluoride in the form of "phosphate rock" produces the same effects as NaF and in nearly corresponding doses. The deleterious effect of phosphate rock is not shared by other insoluble Ca salts (phosphate and carbonate) in equal concentration.

No deleterious effects on growth or food consumption occurred in nine weeks with daily doses of 8 mgm. of NaF per kilogram of body weight, or with smaller doses.

Similar effects from analogous doses have been observed by other writers on other animals. (Literature, Sollmann, 1921.)

Production of Goiter.—Goldemberg, 1921, found that rats which received small doses of sodium fluoride (2 to 3 mg. per day) developed marked goiter, and young rats showed the phenomena of cretinism. Nephritis also set in.

Deposition in Bone and Normal Occurrence.—When fluorides are given in small amounts, greatly diluted, they are absorbed and deposited for the most part in the bones (Tappeiner and Brandl). The bones become unusually hard, white, and brittle, and contain small crystals, presumably CaF_2 . A small amount of the latter is normally contained in the bones and teeth (Gabriel, 1893); but the percentage (0.02 to 0.05) is so small that it can not be regarded as essential (Jodlbauer, 1901). Still smaller quantities are found in the epidermis, hair, thymus, testes, blood, milk, etc. (Gautier and Clausmann, 1913, 1916). Zdarek, 1910, found it present in the entire human body, but relatively richest in the liver, kidneys and bones. In the latter, half of the fluorine is in their fat.

Antiseptic Action.—The fluorides are quite markedly antiseptic. In the proportion of 1:200 they prevent completely the development of bacteria, and are sometimes used for this purpose. They have no important therapeutic application, and small toxicologic importance.

Sodium Fluoride is used extensively against roaches. If it is loosely wrapped in paper, so that it may be reached and eaten by the animals, it is devoid of danger; but it often fails to be effective.

Ammonium Bifluoride in Dentistry.—This was introduced by J. Head, 1913, for the treatment of pyorrhea alveolaris. He uses a 23 per cent. solution, injected once or twice weekly around the loose teeth. It is antiseptic and disintegrates the "tartar."

Hydrofluoric acid is a very violent volatile caustic. The burns suppurate, and heal very slowly.

Sodii Fluoridum (Sodium Fluoride), NaF.—Soluble in 25 parts of water. Used externally as antiseptic. For dressings, 0.5 to 10:1,000; injections, 0.25 to 1:1,000; against fermentation in food, 10 to 15 mg. per liter. 0.25 Gm. are said to have produced dangerous symptoms in man.

STRONTIUM

This cation resembles calcium, and may take its place in some of its characteristic pharmacologic relations; but it is much weaker and also less toxic. Strontium possesses no therapeutic indication.

Like Ca, strontium hastens the coagulation of blood although it is much weaker (Howell, 1914). This action is not shared by Ba or Mg. In dilute solutions only very small amounts are absorbed from the stomach; none from the intestine, since it is converted into phosphates, in which form it is also generally deposited in the bones. The urine contains only traces of strontium, even if this is given subcutaneously; the excretion occurring mainly by the intestine (Wood, 1898). It increases the elimination of uric acid. Its administration to young animals or in intrauterine life disturbs the bone formation. The osteogenetic tissue is stimulated, but the bones are imperfectly calcified, since the Ca is deficient and the Sr is deposited very imperfectly (Lehnerdt, 1909 and 1913; Kinney and McCollum, 1923).

Anion of Strontium Salts.—Strontium salts have been used, in the same dosage as the sodium salts, mainly on the supposition that the anions would be more slowly absorbed, and would therefore have a more gradual and milder action. This theory is without foundation. Iodide, for instance, is absorbed with the same rapidity as from the potassium salt (Krahulik and Pilcher, 1918); and the "toxic" effects of strontium salicylate are just as pronounced as with the sodium salt (Blankenhorn, 1916).

BROMIDES

Fairly large doses of bromides depress the psychic functions and the reflexes; leading to a condition of mental dulness and apathy, which conduces to sleep, particularly in nervous insomnia. The bromides are also employed against other nervous hyperexcitabilities, Graves' disease, hysteria, hyperemesis, cinchonism, etc. Their anticonvulsant action is utilized especially against epilepsy. They generally suppress or mitigate the convulsions, at least in the idiopathic form; but they do not effect a cure. The effects occur only slowly, and are correspondingly lasting. The administration must be fairly continuous. The action seems to be due to the Br ion as such. It is produced by all the bromides, and to a less degree by the organic bromine compounds. NaBr is generally preferred. The mechanism is not explained. The excretion of Br is analogous to that of Cl. A part is retained very persistently. The elimination is hastened by Cl administration; and conversely, the Br retention effects are increased by Cl-poor diet.

Continued administration of large doses often results in bromide acne, and other symptoms analogous to iodism. There may also be considerable psychic depression, malnutrition and lowered resistance. These may contraindicate the use in neurasthenic patients, etc. Acute bromide poisoning is rare, occurring only after enormous doses. Ordinary doses have no effect on the circulation.

Absorption.—The bromides are rapidly absorbed from mucous membranes. It was believed that calcium bromide is absorbed more slowly; but Hales and Fishman, 1908, found it excreted at about the same rate as NaBr. In ligated *intestinal segments*, the absorption of bromides is not delayed by the presence of chlorides; but bromide somewhat delays chloride absorption. The lower segments of the small intestine are said to absorb bromide better than the upper (Bolgár, 1910).

Channels of Excretion.—The excretion occurs as bromide mainly by the urine. Small quantities are also eliminated by the feces, sweat (Tachau, 1911) and other secretions; sometimes in the cerebro-spinal fluid (Hald, 1911).

Course of Urinary Excretion.—This starts promptly but proceeds slowly; *f.i.*, in one to one and one-half days only one-tenth may be excreted, and traces are found after twenty days. The rate is only half or less that with iodides (Herzfeld and Gormidor, 1912). The kidneys are also less permeable to bromides than to chlorides (U. J. Wile, 1923). The bromide excretion depends somewhat on diuresis, but only imperfectly (Hales and Fishman, 1908). The quantity excreted is proportional to that administered, but always with considerable retention. With continued use, the percentage excreted increases until it equals the ingestion, constituting equilibrium or saturation for that dose. When the administration is stopped, the excretion diminishes; at first rapidly, then more slowly, so that traces may be present for a month or longer. The excretion follows the same laws in epilepsy as in normal individuals (v. Wyss, 1906).

Influence of Chlorides.—Chloride administration hastens the elimination of both Br and I (Herzfeld and Gormidor, 1912; Wyss, 1913); while Cl-poor foods slow the excretion (Honda, 1902; Sarvonat and Cremien, 1911). Conversely, the administration of bromides increases the elimination of Cl (Wolf and Opp, 1912; Wyss, 1913). Iodide also displaces Br and Cl. Boenniger, 1907, claims that bromide administration may save animals from chloride starvation, and replace the Cl of the serum completely. This is doubtful.

Bromides on Diuresis.—The urine flow is increased by salt action (Wolf and Opp, 1912).

Bromides in Uranium Edema.—Uranium animals become distinctly less edemic when bromides are administered. These cause a greater diuresis; the Cl excretion is as high as normal; and the urine contains a part of the Br. The body therefore loses both water and salt (Leva, 1912). This may explain the effect.

Bromides on Metabolism.—The actions are not important. Chittenden, 1884, claimed slight increase of N and decrease of PO_4 excretion. Jappelli, 1912 and 1913, found little effect on the total N or P; but diminution of the uric acid and increase of the

purine bases. He considered that this is due to an *inhibitory action on ferments*, analogous to the bromide effect on pepsin (Chittenden) and oxidase (Senter). The claim that bromide increases the elimination of phosphates needs confirmation.

Retention of Bromide.—The retained Br is distributed similarly to the normal Cl, which it partly replaces in the blood, gastric juice, etc. (Nencki and Simonowski, 1893; Ellinger and Kotake, 1911). Apparently, the tissues and kidneys do not differentiate sharply between the two ions (E. Frey, 1910). The replacement of more than 40 per cent. of the Cl of the blood by Br is said to be generally fatal (Bernoulli, 1913).

Distribution in Different Organs.—This has been studied especially by Wyss, 1906. He found the largest quantity in the blood. Even after long administration, the brain contained a relatively small proportion. In an epileptic patient, the percentage in the brain was 0.06; in the blood, 0.14. The quantity in the whole brain figured about 1 Gm. Ellinger and Kotake, 1911, found the distribution proportional to the normal richness in Cl. The distribution after therapeutic administration is described by Carnot and Coirre, 1914.

Condition in Blood.—The Br occurs almost exclusively in the serum (Wyss). However, Boenniger, 1909, states that the corpuscles are permeable to Br and Cl in both directions; that a Br solution may displace all but traces of Cl from the corpuscles; and that the Br in turn can be replaced by Cl.

Absence from Normal Tissues.—Baldi claimed the presence of Br in normal thyroid; but this was not confirmed by Roos, 1898. Pribram, 1906, also found absence of notable quantities in the thyroid and other human organs.

Relative Retention of Organic and Inorganic Br.—The organic Br compounds are apparently retained somewhat more efficiently than the inorganic. This has been cited as a proof of superiority; but it is doubtful whether the retained Br is the bearer of the therapeutic action (Magnus-Alsleben, 1911). Sabromin was retained relatively more in the adipose tissues, but not in the brain (Ellinger). Bromipin was eliminated by the urine, partly in organic combination, but mainly as inorganic bromide (Bermann, 1910). He has also studied the fate of other organic Br compounds). The lipoid-soluble bromural passes at first mainly into the nervous system; but it is rapidly decomposed into a water-soluble form, presumably bromide; which then follows the course of the ordinary bromides (Takeda, 1911).

Historical.—Bromides were first tried as substitutes for iodides. This was unsuccessful, but led to the observation of their sedative action. Their use in epilepsy is said to date from Laycock, 1853; as hypnotic, from Behrend, 1864. The older literature is reviewed by Krosz, 1876.

Sedative Action in Man.—A single dose of 1 to 2 Gm. of bromides has no noticeable action on normal individuals. Above 4 Gm., depression and decrease of reflexes become apparent. The effects are rather different from those of the ordinary hypnotics: The bromides tend to produce a mental calm, aloofness, and imperturbability, progressing to sluggishness, lack of attention and lassitude. These all dispose toward sleep, which it is fairly easy, however, to resist. Perception, observation, and motor reactions may be normal, and the soundness of the mental processes are not impaired, if the effort is made to use them. With the smaller doses the subject awakens refreshed; but with larger doses, the psychic depression persists. Still larger doses (10 to 15 Gm.) cause, besides some nausea, considerable apathy and confusion of speech, but not sleep (Binz). These doses also lower the reflexes from the skin and mucous membranes; so that irritation of the fauces does not produce retching (Krosz, 1876). This was utilized, before the introduction of local anesthetics, for examinations of the throat, etc.

Use of Hypnotic.—Bromides do not enforce sleep, but act rather by permitting sleep through the elimination of excessive worry, restlessness etc. They are more efficient in quieting pathologic excitability; and of no value against pain. The dose should be 2 Gm. or more, one to two hours before retiring. The bromides may be usefully combined or alternated with the more powerful aliphatic hypnotics or morphine. The effect is simply additive (Klammer, 1913); or perhaps slightly potentiated (Janu-

schke and Inaba, 1913). Bromide has little if any action on pain, except that it renders the patient less apprehensive.

Use in Other Conditions of Nervous Hyper-excitability.—The depressant effect of bromide is largely utilized in hysterical conditions; Basedow's disease; acute cerebral excitement; in meningitis; in the nervous vomiting of seasickness and pregnancy; to prevent cinchonism; incontinence of urine; as anaphrodisiac in sexual hyperesthesia; and against delirium tremens and convulsions—epileptic, chorea and others. The dosage for the minor nervous conditions is 0.5 to 1 Gm. two or three times daily; against cinchonism, 3 parts of bromide to 1 of quinine; against seasickness, 4 to 5 Gm. daily for several days before the voyage; in pertussis, it is said to allay the paroxysms, but without shortening the course. Convulsions require at least 15 Gm.; if necessary by rectum. Large doses have been given in acute mania, but probably without much benefit.

Use in Epilepsy.—This is the principal employment of the bromides. They do not seem to be efficient in all cases, probably because epilepsy has different causes. The successful cases amount to something like 90 per cent. in idiopathic epilepsy.¹ Large doses must be employed and continued for some time. In most cases, the attacks become milder and less frequent, or may be suppressed entirely; but they usually return soon after the remedy is removed. The rare cases in which the convulsions disappear permanently are presumably spontaneous recoveries. The disadvantages of bromides have led to the partial or complete substitution of phenobarbital, which is equally effective.

Dosage in Epilepsy.—The effects are secured only when the organism is "saturated" with bromide. The required dose varies for different patients and must be ascertained by trial. The efficiency may be increased by Cl-poor food (Toulouse and Richet, 1900; Ulrich, 1912); or by the administration of calcium (Januschke, 1913). These modifications may succeed when the simple bromide treatment fails. The daily dose of bromide should be divided into three or four fractions, and freely diluted with water. Tablets are undesirable, because of the local salt-irritation.

Poulsson recommended the following routine, to be modified as needed: In the first week, 3 Gm. daily; second week, 4 Gm.; increasing by 1 Gm. each week, until 10 Gm. are reached in the eighth week. If well tolerated, and if the attacks persist, the weekly increase may be continued until 15 Gm. are reached in the thirteenth week. The dosage is then reduced in the same way until the attacks recur; when the treatment is again started in the same way. A few trials ascertain the doses required to reduce the attacks to a minimum. This dosage is then continued as long as needed; and renewed at intervals even after complete disappearance of the attacks, to anticipate recurrence. Bromide acne need not interfere with the treatment; but severe depression necessitates reduction, or even discontinuation.

Other Drugs Used in Epilepsy.—Besides the bromides and phenobarbital the following drugs have been used empirically: opium, valerian, belladonna, zinc oxide, chloral, adonis vernalis, solanum carolinense, salicylates and antipyretics. It is very difficult to form an estimate of their value, since epilepsy is temporarily benefited by suggestion.

The inhalation of amyl nitrite is sometimes useful during the attack.

Central Action of Bromides on Animals.—These are analogous to man, and can be better utilized for studying the mechanism of Br action.

Albertoni, 1882, found that bromides lower the excitability of the motor cortex of dogs, so that a stimulation of the motor areas which, under the conditions of the experi-

¹ Binz gives the following compilation: Total abolition as long as drug is continued, 12 per cent. Diminished number and violence of attacks, 83 per cent. No influence, 2½ per cent. Number of attacks, increased 2½ per cent.

ment, gives rise to general epileptiform convulsions, will, after the administration of a bromide, be confined to the area directly stimulated. The calming effect of bromide renders animals less subject to the "start-reflex," and therefore less liable to *strychnine convulsions*; although the increased primary reflex, for instance the patellar, persists.

Guinea Pigs.—Large doses of NaBr (0.1 to 1 Gm. per pig of 200 to 250 Gm.) produce a deep sleep, lasting two or three days. This is preceded by a long latent period, even if the administration is hypodermic or by vein. The hypnotic effect is antagonized by picrotoxin or strychnine (Januschke and Inaba, 1913).

Frogs.—These do not exhibit acute actions.

Rabbits.—These show both acute and chronic effects closely resembling those observed in man. The symptoms, rapidity and dosage are nearly the same, whether the administration is by mouth, hypodermic or vein (Bernoulli, 1913). Doses of 2.3 to 3.2 Gm. per kilogram, by vein, generally produce little immediate effect. After several hours to three days, the rabbit becomes apathetic and sluggish. The sensibility and reflexes are somewhat depressed and delayed. Muscular coördination is often disturbed and ataxic. Ascending muscular debility and pareses are frequent. *Chronic poisoning* also produces these pareses, but no narcosis or other cerebral depressions (Januschke, 1913). Both forms prevent camphor and picrotoxin convulsions. The rabbits often show slowly developing irritant phenomena in the skin and mucous membranes, analogous to bromism: general dermatitis, loss of hair, conjunctival congestion, coryza, etc. *Outcome.*—If the nervous symptoms are fully developed, spontaneous improvement is exceptional. The rabbits die in coma after several days.

Perfusion of Isolated Respiratory Center.—This is stimulated with iodide, bromide and nitrate ions (Macht and Hooker, 1918). The conditions and concentrations, however, are too artificial for practical application.

Efficiency against Experimental Convulsions.—Intravenous injection of sodium bromide suppresses the epileptic convulsions of camphor and the medullary convulsions of cocaine, but not the spinal convulsions of strychnine or picrotoxin (Januschke and Inaba, 1913). The "Erlenmeyer mixture" of NaBr, KBr and NH_4Br , appears to differ in that it does not suppress cocaine convulsions with acute, but only with continued administration. This is perhaps explained by the observation that the injection of ammonium bromide is convulsive. CaBr_2 is no more efficient than NaBr (Januschke and Masslow, 1914).

Mechanism of Bromide Action.—Wyss proposed the theory that bromides act merely by displacing Cl from the body. This explanation is inadequate. An older theory which attributed their action to the liberation of free Br is not tenable; it appears that the action is due directly to the Br ions.

Chloride-deprivation Theory.—This was suggested by the increased elimination of Cl following Br administration. It was found that the efficiency of bromides was increased by Cl-poor food; and conversely, that the administration of large doses of NaCl (20 Gm.) brought on epileptic attacks in patients who had been under the control of bromides (Wyss, 1913). These observations, however, do not prove the contention; for deprivation of Cl increases the retention of Br; and administration of Cl increases the elimination of Br. The results would therefore equally support the theory of a direct Br action. On the other hand, a number of facts speak very strongly against the Cl-deprivation theory: Simple dechloration may produce ataxia, but lacks the antispasmodic action of bromides. The bromide action occurs even when Cl loss is fully compensated by the food. Recovery from Br may occur even when Cl is withheld. Injection of Cl causes some recovery from bromide poisoning; but citrates, sulphates and nitrates have a similar, though weaker saving action (Bernoulli, 1913). Januschke and Inaba, 1913, found that the bromide depression in animals could not be efficiently antagonized by the administration of NaCl, nor reinforced by Cl-poor food.

The Effects are Due to the Bromide Ion.—The characteristic action is produced in animals by all bromides; but not by organic Br compounds, nor by bromates (Januschke, 1913). Bernoulli 1913, finds that the excised brain and other tissues swell more in bromides than in equimolecular solution of chlorides. He suggests that this may be the basis of bromide action; but this would require stronger evidence.

Actions on Circulation.—Bromide has no effect, except slight depression with single doses above 10 Gm. Sedative doses may indirectly slow the heart and lower the blood pressure somewhat, especially in cardiac neuroses. Large doses of KBr may show the depressant potassium action.

In the cat, the *intravenous injection* of the NaBr, 3 c.c. of 1.5 per cent. per kilogram, had no effect (Lehndorff, 1914).

Perfused Hearts.—The substitution of bromides for chlorides in Ringer's fluid produces practically no effect in cold-blooded hearts, except a slight acceleration in starting. In warm-blooded hearts, there was a slight decrease in rate and amplitude (Greene and Kruse, 1913).

Excised Uterus.—Replacement of Cl by Br or I produces a slight increase of tonus, without affecting the rhythmic contractions. Fluoride increases the tonus and rhythmic contractions, without injuring the muscle (Prochnow, 1911).

Isolated Intestine.—With this and other smooth muscle, the replacement of the chloride of Ringer's solution by bromide increased the tone, amplitude, rate and rhythmic excitability; especially in mammals (T. K. Kruse, 1917).

Secretions.—Bromide somewhat increases the secretion of mucus by salt action. It diminishes the milk. Variable results have been reported as to menstruation.

Gastric Irritation.—Large doses of bromide, especially in concentrated solutions, produce nausea, vomiting and gastralgia, by local salt action.

Acute Bromide Poisoning.—This is rare, but may occur from large doses, especially if the excretion is imperfect in nephritis. There is mild collapse, impaired speech, stupor, and paralytic phenomena. The treatment would be by NaCl infusion.

Bromide Rashes.—These occur frequently, especially in the face, when the administration of Br is prolonged. They resemble those of iodism. The mucous membranes may also be irritated. Similar effects occur in animals (Bernouilli, 1913). Bromide (or iodide) administration may also cause the "lighting up" of latent inflammatory processes, for instance tuberculosis (Block, 1920). The rashes are best prevented or treated by cleanliness. They generally disappear promptly after discontinuation.

The *bromide rashes* resemble acne vulgaris (but without comedones). They sometimes become confluent, forming superficial carbuncles.

Children are especially susceptible and may show pustules and fleshy masses, distributed symmetrically over the face, trunk and limbs, often becoming confluent, and occasionally vegetating (H. MacCormac).

Explanation of the Skin-rashes.—An older explanation (Adamkiewicz) attributed the bromide and iodide acne to direct irritation by the liberation of free bromine or iodine by the acid secretions of the sebaceous glands etc. This cannot be accepted (Unna, 1912) for these elements could not exist free at the reaction of the body (Sollmann).

Presumably the cause lies in a peculiar sensitization of the skin; for bromide administration sensitizes to the "*Luetic*" test, although less actively than iodide (Cole and Paryzek, 1917; Kolmer, 1917).

Chronic Bromide Depression and Cachexia.—Long-continued use of the drug generally leads to psychic deterioration, weak memory, apathy, disturbed speech, ataxia, tremors, somnolence, sexual impotence; and to nutritional disturbances: anorexia, malnutrition, anemia, emaciation, diarrhea and lowered resistance. The symptoms disappear rapidly when the drug is stopped or the dose reduced, and especially if chloride is given (Schabelitz, 1916); but the resistance remains low for some time.

Contraindications to Bromides.—Because of these depressant effects, large doses of bromides should be avoided in mental or physical debility, old age, melancholia, neurasthenia, etc.

Choice of Preparations.—The inorganic bromides are most efficient. NaBr is generally preferred because it is less irritant, and has a less disagreeable taste than KBr, or especially NH_4Br and LiBr. NH_4Br liberates bromine on exposure to air, which is a serious objection. The long continued administration, for instance in epilepsy, of large doses of a single bromide would be expected to disturb the cation balance of the body,

and a mixture of bromides, such as the "Erlenmeyer Mixture" ($\text{KBr}:\text{NaBr}:\text{NH}_4\text{Br}::1:2:1$) might have advantages. However, there are no data that this particular ratio is well balanced; and the normal ratio in the body is perhaps sufficiently well maintained by the adaptation of the excretion. The subject deserves investigation.

CaBr adds the depressant action of Ca and is said to be more efficient; but the continued administration of the large quantities of Ca may be detrimental. The same holds probably also for strontium bromide. HBr is too irritant.

Organic Br Compounds are said to be less likely to produce toxic Br effects; but this could be explained entirely by their low Br content. No real advantage has been established for them, and they are probably much less efficient. No effect can be expected from the bromide in salts which are used in small doses—e.g., bromide of quinine, or arsenic, etc. In these it can be useful only by influencing the solubility or dissociability of the compound.

Sodium Bromide in Roentgenography.—Weld, 1918, reports that the 25 per cent. solution may be used in place of thorium citrate or potassium iodide solutions. The shadows are fully as clear; bromide does not damage the kidneys, is less irritating to the pelvis and ureter, and is less expensive.

PREPARATIONS

Acidum Hydrobromicum Dilutum (Ac. Hydrobr. Dil.), B.P.—10 per cent. of HBr . Colorless, odorless liquid; strongly acid taste. Dose, 1 to 4 c.c., 15 to 60 minims, B.P.; diluted.

Ammon. Brom., U.S.P., B.P.; NH_4Br .—Freely sol. in water (1:1.3); sol. in alc. (1:12). Other characters. Dose, etc., as Sod. Brom.

Calc. Brom., U.S.P.; CaBr_2 .—Granular; very deliquescent. Very sol. in water (1:0.7); freely sol. in alc. (1:1.3). Dose, 1 Gm., 15 gr., U.S.P.

Pot. Brom., U.S.P.; B.P.; KBr .—Freely sol. in water (1:1.5); slightly sol. in alc. (1:250); freely sol. in glyc. (1:4.6). Other characters. Dose, etc., as Sod. Brom.

**Sodii Bromidum* (Sod. Brom.), U.S.P., B.P.; NaBr .—Colorless, cubical crystals or white granular powder; odorless; saline taste. Freely sol. in water (1:1.1); sol. in alc. (1:16). All bromides are *incompatible* with strychnine. Dose, 1 Gm., 15 gr., U.S.P.; 0.3 to 2 Gm., 5 to 30 gr., B.P.; in dilute solution.

Stront. Brom., B.P.; $\text{SrBr}_2 \cdot 6\text{H}_2\text{O}$.—Very sol. in water (1:0.35); sol. in alc. Dose, as for Sod. Brom.

BROMINE

This is a reddish brown, very volatile and intensely corrosive liquid. Only a few instances of swallowing bromine are recorded. In one of these (Snell, 1850), death occurred seven and one-half hours after taking an ounce. The antidotes would be eggs and starch.

Inhalation of Bromine Vapors.—These irritate the respiratory organs with effects similar to chlorine. They are more irritant, but rather less toxic. 1:1,000,000 of air is disagreeable, 10:1,000,000 is said to be dangerous.

Prolonged inhalation of bromine is said to produce marked physiological changes in the thyroid (Pellegrini, 1917). The observation requires confirmation.

Bromine was used somewhat in the war in hand-grenades.

IODIDES, IODINE AND THYROXIN

It appears advantageous to discuss these together, since all iodine compounds have certain features in common. All are convertible into thyroxin, and in this manner effect metabolism and the associated phenomena in thyroid disease. Those which can be administered in relatively large doses, and presumably give rise to iodide ions, produce iodism, and

characteristic inflammatory reactions in syphilitic and other pathologic formations. The inorganic iodides exert osmotic and other indifferent "salt-actions". Elementary iodine is eventually converted into iodide, but first combines with the proteins of the cells and so has local irritant and antiseptic actions.

Historical.—Iodine was discovered accidentally in 1811 by Courtois, was studied by Gay Lussac, 1813, and by Humphrey Davy, about the same period, and was introduced into medicine by J. J. Coindet of Geneva, in 1820, for the treatment of goiter. It aroused at once considerable enthusiasm, and its use was extended to other diseases. Berton, 1829, advocated the inhalation of the nascent fumes. The occurrence of mishaps brought it into disrepute, and the resulting abuse greatly embittered Coindet's life (Journal American Medical Association, 1921, 77:337). Its use in syphilis dates from Wallace, 1836; in scrofula, from Ricord, 1836; and as antiseptic, from Boinet, 1840.

SALT ACTIONS OF IODIDES

The behavior of the iodides in the body is similar to the corresponding chlorides and bromides. The immediate toxicity is low, even with intravenous injection, although these disturb the colloidal equilibrium more profoundly than the physiologic sodium chloride solution; still more so if hypertonic iodide solutions are injected. The acute reactions that occur during or shortly after such injections are salt-colloidal. The special iodide reactions which are more toxic, occur later, and will be described under Iodism. The distribution and excretion of the iodides is also similar to that of the chlorides and bromides, except for the special affinity for the thyroid gland. Like other neutral salts, the iodides are diuretic and expectorant. Salt-action plays a part in these effects; but other factors cooperate at least in the expectorant action. In vitro, iodides tend to render colloids more soluble and less viscid. It is doubtful whether this occurs with the concentrations that are reached therapeutically.

Use as Expectorant.—Iodides increase the secretion of bronchial mucus, and render it less viscid. They are therefore used in cough. The secretion may be partly a reflex from the peculiar saline taste that is excited by the secretion of the iodides in the saliva and mucus. However, there may be a more direct effect, for E. J. Stieglitz, 1923, found by histochemical methods that the free borders of the bronchial and tracheal epithelium become especially rich in iodides.

Secretion of Saliva.—This is not normally affected by iodide administration (V. E. Henderson, 1910); but inflammation of the parotid gland is one of the phenomena of iodism.

Urine Flow.—Iodides have a saline diuretic action somewhat greater than that of chlorides (according to Cushny's theory, because they are not reabsorbed as well from the urinary tubules).

Acute Effects of Intravenous Injection of Sodium Iodide.—These are practically important because it has been proposed to administer the drug clinically in this manner. The immediate toxicity is not very high. Weld, 1918, for instance observed no acute toxic effects in dogs with 8 c.c. of 25 per cent. per Kg., i.e., 2 Gm. of NaI per Kg. Potassium iodide would, of course, be toxic in much smaller quantities, by its potassium ions. However, more discriminate methods of observation would doubtless also reveal important changes shortly after the NaI; for instance, Hanzlik, De Eds and Tainter, 1925, obtained very marked increase in the sedimentation rate of the corpuscles, i.e., definite evidence of disturbance of the colloidal equilibrium. Indeed, doses of 0.8 Gm. per Kg. are followed

in $\frac{1}{2}$ to $1\frac{1}{2}$ days by edemas and nervous phenomena, often fatal, (see below). Clinically, 5 to 20 Gm. of NaI as 20 per cent. solution are injected slowly; symptoms arise when 10 Gm. (about 0.15 Gm. per Kg.) are exceeded. Up to this dosage it is said to be generally safe (E. D. Osborne, 1922). However, the possibility of undesirable changes in blood colloids should be born in mind; and as the iodides are absorbed rapidly and completely there seems no reasonable justification for intravenous administrations; unless indeed the colloidal "reactions" are desired, and not the iodide effects. For roentgenography, the intravenous injection is definitely more effective. In any case, before injecting iodide intravenously the patient should be tested for the absence of exaggerated susceptibility, by administering by mouth, 1 Gm. three times a day, for two days (Osborne).

Delayed Toxicity of Intravenous Injections; Iodide Edema.—Large doses (0.8 Gm. NaI per kilogram) produce death in twelve to thirty-six hours, with symptoms of central paralysis. Autopsy shows pleural exudation, often with pulmonary edema and pericardial effusion (Boehm, 1876; Chiari and Januschke, 1910). Similar effects are produced with hypodermic but not with oral administration (Sgalitzer, 1908). The symptoms are complex, and the statements regarding central actions are contradictory, and probably untrustworthy (Barbera, 1900; Jodlbauer, 1902; Heinz, 1898).

Other Acute Actions of Iodide.—Intravenous injection is said to paralyze the vagus endings and to lower the excitability of the depressor. In frogs the iodides produce rigor and acidity of the muscles (Stockman and Charteris, 1901).

The perfused respiratory center is stimulated by iodide, bromide and nitrate ions (Macht and Hooker, 1918).

Intravenous Injection of Iodine.—Boehm, 1876, found that 0.04 Gm. per Kg. was fatal. Symptoms set in only after 6 or 8 hours, with exhaustion, dyspnea, and death in 12 to 24 hours. Necropsy showed bloody pulmonary and pleural exudate and renal congestion and hemorrhages. Salant and Livingston, 1916, reported that the intravenous injection of iodine depresses the circulation greatly in cats, not in dogs.

Local Action of Iodine on the Heart.—Perfusion of excised frog hearts with dilute iodine solutions produces irregularities, followed by depression. Stronger solutions result in diastolic arrest.

Musser and Hermann, 1925, reported that the application of 1 to 2 c.c. of the U.S. P. Tr. Iodine directly to the surface of the hearts of dogs and rabbits results in prompt death, preceded by ventricular tachycardia, flutter and fibrillation, and auriculo-ventricular block. They suggested that this might be due to the alcohol, which they had not tried.

LOCAL EFFECTS OF IODINE

Elementary iodine precipitates proteins, the iodine being partly adsorbed, partly loosely bound, and partly converted into iodide ions. This precipitation causes persistent irritation, usually short of corrosion. Since the iodine itself is but loosely bound, it continues to penetrate, so that the action extends deeply. It may be conveniently graduated by successive application of the alcoholic or watery solutions. The official tincture, as well as the "compound solution" (Lugol's solution) contain potassium iodide to make them more stable and more miscible with water. Iodine ointments give up their iodine slowly, so that their action is milder. A part of the iodine is chemically combined with the base—all, in some proprietary ointments—so that it cannot react with the proteins, and is therefore ineffective.

Local Phenomena.—Applied to the skin iodine produces a mahogany color, smarting, erythematous inflammation, infiltration of subcutaneous tissue, desquamation of the epidermis in large shreds; if repeated, vesication results. The effects on mucous membranes are more severe and may produce corrosion. Its action is chemical, since it precipitates proteins

as easily dissociated compounds. It is absorbed somewhat from the skin and excreted mainly in the urine as iodide.

Employment as Counterirritant.—Iodine is used especially in chronic pleural effusions, chronic rheumatism, diseased joints, enlarged lymph glands, lymphangitis, etc. It has also been employed in erysipelas, painting the tincture from the periphery toward the center, five or six times daily (Ferrari, 1911); but Wood warns that the action must be graded very mildly, or it will produce extensive necrosis.

The "absorptive" effect of iodine has been demonstrated experimentally on the fibrous nodules following intradermic injection of local anesthetics (Sollmann, 1910). Positive results were obtained only if the iodine was applied daily for 8 days, and pushed to considerable irritation of the skin. Shorter continuance was ineffective, even if a larger amount of iodine was applied and the irritation was more intense.

Injections into cysts, hydrocele, empyema, etc., produce at first increase of the fluid, then adhesive inflammation. The injections are painful, and have often caused serious poisoning. They are now displaced by surgical procedures.

Toxic effects from iodine absorption from cysts consist in cyanosis, salivation, vomiting, skin eruptions, high fever, and collapse. The urine is scanty and albuminous. The intoxication may persist for several days and then end with sudden death.

Toxicity of Iodine Fumes.—The inhalation of iodine vapor produces pulmonary irritation (dyspnea, etc.). The inhalation of more than 18 mg. per Kg. is fatal. The danger is increased by the presence of respiratory disease, bronchitis, etc. This should enjoin caution in the therapeutic use of iodine inhalations. The iodine is partly absorbed, appears promptly in the urine, and produced histologic changes in the thyroid (Luckhardt et al, 1920).

ANTISEPTIC ACTION OF IODINE

This is used especially for disinfecting wounds, and for preparing the skin for operations (Woodbury, 1907; Strattan, 1909, 1915). For the latter purpose, a 3 per cent. alcoholic solution, is painted over the dried skin of the operative field on the preceding day, and again just before operating. The official tincture is used on recent wounds.

The clinical results are excellent; even dirty wounds healing rapidly. The simple alcoholic solution deserves preference for skin disinfection. Sometimes there is rather severe irritation (Herzog, 1914). The stain may be removed by warm concentrated solution of sodium thiosulphate (Snoy, 1911) or by ammonia.

The action has been attributed to the formation of antiseptic compounds with the tissues (Schumacher, 1915). Streptococci in cultures are destroyed by iodine, 1:1000, in $\frac{1}{4}$ minute, even in moderately albuminous fluids (Albert and Taylor, 1918).

Experimental results with infected wounds were also good, the iodine being effective within five hours after infection, *i.e.*, until the bacteria have spread too deeply (Brunner, 1915).

On the other hand, bacterial tests from the skin after iodine application, have given only equivocal results.

Experiments with *tissue-cultures* showed that iodine is rather more toxic to bacteria than to human connective tissue-cells. It tends to dissolve the fibrin of the cultures (R. A. Lambert, 1916).

Spirochete cultures are not especially susceptible to iodine; the fatal concentration is 1:75 in KI solution (Akatsu, 1917).

Iodine against Burns.—A 10 per cent. tincture has been used. It causes severe pains for 4 or 5 minutes, said to be succeeded by complete relief of pain (Mercier, 1919). This is presumably due to a precipitation-pellicle. The advantage of iodine over other astringents is doubtful; and the irritation and systemic effects may be harmful.

Pharmaceutic Preparations.—Simple alcoholic solution of iodine spreads more evenly and coagulates protein more readily. These are advantages in skin infection. The skin should be dry, to avoid precipitation of the iodine. The presence of KI, as in the official Tincture, and in Compound Solution, delays precipitation and favors penetration, and is therefore better for wound disinfection. It is not more irritant to the skin.

The presence of an iodide is essential if the iodine is to be diluted with water. It also retards the formation of HI in the tincture. Some proprietary "soluble iodines" use HI in place of KI. This has no advantage, either as to efficiency or irritation (Sollmann, 1919). Benzene which dissolves up to 10 per cent. of iodine has been used as a solvent in war-practice.

"Starch Iodide," the blue adsorption product of iodine and starch, combines slowly with protein and is therefore but slightly irritant. Starch containing 1 per cent. of iodine has been used as an antiseptic wound dressing (Luncere, 1917).

TOXICOLOGY OF IODINE

The *symptoms* develop in the order: gastric uneasiness, disagreeable metallic taste; vomiting; violent abdominal pain; severe collapse with feeble pulse; diarrhetic stools, sometimes bloody. Severe cases may develop hemorrhagic nephritis. The collapse may be postponed to the second day. The vomit has the color of iodine, or is blue if starch is present. Extensive application to the skin sometimes produces nervous phenomena and fever.

The *treatment of iodine poisoning* consists in evacuation; demulcents (eggs, milk, oils, and cooked flour or starch, which form loose compounds with iodine); dilute alkalis (NaHCO_3); and 5 per cent. sodium thiosulphate ("Hypo"). The last binds the iodine: $2\text{Na}_2\text{S}_2\text{O}_3 + 2\text{I} = 2\text{NaI} + \text{Na}_2\text{S}_4\text{O}_6$ (Sabbatani, 1913). The further treatment would be symptomatic.

The *prognosis* is generally favorable; but Velpeau recorded 30 deaths, in 130 cases.

The *fatal dose* is usually to about 2 or 3 Gm.; but recovery is said to have occurred after 10 Gm.

IODINE COMPOUNDS IN ROENTGENOGRAPHY

Iodides and other iodine compounds are relatively opaque to Roentgen rays. This is utilized by the local injection of sodium iodide; employing the 15 per cent. solution for the urinary bladder; 25 to 30 per cent. for the renal pelvis; and 50 per cent. for sinuses (D. F. Cameron, 1918). The excretion of sodium iodide into the urine, after systemic administration suffices to cast shadows sufficiently dense for urologic radiography. Fairly large doses are required: 5 to 20 Gm. as 10 per cent. solution intravenously, or 9 Gm. by mouth (3 Gm. well diluted every hour for 3 doses). The pictures are taken about an hour later, *i.e.* at the time of the maximal concentration in the urine (E. D. Osborne et al., 1923). Sodium bromide may also be used intravenously (E. H. Weld, 1918), and presumably by mouth; but it is somewhat less effective.

Iodized vegetable oils (with the iodine completely combined) are used for local injections in situations where sodium iodide would be irritant, for instance in the trachea.

ABSORPTION, FATE AND EXCRETION

These are similar to the Cl, Br, SCN and NO_3 ions. They may mutually displace each other in their excretion. The elimination of iodide is more rapid than that of the related ions. A limited amount of iodine is stored as a special organic compound in the thyroid gland.

Absorption of Iodine from the Digestive Tract.—The inorganic iodides are rapidly absorbed from mucous membranes; so that, with oral administration, the absorption occurs principally from the stomach (Boruttau, 1910). The rectum is said to absorb even more rapidly (A. Fried-

mann, 1910); but the rectal absorption is less complete, and is limited, in man, to about 2 to 3 Gm. per day (E. D. Osborne, 1922).

Rapidity of Absorption.—Administering KI to dogs with duodenal fistulas, iodide could be detected in the duodenum within five minutes; the absorption was completed in about three hours (L. Metzger, 1911).

Intestinal Loops.—Hanzlik, 1912, found the absorption of NaI solutions, placed in ligated loops, nearly equal from all parts of the small intestines; somewhat less from the stomach and colon. The rapidity of absorption was not materially influenced by the extent of surface, or by the concentration of the solution. The absorption is very rapid at first; but becomes slowed when one-half to three-fourths has been absorbed. This inhibition is due to a local change in the epithelium, which is also produced by the local application of dilute NaCl solution; but not by altering the haloid content of the tissues.

Absorption of Iodide and Iodine from the Human Skin.—The iodide ions are absorbed to a limited extent from ointments; but not sufficiently to render this method advisable for therapeutics. Elementary iodine is absorbed more effectively, but still only in very small quantity.

Iodide Ointments.—The absorption varies with the iodine compound, the ointment base, and the texture of the skin. It is best for the scrotum. Herzfeld and Elin, 1912 (who also studied several compounds), state that petrolatum secures the best absorption; while Bartenbach, 1909, found it better from lard than from petrolatum or woolfat. In the absorption of iodide from petrolatum ointments, the cation remains unabsorbed (Hirschfeld and Pollio, 1904), unless the epidermis is injured. The separation of the ions must therefore occur after they have passed through the epidermis. This applies also to excised skin (K. G. Zwick, 1917).

Iodine Absorption from Human Skin.—Iodide does not appear in the urine after a single application of the tincture or ointment, so that only very little is absorbed (Wetzel and Sollmann, 1920); sufficient, however, to modify the iodine-content of the thyroid (Marine). More is probably absorbed if the skin has been injured by repeated applications. Luckhardt et al., 1920, report some absorption from large doses.

Fate and Distribution in the Tissues.—The major part of the absorbed or injected iodide circulates in ionic form, and diffuses into all the tissues, liquids and secretions of the body and is removed through the excretions, similarly to chlorides. A limited quantity is stored in the thyroid gland as thyroxin as will be discussed later. Very much smaller quantities of iodine compounds occur normally in the other tissue, mainly as lipid combinations. The dry thyroid contains 0.01 to 1.16 per cent. of iodine, the other tissues less than 0.001 per cent. (Cameron, 1915; Blum and Gruetzner, 1914; Adler and Czapski, 1914; Justus, 1902, 1908). Iodide medication increases both the water-soluble and the lipid compounds in the tissues. Pathologic tissues become especially rich in lipoidal iodine.

Free iodine cannot be formed at the alkaline reaction of the tissues; and if introduced it cannot persist, but is rapidly converted into iodide and protein compounds (Sollmann, 1917).

Iodine Storage.—The distribution has been investigated by Heubel, 1865; O. Loeb, 1907 and 1913; Boruttau, 1910. The highest percentage is found in the thyroid; then comes the blood; then the secretory and lymph glands, kidneys and lungs; much less in the muscles, intestines, testes and bones; traces in the hair; none in the brain, spinal cord, fat or bone marrow (except traces if the lipid-soluble organic forms are given). On withdrawal, iodine (organically combined) is retained in the liver and sometimes in the blood.

Histochemical tests show that the administered iodide is localized chiefly in the parenchymatous secretory cells; in the kidney, especially in Henle's loop; in the liver, and in the outer border of the tracheal and bronchial epithelium (E. J. Stieglitz, 1923).

Partition of Iodine in Cell Constituents.—McLean, 1914, investigated the proportion of the retained iodine in the water-soluble, protein and lipid fractions of the liver, both after administration to an animal, and after direct addition to the excised liver tissue.

With KI, the results were the same in either case: 68 per cent. in the water-soluble fraction, 32 per cent. in the lipid, and none in the protein. This held also for iodalbin administration. With iodized fat (calcium iodobenenate) administration, the lipid fraction showed a larger (58 per cent.), and the water-soluble a smaller (42 per cent.) fraction.

Distribution in Pathologic Tissues.—These generally contain more than normal. This is not explained by simple diffusion, since the tissues may contain more than the blood (O. Loeb, 1913).

The increased quantities have been found in tuberculous tissue (Loeb and Michaud, 1907) particularly in the necrotic areas (R. Weil, 1916); carcinomatous tissue (Velden, 1908; Takamura); syphilitic tissue (Loeb, 1912); pus (Loeb, 1907); other necrotic tissue and implanted agar (Wells and Hedenburg, 1913); and organs rendered hyperemic by Bier's stasis (Salomon, 1913). Tuberculous tissue is said to contain iodine even in animals to whom no iodine compound has been administered (P. A. Lewis and Krauss, 1914).

Form of Iodine in Pathologic Tissues.—Fujisawa, 1919, again confirms that tuberculous foci contain the highest concentrations of iodine. It exists there as organic compounds of lipins; not as proteins. Syphilitic tissue behaves similarly. Pus is rich in iodine, but here it exists as inorganic iodide. Exudates also contain iodine solely as inorganic iodides.

Reactions Liberating Iodine.—When iodine is placed with an alkali, it forms combinations containing iodide and iodate, or iodide and hypoiodite. From these mixtures free iodine is liberated on acidulation. Free iodine is also liberated from acid mixtures of iodides and nitrites, and from thiocyanates and iodates. All these reactions, however, occur only in strongly acid media ($H_p = 4$ or more), and therefore could not occur in the organism anywhere except in the stomach (Sollmann, 1917).

Excretion of Iodide and Distribution in Body Fluids.—The iodide is excreted mainly by urine, practically if not solely as iodide ions. It occurs also in the other secretions and body fluids. The excretion starts very promptly, so that iodide can be demonstrated in the urine and saliva in 6 to 20 minutes after oral administration; the greater portion of this time being consumed in the absorption. It reaches its maximum in one or two hours. The permeability of the kidneys appears to be somewhat greater for iodide than for chloride or especially for bromide. Generally four-fifths of a single 1 Gm. dose of iodide are excreted within twenty-four hours; this serves as a test for kidney function, since certain forms of nephritis impair the permeability to iodides, as to chlorides. The excretion and retention are essentially the same with intravenous as with oral administration (Osborne, 1922). The retained iodide is excreted with diminishing velocity; the last traces very slowly (Heubel, 1865). The excretion can be hastened by the administration of chlorides or similar ions, but not by diuresis. It should be remembered that iodide passes also into the milk.

Rapidity of Urinary Excretion.—The excretion is twice as rapid as that of Br (Heimann, 1912); but considerable retention occurs (from one-sixth to one-half after a single dose). With doses of 0.5 to 1 Gm., the iodide reaction persists for forty hours; after larger doses or continued administration, traces persist over twenty days.

Influence of Cations.—Sodium, potassium and strontium iodides are absorbed and excreted precisely alike, both in regard to rate and total quantity (Krahulic and Pilcher, 1918).

Influence of Related Ions.—The administration of chlorides and related ions hastens the elimination of iodide (Herzfeld and Gormidor, 1912); while Cl-poor food increases the retention (Sarvonat and Crémien, 1911).

Concentration of Iodide in the Urine.—With the administration of 5 to 20 Gm. of sodium iodide, by vein (as 10 per cent. solution) or by mouth the maximum concentration in the urine is reached in one-half to four hours and corresponds to 0.85 to 1.33 per cent. of iodine (Osborne et al., 1919).

Iodide Test of Renal Efficiency.—If a single test-dose of 1 Gm. of KI is taken after a meal, a healthy individual excretes on the average 80 per cent. of the iodide in the first twenty-four hours, and 15 to 20 per cent. between twenty-four and forty-eight hours.

independently of the quantity of urine. At the end of this time, the urine fails to respond to the ordinary iodide test.

A smaller excretion or more persistent reaction shows diminished permeability of the kidneys. With interstitial nephritis, for instance, the excretion may be only 17 per cent. and extend over five or six days. Tubular nephritis, acute or chronic, shows nearly normal excretion (Sivert and Kaminsky, 1914). Considerable delay occurs in experimental chronic passive renal congestion (Rowntree). The iodide delay would therefore seem characteristic of vascular rather than tubular disturbance, contrary to the view of Schlayer and Takayasu, 1913. The elimination of KI, after 1 Gm. by oral and rectal administration, has been studied in a variety of clinical conditions by Wovschin, 1915.

Differences with Age.—Amstad, 1915, found the excretion in sucklings the same as in adults (64 to 72 per cent.); but older children appeared to excrete less effectively. He offered no explanation for this curious observation.

Form of Iodine in Urine.—This exists mainly, if not solely, as iodide ions. A small part is probably excreted in organic combination (Crespolani, 1909), but the evidence for this is somewhat controversial (Schuerhoff, 1905; Harnack, 1910).

Salivary Excretion.—This begins usually in six and one-half to eleven minutes. It is somewhat delayed when the stomach is filled, and much more in gastric diseases. This has been proposed as a diagnostic test (0.2 Gm. KI in gelatine capsules); but it is inconstant and unreliable. The salivary excretion gives rise to a persistent disagreeable metallic taste; best corrected by a gargling with bicarbonate.

Fecal Excretion.—With oral or intravenous administration of 5 to 20 Gm. of sodium iodide, about 200 to 250 mg. of iodine are excreted by the stools (Osborne, 1922); the quantity doubtless being determined mainly by the water-content of the feces.

Iodide Content of the Serum.—In man, an hour after the intravenous injection of 10 Gm. of NaI, as 10 per cent. solution, the iodine content of the plasma is about 0.045 per cent., in 4 hours it has fallen to 0.025 per cent.; and in 24 hours to 0.007 per cent. With oral administration of 5 Gm. of NaI, three times daily, the plasma iodine is maintained between 0.02 and 0.04 per cent. (E. D. Osborne, 1922).

Other Fluids.—The sweat contains only traces (Kellermann, 1905; Tachau, 1911). The bile in man excretes about 1 per cent. of the administered iodide in twenty-four hours, the maximum being in three hours (Frickes, 1908). Its presence in *effusions and cerebro-spinal fluid*, five to fifteen hours after administration, has been confirmed by Achard and Ribot, 1909. Its passage into the cerebro-spinal fluid is not constant (Hald, 1911). Catton, 1916, also failed to find it in his patients after the daily administration of 6 Gm. for 11 weeks, and after 17 Gm. at a single dose.

Iodide also passes into the *milk* (Reipt and Scheffer, 1908).

Fate of the Organic Iodine Preparations.—Several different types of these have been introduced to avoid the undesirable actions of potassium iodide. This can be accomplished only very imperfectly. Their slight and doubtful advantages do not compensate for the extra cost (McLean, 1912). They are all decomposed in the body, and develop the iodide action only when the iodide ion is regenerated from them (Erlenmeyer and Stein, 1909). They do not therefore avoid iodism if active doses are given. The iodine-protein compounds are decomposed before they reach the blood, and behave practically like inorganic iodides. Iodized fats and fatty acids are absorbed largely unchanged and excreted more slowly, and therefore furnish a more steady supply of iodide. Their temporary distribution in the tissues is also different. They are held for a time in lipid-soluble form by the cells, and therefore enter more readily into nervous and other lipid tissue. However, this would probably not favor their penetration of syphilitic tissue. It is not clear that these features are especially advantageous (Dock, 1909); nor are these drugs entirely free from undesirable side actions (Notthaft, 1910; iodipin, Seifert, Nebenwirk, 1915, p. 214).

Iodine-protein and Similar Compounds.—Iodo-albuminates, -peptonates, -tannates, -gelatin; idon, idolose, iodethylglycin, are so rapidly decomposed that they behave and are excreted practically like inorganic iodides; and have no advantage (Filippi, 1912;

McLean, 1914). Even the relatively firm iodalbacid is completely decomposed before it reaches the blood (Fuerth and Friedmann, 1908; McLean, 1915).

Iodized Fats and Fatty Acids.—Calcium iodobehenate (sajodin), iodipin, etc., are absorbed, decomposed and excreted more slowly (Winternitz, 1893; Boruttau, 1910; Bonanni, 1911; Abderhalden and Hirsch, 1911). This applies also to iodostarine (biniodotaric acid) and lipiodin (ethylester of biniodo-brassidinic acid) (Filippi, 1912; Hassel, 1914).

McLean found that they are retained mainly in the lipid-soluble fraction of the cells; and therefore enter the nervous system more freely than inorganic iodides. Their final excretion is in inorganic form (McLean, 1914, 1915).

M. Jacoby, 1916, claimed that the storage of iodine in tissue fat does not occur when iodized fatty acids are administered as such, by mouth; but only when they are given in the form of their calcium salt. This needs confirmation.

THYROXIN

An important group of phenomena arises from the relation of iodine to the formation of thyroxin, and through this, to thyroid function and disease. The administration of thyroid gland is highly successful in combating the phenomena of thyroid deficiency—myxedema, cretinism, etc.—whether the deficiency be congenital or acquired by disease or operations. The benefit persists practically only as long as the administration is continued. Metabolism is increased also in normal individuals, first the nitrogen, then fats. Thyroid is therefore used against obesity. However, it is a dangerous remedy, excessive doses causing nervous symptoms. Thyroid administration alters the susceptibility to certain poisons. Acute effects are slight and inconstant, even on intravenous injection.

Deficient income of iodine tends to produce hyperplastic goiter. This occurs on an endemic scale in the "goiter regions;" adolescent girls being especially affected. It may be prevented absolutely by the administration of appropriate minute doses of iodine compounds. When the hyperplasia has occurred, iodine administration converts this into the less harmful colloid involution. The prophylactic use of these minute doses of iodine, is harmless, but if the thyroid is already diseased, and therefore especially in older individuals, iodine administration is occasionally followed by serious results.

Larger doses of iodine are administered temporarily to patients with exophthalmic goiter, preparative to operations. They are usually very helpful, but occasionally produce dangerous exacerbations.

Active Constituents of the Thyroid.—E. C. Kendall, 1918, isolated a definite, crystalline derivative containing 65 per cent. of iodine, which he named thyroxin. This represents the full activity of the thyroid glands, although it probably does not exist there in this form, for its isolation requires severe treatment with alkalis. Presumably it is a cleavage-product of the chief protein component of the colloid, the "thyro-globulin"; the relation is somewhat analogous to that of hemin and hemoglobin.

Relation of Activity and Iodine Content.—The relatively large percentage of iodine in thyroid gland early fixed the attention of investigators. When criteria of thyroid activity were developed, such as the therapeutic efficiency, increased nitrogen excretion, acetonitrile test, tadpole test, etc., it was found that these are closely proportional to the iodine content of the thyroid preparations (Hunt, 1911; 1925; Marine, 1913) so that on the one hand, there is no "inactive" iodine in the thyroid gland (unless an iodine compound has been administered so recently that it has not had time to be assimilated); and on the other hand, the iodine-compound is the

only active constituent of the gland (except sometimes in fetal glands; but this is of a quite different order of magnitude; Hunt, 1925).

Specificity of Thyroxin Iodine.—The characteristic thyroid actions are not produced by the inorganic and most of the organic iodine compounds, not even by most iodized proteins, except after they are assimilated by the thyroid.

Thyroxin, on the other hand, produces all the effects of thyroid administration, although its yield from the fresh gland is generally only 1:10,000, at most 1:4,000. A considerable amount, however, must be lost in the isolation. Glands practically devoid of iodine may also possess a slight activity.

Thyroglobulin.—Oswald (1899, 1908, and 1909) recognized that the activity of the thyroid is confined to its iodine containing colloid, thyro-globulin. The iodine content of this globulin averages about 0.35 per cent. but varies from 0 to 1.3 per cent. It was therefore assumed that the globulin may either take up various amounts of iodine (Hunt, 1911), or that the gland contains a mixture of iodinated and iodine-free globulin (Oswald).

The iodine is confined to the colloid; practically none is present in the cells of the thyroid (Tatum, 1919).

Cleavage Products.—The iodized thyroglobulin has been further fractionated. F. C. Koch, 1913, finds that the full activity is contained in the metaprotein fraction of the thyroglobulin; the simpler cleavage products showing less and less activity per unit of thyroid. Pick and Pineles, 1909, also claim that completely digested thyroid is less efficient in myxedema. Both statements appear to conflict with the universal experience that oral administration is effective, although it may be assumed that complete cleavage occurs before the tissues are reached.

Iodothyrim.—This is a cleavage product prepared by Baumann, 1896, containing from 4.5 to 15.3 per cent. of iodine (Oswald; Koch, 1903). It does not give the protein reactions, and is very resistant to heat and reagents. Baumann and Ross, 1896, and Hildebrandt, 1896, claimed that it has the therapeutic actions of thyroid; but most later observers have obtained rather negative results. The commercial product contains much less iodine (as little as 0.014 per cent.; Hunt and Seidell, 1910), sometimes in loose combinations.

Iodine Content of the Glands.—This ranges from 0.01 to 1.16, and averages about 0.15 to 0.3 per cent. for dry, and 0.03 to 0.06 per cent. for moist glands. (The average percentage for moist glands is given by Aldrich, 1913, as 0.025 for sheep; 0.036 for beef; 0.047 for hogs.) It is subject to great variations, particularly in *goiter*. In hyperplastic goiters, the percentage and total iodine are both greatly diminished, proportional to the histologic changes. In colloid goiters the percentage is diminished to a less degree (Marine and Williams, 1908). Iodine is said to be absent in wild carnivorous animals, and sometimes in domestic (Roos, 1899), but this must be rare. Contrary to older statements, Fenger, 1912 and 1913, found it in the *fetus* of domestic animals long before birth. Its asserted absence from the human fetus therefore seems to require further confirmation.

The iodine undergoes marked *seasonal variations*, the percentage being three times greater (with smaller glands) in June to November, than in December to May. It diminishes gradually from about September till March or April, and then increases abruptly until September. The changes appear to be connected mainly with the prevailing temperature; although diet and the reproductive season are not definitely excluded (Seidell and Fenger, 1913 and 1914). The iodine content of the gland was not affected by *stimulation of the cervical sympathetic nerve* for $3\frac{1}{2}$ hours (Van Dyke, 1921).

Effect of Administration of Iodine Compounds.—These, whether inorganic or organic, materially increase the iodine content of the gland, with corresponding increase of its activity, and characteristic anatomic changes (involution of hyperplasia (Marine)). The selective affinity of the thyroids is very high, relative to the other tissues (Marine, 1915). Hunt, 1907, pointed out that part of the pharmacologic action of ordinary iodides may be explained by their conversion into thyroid secretion; and this is obviously their effect in thyroid disease.

When iodine compounds are fed, iodine is taken up by the thyroid tissue to the point of saturation, which averages about 5 to 6 mg. of iodine per gram of dried thyroid. The selective affinity is so strong that as high as 18.5 per cent. of a given intake (oral) of iodine was recovered from a thyroid whose ratio to the body weight was 1:687 (Marine, 1915). The iodine of seaweed (bladderwrack) appears to be more easily assimilated by the thyroid than are other compounds (Hunt and Seidell, 1910).

The iodine content can also be increased by the injection of blood of hyperthyroid, and decreased by that of thyroidectomized animals (Jones and Tatum, 1913).

Elaboration of Active Iodine Compound.—This has been investigated by Marine and Rogoff, 1916. Inorganic iodide was injected into the veins of dogs; the thyroids were excised after various intervals, and tested chemically and on tadpoles. The iodine is fixed by the gland within five minutes after injection; but the active compound is not formed until 8 hours, and is not complete for 20 hours. This is about the time when the histologic involutionary changes start, supporting the view that the iodine elaboration and the involution are connected.

The rate of the formation of the active iodine compound varies in different dogs, independent of the total iodine or histologic condition of the gland, of age, sex, etc. It is suggested that this may depend on differences in the quantity of a hypothetical "mother-substance." Rats gave similar results (Hunt, 1925).

Artificially Iodized Proteins.—Rogoff and Marine, 1917, obtained a positive tadpole test from artificially iodized ox serum. The activity was less than that of thyroid, and was destroyed by alkaline hydrolysis.

Perfusion of Thyroid.—Freshly excised thyroid takes up and fixes potassium iodide from the perfusion fluid, presumably in an organic form, so that it can not be washed out by Ringer's solution. The amount fixed is independent of the iodide concentration of the perfusion fluid, but is larger for hyperplastic than for colloid glands, and is about equal to the amount fixed in the living animal, in the same time (an hour), with intravenous injection. In neither case does the iodine absorbed by the thyroid produce the specific effect on tadpoles; so that a further elaboration in the gland is necessary (see above). The iodine fixation on perfusion does not occur when the gland becomes disorganized by autolysis; nor does it occur on perfusing other organs than the thyroid (Marine and Feiss, 1915).

Passage of Active Thyroid Secretion into the Circulation.—It must be supposed that the thyroid secretion is distributed by the blood; however, the concentration in the blood is too small to be demonstrated even by the tadpole test (Rogoff, 1918).

Fate of Thyroxin.—When large doses are administered, nearly two-thirds are rapidly excreted especially by the bile (to 60 per cent.) and urine (to 8 per cent.). About a third is retained in the body for longer periods (Kendall, 1919).

EFFECTS OF THYROXIN

The fundamental effect of thyroxin consists in acceleration of the basic metabolism; this is followed by increased pulse rate and by symptoms of heightened nervous irritability, quite probably as consequences of the accelerated metabolism. These actions counteract completely the phenomena of thyroid deficiency; whilst the effects of over-dosage coincide exactly with those of thyroid hyperactivity or of over-dosage with thyroid gland. The effects start only a day after the administration, even with intravenous injection, and then continue to increase, reaching their maximum in about 10 days, after a single dose; they persist for about 3 weeks. Continued administration therefore tends to produce cumulative effects. At the height of its action a milligram of thyroxin increases the basal metabolism of human adults about 2 per cent., and larger doses, within limits and if properly spaced, approximately in simple proportion, *i.e.*, 10 mg. would result in a 20 to 30 per cent. increase (Kendall, 1918, 1919). The results are about equal whether the thyroxin is administered by mouth or by vein. There is little if any immediate effect. After 24 to 36 hours, the pulse-rate begins to increase with some loss of weight and nervous manifestations. If an excessive dosage is continued, the phenomena of hyperthyroidism become marked by the fifth or sixth day. These are

practically important for recognizing overdosage in the therapeutic administration of thyroid preparations.

Phenomena of Clinical Overdosage.—These consist in circulatory, nervous, digestive, and metabolic disturbances, resembling those of Graves' disease. *Palpitation*; rapid and often irregular *pulse*; vascular congestions. Headache and muscle pains; *tremors* of extremities; nervousness; *insomnia*; delirium; *diaphoresis*; irritations of skin; *hyperpyrexia*. Polyphagia, or loss of appetite, nausea, vomiting and *diarrhea*. Sometimes albuminuria and glycosuria. Scotoma has been described (Snydacker, 1911). *Fatal cases* show uncontrollable vomiting, collapse and coma. Cretins are said to be more susceptible to the toxic effects (Basinger, 1916).

Overdosage Phenomena in Animals.—These are similar to the clinical effects, but the resistance varies greatly in different animals, carnivoræ being less susceptible. The most constant features are emaciation, gastroenteritis and diarrhea; but no tachycardia, nervousness or exophthalmos. Death may occur with convulsant or depressant symptoms. Fresh, dried, or stale glands produce the same effect (Carlson, Rooks and McKie, 1912; French, 1912). Hypertrophic thyroid is less toxic than normal, in accordance with its lower iodine content (Stoland, 1912).

The effects of thyroxin are produced so slowly that they are in large part indirect; for a single massive injection is generally almost inactive; whereas the same dose may be fatal when divided over a number of days (Kendall, 1919).

Gudernatsch, 1915, found that small doses of thyroid fed to rats tend to prevent conception. If pregnancy occurs, the young either abort, or die early, or grow less than normals. The detrimental results are the same whether the feeding has been to the mother or father alone.

Synergism with Amino-acids.—Kendall, 1916, found that thyroxin alone produces symptoms analogous to exophthalmic goiter, but has no direct effect on the pulse rate, even on intravenous injection. If, however, amino acids are injected at the same time, there are marked disturbances of the pulse rate and of metabolism, which may even be fatal. Kendall (1917) believes that this involves also the suprarenal and parathyroid glands, but the evidence is not convincing.

"Experimental Hyperthyroidism."—Cannon, Binger and Fitz, 1915 and 1916, aimed to produce this condition by fusion of the phrenic with the cervical sympathetic nerve, believing that this would result in continued stimulation of the sympathetic structures, including the thyroid.

They obtained symptoms which they interpreted as "hyperthyroidism." However, careful repetition of the work by others (Troell, 1916; Burget, 1917; Marine, Rogoff and Stewart, 1918) gave uniformly negative results, although electric stimulation proved perfect functional union. The effects described by Cannon *et al.* must therefore have been accidental (perhaps distemper?).

Increased Metabolism.—This is one of the most constant effects of thyroid administration, occurring in normal animals, but much more marked in the low metabolism of thyroid deficiency (Magnus-Levy, 1897; DuBois, 1914). The heat production in Basedow's disease is also much above the normal. The metabolic effects of thyroid administration are shown by increased excretion of nitrogen (Ord and White, 1893; Mendel, 1893) and carbon dioxide, and increased consumption of oxygen; with improvement of appetite and rapid loss of weight (Leichtenstern, 1893). The first effect is on fat, the proteins being drawn upon when the fat has been reduced to a certain minimum. When the administration is started, the heat production rises slowly; and when the dosage is stopped, it declines as a logarithmic curve. From the latter, it may be estimated that thyroxin is destroyed in the body at the rate of 0.2 to 0.4 mg. per day (Plummer and Boothby, 1920).

Manner of Action.—It is doubtful whether the increased metabolism of carbohydrates is due directly to stimulation of oxidation; or whether it is an indirect result,

perhaps of increased mobilization of liver-glycogen (Cramer and McCall). The evidence is incomplete and contradictory.

Cramer and McCall, 1918, found in rats that total removal of the thyroids and parathyroids does not impair the power of the cells to oxidize carbohydrates (as judged by the respiratory quotient). This would indicate that the increase of carbohydrate metabolism in hyperthyroidism is not due to a direct influence of the thyroid on cell oxidation. They consider that the action of thyroid consists in mobilization of the liver-glycogen.

It is claimed that thyroidectomized animals do not utilize sugar on parenteral administration as well as normal animals (Underhill and Saiki, 1908); and that they do not react with glycosuria to some of the procedures which are ordinarily effective (King, 1909).

Jamey and Isaacson, 1918, excised the thyroids from dogs, leaving the parathyroids. This resulted in hypoglycemia, with increased sugar tolerance. Similar findings have been recorded for myxedema and cretinism.

Total Nitrogen Excretion.—In dogs fed only on sugar, thyroid administration (0.1 to 0.15 Gm. of the dried gland, per Kg) increased the nitrogen output about 50 per cent. in a 5 to 7 day period (Rohde and Stockholm, 1910).

Nitrogen-partition.—Jamey and Isaacson, 1918, found the ratio of urea and ammonia to total nitrogen unchanged by administration of thyroxin. *Creatinine* excretion was unaffected, even when there was extensive tissue destruction. *Purin* excretion was diminished after excision and in cretins; increased after thyroxin and in Basedow's disease.

These results differ markedly from those of Krause and Cramer, 1912. These found that on a meat-free diet, the nitrogen increase concerns especially the urea, ammonia and creatine, whilst the uric acid and creatinine are very little changed.

Studzinsky and Kaminsky, 1915, state that thyroid administration increases the urate excretion in hypo-thyroidism, but not in normal subjects.

Increased Metabolism in Basedow's Disease.—Du Bois, 1916, considered this the most definite feature of the disease. Heat production is 50 per cent. above the normal in severe, and 75 per cent. in very severe cases. The excessive heat production accounts largely for the tachycardia, cardiac enlargement, emaciation and mental irritability.

This feature also throws light on the efficiency of treatment: Rest in bed for a week diminishes the excessive heat production by 10 per cent. or more; psychotherapy was also of some value. Negative results were obtained with thyroidectin, X-ray, thyroid "residue," ergot, quinine, and Beebe serum.

The high metabolism means that the patients need $1\frac{1}{2}$ to 2 times as much food as normal individuals.

In *cretins*, the heat production was found 20 per cent. below normal. This was corrected in a few days by thyroid administration.

Similar results are reported by Means and Aub, 1919.

Halverson, Berghelm and Hawk, 1916, have also made a study of the effects of thyroid and thymus treatment on metabolism in exophthalmic goiter.

Use in Obesity.—Thyroid administration is often strikingly effective in reducing the fat in constitutional obesity (menopause, etc.), much less so in superalimentation. In any case, the result is not permanent and is connected with the sometimes dangerous effects described under overdosage. Only small doses should be used, under strict medical supervision. The protein income should be kept high to compensate the loss (v. Noorden, 1915).

Other Therapeutic Uses.—Thyroid has been tried in the following conditions, but the inconstant results indicate that it is probably useless: Skin diseases; psoriasis, eczema, lupus, chronic rheumatism, gout, arteriosclerosis, rickets, infantile cachexias, hemophilia, etc.

Eppinger and Hofer, 1918, claims that local application of thyroid extract to indolent wounds promoted healing and especially the proliferation of epithelium. This also requires confirmation.

Larval Growth and Development.—Gudernasch, 1912, made the important discovery that feeding thyroid to tadpoles checks their growth, but at the same time hastens their development into frogs.

This has been abundantly confirmed. The action probably consists in increased autolysis and phagocytosis.

The effect on tadpoles is due to the thyroxin (Marine and Rogoff, 1916), specifically to the iodine component. This is in contrast to the effect on oxidative metabolism in mammals, which is due to the indoxyl group (Kendall, 1919).

The tadpole effect is therefore roughly parallel to the iodine content of the gland (Lenhart, 1915, Hunt, 1925).

This method has been for the *standardization of commercial* thyroid preparations (Rogoff, 1917; Hunt, 1925).

Exposure to X-rays increases the efficiency of thyroid feeding on the tadpole metamorphosis (McCord and Marinus, 1918).

Other Thyroid Constituents and Iodized Products Tested by Tadpole Method.—Morse, 1914, found that the nucleoproteins, lipoids, etc., of the thyroid are ineffective. Positive results are produced by iodothyryl, iodated tyrosin, iodized Witte's peptone and iodized serum proteins; not by inorganic iodine or iodides, iodized starch, iodized lecithin, or marine algæ.

The insufficiency of inorganic iodides, however, seems to be only quantitative; for their administration starts the metamorphosis of thyroidectomized tadpoles, which does not take place without this stimulus (Swingle, 1910).

Allen, 1919, also observed that this does not occur if either the pituitary or thyroid are removed; but that it occurs in the absence of both glands if iodine is administered.

The feeding of *other gland and tissues*, yeast and foods in general influence the growth and somewhat the metamorphosis of tadpoles. Their effects are of quite different magnitude from those typical for thyroid feeding; but they should be checked by control experiments (Rogoff and Rosenberg, 1922).

Protozoa.—The presence of thyroid tissue increases very markedly the multiplication of paramecium (Nowikoff and Shumway; Budington, 1915).

Plant-growth.—Thyroid, when added to the culture medium, produces remarkable retardation of the root-growth of onion bulbs. This effect is not produced by potassium iodide, nor by pituitary or suprarenal.

Susceptibility of Poisons.—The metabolic disturbances alter the destruction of poisons in the body. In mice, *f.i.*, the toxicity of acetonitrile is greatly diminished, whilst that of morphine is increased.

Acetonitrile Test.—Hunt (1905, 1907, 1908) found that the administration of thyroid to white mice, for a few days, markedly increases their resistance to acetonitrile. The toxic effects of the latter are due to the liberation of HCN. Thyroid feeding does not affect the toxicity of HCN when administered as such; so that its protective influence must be due to a retardation of the metabolic processes which convert acetonitrile into HCN. In rats and guinea pigs it has the opposite effect, increasing the toxicity of the nitriles.

The acetonitrile response is a delicate and nearly specific test by which a milligram of active thyroid tissue can be readily detected. It may also be used for comparing the relative activity of different thyroid products. This is found to go parallel with their iodine content. The administration of iodine therefore renders dogs' thyroid more active. Thyroid in which no iodine can be detected by the ordinary chemical tests, as well as certain other organs, show a very feeble activity (Hunt and Seidell, 1908), and this may be due to traces of iodine compound, which are not revealed by the ordinary test.

Trendelenburg, 1910, and Lussky, 1912, claim that the blood of cats gives the test even after removal of the thyroids. This removal does not seem to alter the response of the mice. Application of the test to the blood of Basedow's disease has not given conclusive results.

Effect of Diet.—Certain diets, dextrose, oatmeal, liver, or kidney, also increase the resistance of the mice to the nitrile, as compared with cracker, milk, cheese or egg diet. This seems to be due to an action on the thyroid; for the difference is diminished if the thyroids are excised; and these glands present anatomic changes (Hunt, 1910, 1911).

Thyrotropic Iodine Compounds.—Other iodine compounds also have some protective action, presumably by being converted into the thyroid compound. None reach the same activity, but they present interesting differences. The iodine of the seaweed, bladderwrack, is about 100 times as active as the iodine of potassium iodide (Hunt and Seidell, 1910); and a diet of seaweeds increases the iodine content of the glands (Hunter and Simpson, 1915). Iodothyryl has a varying activity (none, Trendelenburg, 1910).

Resistance to Morphine.—Thyroid feeding lowers the resistance of mice, rats and guinea pigs to morphine (Hunt). Gottlieb, 1911, claimed to have demonstrated that this is due to lessened destruction of the morphine. According to Olds, 1910, the resistance to morphine is not increased by excision of the thyroids, as might perhaps be expected.

It has been pointed out that the metabolic changes of thyroid deficiency are similar to those of chronic morphine poisoning; and the latter are also corrected by thyroid administration (Hildebrandt, 1922).

Sensitization to Autonomic Stimulation.—Injection of thyroid, or increased secretion secured by stimulation of the superior laryngeal nerve, does not produce any characteristic autonomic stimulation directly; but it increases the response to epinephrine, splanchnic, and depressor stimulation (see Literature under Epinephrine); and to the depressant action of histamine (Oswald, 1915). It may be noted that the phenomena of overdosage are similar to those of epinephrine poisoning, although there are important differences, for instance, in the blood pressure. Patients with Basedow's disease sometimes give alarming reactions to epinephrine. This, however, may involve different mechanisms than the peripheral autonomic sensitization.

The peripheral sensitization to epinephrine would be situated at the receptive mechanism (Asher, 1916).

There is also a synergism with epinephrine on the *excised heart*. Here again, the heart is not affected by thyroid alone (Asher et al. 1916).

Epinephrine on Thyroid Secretion.—Injection of epinephrine, 0.001 to 0.002 mg., evokes an action-current in the thyroid. The same result follows stimulation of the cut splanchnic; but it is absent if the adrenal blood is prevented from reaching the circulation (Cannon and Cattell, 1916).

Temperature and Drugs on Thyroid Functionation.—Judging thyroid activity mainly by morphologic criteria (higher cells and decreased colloid), C. A. Mills found increased activity by exposure to high temperature and the reverse with low temperatures. Large doses of morphine or quinine also appear to diminish thyroid activity, presumably as the result of diminished metabolism and heat production. Conversely, strychnine in just sub-convulsive doses increased the thyroid functionation.

Animals fed on thyroid die more rapidly when kept in a warm temperature than when kept cool (Stoland and Kinney, 1919).

Cocaine.—The symptoms of cocaine poisoning resemble those of "hyperthyroidism," since both involve sympathetic stimulation. There is no causal connection. Oft-repeated injections of cocaine do not produce any histologic changes in the thyroid (Mills, 1919).

Effects on the Circulation.—These vary, and are probably indirect, due to increased excitability of the sympathetic and parasympathetic nerves (Oswald, 1915).

Usually the intravenous injection produces fall of blood pressure and slowing of the heart, probably due to its choline content (Lohmann; Fuerth and Schwarz, 1908; Fuerth 1909; Schoenborn, 1909). Pressure juice produces little effect in dogs and cats, but marked collapse in rabbits (Caldwell, 1912). These effects are not specific but due to proteins, embolism, etc.

Cardiac Vagus.—The response of the heart to vagus stimulation is not affected by thyroid (R. L. Levy, 1918). Complete excision of the thyroid-parathyroid apparatus lowers the vagus excitability (Coronedi, 1913).

Secretion of Cerebro-spinal Fluid.—This is said to be inhibited by thyroid and increased by brain extract, independent of blood-pressure changes. Other organ extracts act only mechanically, through the circulation (Frazier and Peet, 1915).

Bile Secretion.—This is not affected by thyroid administration (Downs and Eddy, 1919).

Innervation of Thyroid.—The gland is abundantly supplied with non-medullated fibers, probably derived from the cervical sympathetic, and going to the cells as well as to the blood vessels. An action-current develops in the gland on stimulation of the sympathetic, high in the thorax, even when the superior and recurrent laryngeals have been cut. Vagus stimulation or pilocarpine does not generate the action-current (Cannon and Cattell, 1916).

On the other hand, autografts of thyroid show evidence of growth and function, so that the nervous connections are not indispensable (Manley and Marine, 1916).

THYROID DEFICIENCY

The results that follow excision of the thyroid gland are essentially the opposite to those of thyroid overdosage; *i.e.*, they consist in diminuation of the basal metabolism and sluggishness of the nervous processes. When the parathyroids are also removed, these phenomena are complicated by parathyroid tetany. Continued thyroid deficiency when occurring in adults, results in *myxedema*, with conspicuous skin changes and nervous disturbances ending in mental deterioration. Congenital deficiency produces the condition of *cretinism*.

Phenomena of Thyroidectomy.—Complete excision of the thyroid apparatus (*Cachexia strumipriva*) causes a series of acute effects, motor, nervous and metabolic, which are more or less rapidly fatal in most animals, especially in carnivoræ. (These results were first described by Schiff, 1856; Reverdin, 1882; and especially Kocher, 1883; the literature is reviewed by Vincent, 1911.) If the parathyroids are spared, the motor symptoms and fatality are much less; and the metabolic disturbance, though no less severe, runs a more chronic course. Such animals have a low basal metabolism with high respiratory quotient. They are hypersusceptible to oxygen deficiency (Hildebrandt, 1922).

Experimental Cretinism.—Complete thyroidectomy in young rabbits is said to be followed by typical cretin phenomena, such as dry, rough hair, retarded growth, skin changes, etc. These are perfectly controlled by feeding dried thyroid or its cleavage products if the hydrolysis has not gone too far (H. R. Basinger, 1916).

Therapeutic Results of Thyroid Feeding.—The deficiency symptoms are more or less completely relieved by the administration of thyroid by mouth (Howitz, Mackenzie, Fox, 1892), as well as by intravenous injection (Colzi, 1884; Murrey, 1891) of thyroid extracts, or by implantation of thyroid tissue (Schiff, 1884).

Administration.—This must be practically continuous and, the dosage must be carefully adjusted to avoid toxic effects. It is sufficiently attained by the oral administration of the dried gland of standardized iodine content. This may be taken as tablets or in capsules. The isolated thyroxin does not possess sufficient advantage to offset its much higher cost, except for experimental use. The proper *dosage* must be determined by trial, preferably by the effect on basal metabolism. The daily dose for adults ranges between 0.13 and 1.3 mg. of thyroxine iodine, equivalent to 0.2 to 2 mg. of thyroxin or 0.065 to 0.65 Gm. of the U.S.P. dried thyroid (which is required to contain between 0.17 and 0.2 per cent. of iodine). For continuous use it should lie near the lower rather than the higher limit. The dose is reduced for children in proportion to the body weight.

If metabolism determinations are not practical, the dosage may be begun with 0.15 Gm. per day, increasing by this amount every few days to a maximum of 0.25 Gm., 4 gr., three times daily, best on an empty stomach. If "toxic" effects appear, the dosage must be temporarily reduced. When the full therapeutic action has been reached, the dose may be reduced to 0.3 Gm., 5 gr. daily, and then every second day for a month. The administration may then be intermitted for a time and resumed in a similar way when the indications again arise.

Means and Aub, 1919, found that the basal metabolism in hypothyroidism is restored to normal by daily doses starting with 0.2 to 0.25 Gm. (3 to 4 gr.) of the dried gland, and later 0.05 to 0.1 Gm. (1 to 2 gr.). According to Plummer and Boothby, 1920, the total need of the body for thyroxin lies between 0.2 and 0.4 mg. per day, as calculated from the "decay curve," which would be supplied by 0.065 to 0.15 Gm. of the U.S.P. thyroid powder.

GOITER PROPHYLAXIS

Endemic Goiter.—In regions distant from the sea and from other deposits of iodine, the natural income of iodine through food and drink

is quite limited and tends to become inadequate when the demand for thyroid secretion are high, especially in adolescent girls. This leads to excessive proliferation of the thyroid epithelium, perhaps through futile efforts to compensate for the iodine-deficiency. This hyperplasia is the first stage of "*endemic goiter*." If the excessive demand ceases, or if the deficiency is met by the administration of an iodine compound, the hyperplasia stops, the acini become filled with colloid, and the goiter changes to the resting, relatively harmless but deforming "*colloid*" type. Repetition of the iodine deficiency causes this to revert again to the hyperplastic type, and so on (Marine, 1907-1913).

Transplanted thyroid tissue reacts in exactly the same way, by hyperplasia or involution, to removal of thyroid tissue or to iodine; so that the changes are evidently independent of the nerve supply (Manley and Marine, 1915).

The relation of these changes to the "*toxic*" symptoms of Basedow's disease is not understood; for the symptoms do not occur typically in animals. It is commonly assumed that these "*toxic*" symptoms are due to excessive or perverted secretion of the thyroid (hyperthyroidism, dysthyroidism). The evidence for this theory is not conclusive, for it is based mainly on the resemblance of the clinical nervous symptoms to those of thyroid feeding; and on the beneficial results of partial thyroidectomy. These may have other explanations, and are opposed by the fact that improvement also follows the graduated administration of iodide. (Blackford and Sanford, 1913, assert the presence of a powerful depressor substance in the blood and thyroids of Basedow patients.)

Iodine as Preventive of Simple Goiter.—The apparent relation of the iodine-content of food and drink to the occurrence of endemic goiter and cretinism was pointed out by Chatin in 1850, and he believed that these diseases could be avoided by the continued administration of small quantities of iodine, by the selection of foods relatively rich in iodine, and by iodized table-salt. The success of iodine prophylaxis was first conclusively demonstrated through the brilliant results reported by Marine and Kimball, 1917, 1918, 1920, for large groups of school girls in the Lake Erie goiter district. The administration of iodide prevented the appearance of goiter in over 99 per cent. of the girls and diminished the size of the thyroid in most cases where the gland had been enlarged before medication. Iodide rash occurred in less than $\frac{1}{2}$ per cent., and was always mild. None developed any symptoms of hyperthyroidism.

Similarly beneficial results were obtained in the goiter-districts of Switzerland. At St. Gall the weekly administration of an organic iodine compound to the children reduced the goiter incidence from 88 to 13 per cent.

Administration for Goiter Prophylaxis.—This is especially important with girls between 11 and 16 years; and during pregnancy. The iodine may be administered daily; or by taking advantage of the storage-capacity of the glands, the administration may be made intermittent, *i.e.*, weekly, monthly or semiannually. Both the intermittent and continuous methods are effective in practice; so that the choice may be determined by convenience, or rather, by the faithfulness with which the prophylaxis is likely to be carried out. The intermittent methods can be more effectively supervised, and are therefore generally preferable. They require a large dosage, to insure "*saturation*" of the glands; but this is not a serious disadvantage when the administration is intermittent. The compound in which the iodine is administered is immaterial for the effect. The organic forms can be made into tasteless or flavored tablets, and are there-

fore usually preferred for the weekly dosage. They are not as well suited for the larger doses needed in the intensive semi-annual method.

Semiannual Method.—In their decisive experiments, Marine and Kimball administered sodium iodide twice a year, in May and December, in courses of ten days each. Up to 10 years, the daily dose was 0.2 Gm. from 10 to 16 years, 0.4 Gm., taken in a little water. This plan has been continued in many of the American schools which practice goiter prophylaxis, and the results have not been surpassed by any other method. The iodine dosage by this method amounts during the administration to 0.170 to 0.330 Gm. per day, 1.7 to 3.3 Gm. during the course, 3.6 to 6.6 Gm. during the year. The lower dosage is probably more than sufficient.

Weekly Method.—This was introduced in Switzerland, and has given equally good results. It administers 5 or 10 mg. of iodine, one day each week; usually in the form of tablets of organic iodine (iodostarine etc.), although sodium iodide would answer equally as well. The iodine medication by this method averages 0.7 or 1.5 mg. per day, 0.25 or 0.5 Gm. per year. The smaller dosage may be advantageous if there is reason to fear hypersusceptibility.

Daily Method.—With this it is aimed to give 0.1 to 1 mg. per day, 35 to 350 mg. per year. The lower dosage is doubtless sufficient and absolutely safe; 1 mg. may perhaps become deleterious if it is taken continuously. Since the daily dosage is almost certain to be neglected after a time, it is usually attempted to administer it by some indirect and automatic means, for instance as "iodized table salt", *i.e.*, salt to which sodium iodide has been added. The Swiss Goiter Commission advises 5 mg. of iodide per Kg. of salt. The average daily consumption of salt in cooking and at table, *i.e.*, 10 Gm., would represent 0.04 mg. of iodine. This is quite harmless, and probably sufficient. In the United States, the iodized table salts generally contain 20 times this quantity, *i.e.*, 100 mg. of NaI per Kg. This would introduce 1 mg. of sodium iodide per day. Hartsock, 1926, reported observations which he interpreted as suggesting that such iodized salt was a causative factor in the outbreak of hyperthyroidism in a number of adult patients.

Iodation of Water Supply.—In Rochester, N.Y. sodium iodide has been added to the city water supply for periods of three weeks, twice a year, so as to bring the iodine content from 1 to 2:10⁹ up to 50:10⁹; *i.e.*, 0.05 mg. per liter (reference, J.A.M.A. 81:1701). It may be doubted, however, whether the additional iodine income (about 0.4 mg. per year, or an average of 0.001 mg. per day) would have any material effect. McClendon and Hathaway, 1924, advised to maintain the iodine level of water continuously at 1:10⁸ (0.01 mg. per liter).

Advantages and Potential Dangers of Routine Iodine Prophylaxis.—

There is no doubt as to the usefulness of iodine administration in simple hyperplasia from iodine deficiency. In goiterous regions this hyperplasia may be expected to occur in some degree in adolescent girls and in pregnancy, unless iodine is administered; and as the early stages are not easily recognized, it is advisable to administer iodine as a routine, at these periods. Hyperplasia occurs also under other conditions in both sexes and at any age, forming a fruitful soil for the development of serious thyroid diseases. It would therefore be advisable to make iodine prophylaxis universal in goiter regions, unless there were possibilities of harm. It has indeed been averred that the incidence of toxic goiters has been increased by the introduction of promiscuous iodine prophylaxis (A. S.

Jackson, 1925), although it may be doubted whether this could be supported by convincing data. However, there is no doubt that injudicious overdosage of patients with extensive chronic hyperplasia may precipitate hyperthyroidism (Oswald, 1915; Kimball, 1925; Magendie, "Formulaire," 1824). No instance of this has been reported with the weekly dose, if this did not exceed 10 mg. of iodine; nor has it ever occurred in school children even with the more intensive but brief dosage of Marine and Kimball. With adults, however, the Marine-Kimball dosage must be carefully watched. The chief danger arises in the use of large doses of iodine, for therapeutic purposes, or through carelessness or misunderstanding in self-medication. Excessively iodized table salt is particularly subject to this abuse.

Iodine Income, Requirements and Storage.—The daily income of iodine differs materially in goiterous and non-goiterous regions. The iodine salts that occur in the soil are easily leached out, so that the soil-water can contain notable amounts of iodine only if this is being constantly renewed, by diffusion or spraying from the ocean, or by the neighborhood of considerable iodine-salt deposits. These geographic and geologic relations are reflected in the distribution of endemic goiter. The iodine-content of the springs, rivers and lakes of goiterous regions ranges generally between 1 and 22: 10^{11} , that of the non-goiterous regions lies between 23 and 18,000: 10^{11} . The median iodine content of the waters of the non-goiterous is 145, that of the goiterous 6: 10^{11} ; *i.e.*, about $\frac{1}{25}$ of the normal. Water-bodies contaminated by the waste of large cities may have their iodine content considerably increased; for instance the iodine content of Lake Erie at Cleveland is 86: 10^{11} , although this lies in the goiter belt.

The iodine content of the water is important but not through the amount of water consumed directly, as food or drink; for a liter of 100: 10^{11} represents only 0.001 mg. The real importance of the iodine in the water is that it determines the iodine content of the foods raised in the region. All plants and animals and therefore practically all natural foods contain small quantities of iodine (Forbes and Beegle, 1916; Bohn, 1917). The content varies materially in goiterous and non-goiterous regions; McClen-don and Hathaway, 1924, for instance found that carrots grown in the goiter belt of Oregon contained only $\frac{1}{45}$ as much iodine as those grown on the California coast; the iodine content of oats from Minnesota was $\frac{1}{15}$ that in Maine etc. Wheat, incidentally is very low in iodine; relatively rich are fruits, leafy vegetables, whole milk and butter, and animal foods (v. Fellenberg, 1923).

The actual total income of iodine in the normal diet of the Minnesota goiter region was determined by McClen-don and Hathaway, 1924, as 0.019 mg. per day. For Switzerland, the iodine income for a goiter region was estimated by v. Fellenberg, 1924, as 0.014 mg. per day; for a non goiter region as 0.031 mg. per day, *i.e.* about twice as high. The actual difference, however, is less than 0.02 mg.! From all the available data, it may be estimated that the daily requirement of iodine is of the order of magnitude of 0.03 to 0.05 mg. of iodine; or 10 to 20 mg. per year. This is about the same as the total iodine content of the body, which is therefore renewed yearly. This shows great efficiency in the iodine economy: Since the destruction of thyroxin approximates 0.2 to 0.4 mg. per day, equivalent to 0.13 to 0.27 mg. of iodine, and the daily diet need supply only 0.03 mg. of iodine, $\frac{1}{5}$ of the iodine of the destroyed thyroxin must be reconstructed into thyroxin.

Iodine Storage in the Thyroid Gland.—Iodine administration may raise the iodine content to 4 mg. per Gm. of dried thyroid; *i.e.* to 20–30 mg. in the whole normal gland of man. This represents an excess of 10 to 20 mg. over the normal content of 10 mg. as was explained in the preceding paragraph. This excess is sufficient to supply the iodine needs for half a year or a year; and this explains the persistent effect of the periodic iodine medication, as in the method of Marine and Kimball.

IODINE THERAPY OF TOXIC GOITER

Marine, 1911, pointed out that the pathologic changes of toxic goiters are the same as those of non-toxic goiters and therefore presumably also represent a struggle of the thyroid gland against iodine deficiency, which would call for iodine administration. He advised, however, that this should be practiced very cautiously, lest it lead to an over-production of thyroxin by the hyperplastic glands, before involution had set in. This fear prevented adequate clinical trials of the suggestion until it was reintroduced by Plummer, 1923, in a modified form.

Plummer found that the "toxic" phenomena of exophthalmic goiter are very definitely and markedly alleviated, for a time, by the administration of fairly large doses of iodine, 0.25 to 0.75 Gm. per day. The beneficial effects increase progressively for 10 to 20 days. The nervous tension relaxes, the sleep and appetite improve, the tachycardia is markedly slowed, the excessive metabolic rate is diminished by 25 to 30 per cent., and the patient gains in weight and strength. The more severe the "toxic" symptoms, the greater is the improvement under the iodine. However, the results are often not permanent. After some weeks the metabolism tends again to rise and the symptoms to return gradually even if the iodine is continued; and very rapidly if the iodine is intermitted. The method is therefore used mainly to prepare patients for surgical treatment: The sedative effect diminishes very markedly the surgical risk, especially by protecting the patients against a critical reaction to the fear and excitement of the operation and to the post-operation discomfort. The convalescence is also shortened (Pemberton, 1925; Starr, Segall and Means, 1924; Cowell and Mellanby, 1924). However, in patients with markedly hyperplastic "adenomatous" goiters, this iodine treatment is likely to precipitate hyperthyroidism (Boothby and Rowntree, 1923).

Administration.—For some insignificant reason, the compound solution of iodine (Lugol's Solution) was introduced for this purpose, although sodium iodide answers equally well; 1 c.c. (20 minims) of the compound solution contains iodine and potassium iodide equivalent to 0.13 Gm. (2 grains) of iodine, or 0.16 Gm. ($2\frac{1}{2}$ grains) of sodium iodide. Usually $\frac{1}{2}$ c.c. (10 minims) of the solution (or $1\frac{1}{4}$ grains of sodium iodide) is administered (best in milk, after meals) from one to three times a day (generally the latter) for 5 to 7 days before the operation. With patients in a crisis, the dosage may be increased to 4 to 6 c.c. per day, until the crisis subsides, then 2 c.c. daily for 10 to 21 days. The administration is also continued during the first week after the operation (Pemberton, 1925).

The mechanism of this method is not clear. The brief duration of the results indicates that they are not due to the removal of iodine deficiency; nor to "dysthyroidism" in the sense of faultily iodized thyroxin; and, incidentally, there is no proof of the actual existence of such hypothetical toxic substances. It is conceivable that relief from the deficiency-strain, while it is novel to the patient, may cause a better mental state,

and therefore a more sedative effect, than can be maintained when the novelty wears away. Marine, however, seems to believe that the temporary improvement is due to an accumulation of colloid (Rienhoff, 1925) so rapid that it compresses the vessels, and therefore temporarily slows the absorption of thyroxin into the circulation; and that the disappearance of the improvement coincides with the reestablishment of the circulation and of the absorption of thyroxin.

Antithyroid Serums.—These were introduced on the hyperthyroidism theory of Graves' disease as substitutes for operative removal (Ballet and Enriquez, 1894; Beebe, 1906, 1915); but they had only a short popularity.

Toxic Effects of Iodide Administration in Goiter.—The existence of thyroid abnormalities should always be taken in consideration before deciding on the administration of iodides for other purposes, especially those that require long-continued use of large doses; for these may start serious toxic hyperthyroidism, which tends to persist even after the administration is discontinued (Oswald, 1915; history; description of symptoms and cases).

Metabolism of Normal Individuals.—In the absence of thyroid disease, iodide administration does not alter the basal metabolism. The urinary nitrogen may be increased, and with KI (1 Gm. per day) the non-protein nitrogen of the blood may rise 30 per cent.; although the phthalein excretion remains normal (Grabfield, Alpers and Prentiss, 1923). Some increase of urea, total nitrogen, uric acid, purin bases and chloride excretion was also reported by Chistoni, 1911.

Hypodermic injection of large doses may produce no effect or considerable increase or decrease of metabolism (Sgalitzer, 1908).

Long continued use of large doses of iodides leads to the malnutrition described under iodism.

Sexual Functions.—Iodides are said to increase menstruation; to decrease the secretion of milk; and to cause atrophy of the mammary gland. Free iodine or loose iodine compounds (not KI) produce sterility in both sexes. The spermatoblasts show histologic changes, and the formed spermatozoa are also affected (L. Adler, 1914).

THYMUS GLAND

The development and involution of this gland is inter-related with the functional activity of the thyroid and of the gonads (Marine, 1924); but the nature of the relation is not clear.

Effects of Injection.—Intraperitoneal injections of thymus extracts into guinea pigs result in muscular spasm, dyspnea and convulsions. Smaller doses lead to loss of weight (Olken, 1918).

Ott and Scott, 1912, described increased milk secretion in goats, following the administration of boiled extracts.

Frog Larvæ.—Feeding with thymus hastens growth and retards metamorphosis (Gudernatch); but only as does any other food (Swingle, 1917; Uhlenhuth, 1917).

Salamander Larvæ.—Thymus produces convulsions when fed to salamander larvæ that are devoid of parathyroid (Uhlenhuth, 1918).

Therapeutic Uses.—Thymus administration has been tried, but with very doubtful results, in Graves' disease, rickets, tuberculosis, hemophilia, infantile atrophy and marasmus. Other lymph glands, *spleen*, etc., have also been employed in obscure conditions.

PINEAL GLAND

This is a vestigial remnant of a primitive dorsal eye, but presents some evidence of glandular structure, with sympathetic innervation. It begins to involute early in *homo*, between the seventh year and puberty; but its degeneration is never complete.

The literature of the pineal gland abounds in apparently contradictory results (an extensive bibliography is given by McCord, 1917). The phenomena seem to be confined to the prepubertal years, *i.e.*, before the gland has undergone involution.

Neoplasms of the pineal gland are said to be often associated with precocious physical, mental and sexual development, and general overgrowth of the body. Only a few cases are on record, and the reliability of the connection is not established.

Extirpation experiments have not yielded conclusive results. The early effects are inseparable from traumatism. There are no late changes in adults; in young animals, ablation is said to lead to precocious development (Sarteschi, Foa), but the effects, at best, are not very striking.

Intravenous injection of extracts does not have any pronounced action on the circulation (Dixon and Halliburton 1909). It is also practically inactive on excised heart and uterine or intestinal muscle (Fenger, 1916). Ott and Scott, 1912, claim that it increases the milk secretion in goats. This would need to be confirmed.

Continued Oral or Hypodermic Administration.—Hastened growth and development of young animals has been reported (Dana and Berkeley; McCord, 1914); but these seem to have been experimental accidents, since the careful experiments of Sisson and Finney, 1920, failed to show any effect, at any period.

Tadpoles.—Feeding with pineal hastens growth and differentiation. There is also a second constituent which contracts the pigment under the skin, thus rendering the color much lighter (McCord and Allen, 1917).

Protozoa.—*Paramecia* fed with pineal divide twice as rapidly as controls (McCord, 1917). Pineal extracts increase the pulsation frequency of the contractile vacuole, as do also epinephrin and pituitary solution (Feather, 1919).

Therapeutics.—Dana and Berkeley administered dried pineal (3 to 6 mg., $\frac{1}{20}$ to $\frac{1}{10}$ gr., three times daily) in backward young children (to twelve or fifteen years). It had no effect on growth, but they claim improvement of the mental development. This lacks independent confirmation.

IODISM

If the administration of iodine compounds is continued beyond a certain dosage, which varies for different individuals, irritative phenomena tend to develop in the skin and in mucous membranes. These are quite distinct from the local action of iodine, or the ordinary salt action of iodides, or from the thyroxin actions. Iodism tends to light up certain sluggish inflammatory processes, such as tubercular and gummatous lesions, and to sensitize the skin to the injection of agar solutions. It appears quite probable that iodism consists in the unmasking of latent inflammations or sub-threshold irritations. However, this intensifying effect has been demonstrated only for a few types of irritation. The provocation of this acute inflammatory reaction is also the most plausible explanation of the therapeutic effect of iodides in syphilis and other interstitial inflammations. Phenomena entirely analogous to iodism are produced by bromides, nitrates and thiocyanates. Thiocyanates produce similar therapeutic effects; bromides and nitrates have not been used successfully for these actions, but the difference may be merely quantitative.

Phenomena of Iodism.—The irritations take the form of various rashes, and of coryza, headache, conjunctivitis, laryngitis, bronchitis, etc.—*i.e.*, the various manifestations of a "cold." Less common are stomatitis, parotitis, anorexia, etc. The skin affections generally occur somewhat later. They may consist in acne, furuncles, erythema, purpura, urticaria, vesication, etc., and these may be accompanied by fever. The lesions sometimes resemble gummas.

The *susceptibility* to these irritations varies greatly. They may set in a few hours after a relatively small dose or only after the long-continued use of large doses; or again, the symptoms produced by small doses may disappear when the dosage is increased. They are more common when the excretion is interfered with by nephritis (v. Noorden, 1908). They disappear in a few days when the drug is discontinued. They may be produced by any iodine compound, *e.g.*, iodoform; but probably only after the dissociation of the iodide ion.

Iodide Cachexia.—The continued administration of iodide may also lead to anemia, emaciation, lowered tone, mental depression, nervousness, insomnia, nervous tachycardia, sexual impotence, etc. These phenomena result partially from the catarrhs, the thyroid action, etc.

Agar and Luetin Reaction.—The intradermal injection of agar or starch solutions, or of "luetin" which contains agar, produces only temporary wheals in the skin of normal individuals; but if it has been preceded by the administration of a sufficient amount of iodine compounds, there is a much more marked nodular or pustular reaction (Sherick, 1915, Kolmer, Matsunami, and Broadwell, 1916; Stokes, 1917).

The minimal total dose of KI required to provoke the reactions is about 60 to 75 grains. The dose of organic iodine compounds is not strictly proportional to their iodine content (Paryzek, 1917). Bromide and nitrates also provoke the reaction, but not as powerfully (Cole and Paryzek, 1917; Kolmer et al., 1917).

Mechanism of Iodism.—This has not been definitely established. It is not due to the liberation of free iodine, nor to anaphylaxis in the ordinary sense; presumably (somewhat vaguely) to alteration of the colloid equilibrium.

Iodism was formerly attributed to the *liberation of free iodine* by carbonic acid, sebaceous secretion etc. (Binz, 1875, and 1894; Adamkiewicz); but this was not supported by good evidence (Unna, 1912) and is incorrect, since elementary iodine could not be liberated under the conditions of the body; moreover, entirely similar phenomena are produced by thiocyanates, from which no chemical irritant could be liberated.

Nor is iodism due to a *anaphylaxis* in the ordinary sense; for the skin of iodism or bromism patients is not hypersensitive to the intradermal injection of iodides or bromides (Wile, 1921); nor does the serum of iodism patients, when injected into guinea pigs, render these hypersusceptible (Cole, 1911), as had been claimed (Bruck, 1909; Klausner, 1910). Serum treated with free iodine *in vitro* has rather peculiar anaphylactic relations; for its injection leads to the production of a universal, *i.e.*, non-specific serum precipitin (Obermeyer and Pick, 1904), and also to a hypersensitivity to iodine injection (Friedberger and Ito); but artificially iodized serum is evidently not comparable with the administration of iodide.

Ferment Theory.—The resorptive action of iodides on various pathologic tissues, and the similarity of its febrile and inflammatory reactions to anaphylaxis, suggest the possibility that it may cause or favor proteolysis under certain conditions.

These views, although plausible have as yet no firm experimental foundation.

Several observers have described a rather doubtful acceleration of *autolysis* by the addition of iodide, *in vitro*; and a more definite acceleration after the administration of iodide (Stookey, 1907; Kepinow, 1911; Kashiwabara, 1912; Morse, 1915).

Dick suggested that iodides lead to the production of a proteolytic ferment. Jobling and Peterson, 1914 and 1915, on the other hand, believe that they restrain the antitryptic activity of the serum and tissues, by binding the unsaturated carbon atoms of the antitryptic lipoids, thus permitting the autolytic digestion of the necrotic, leucic or tubercular material, etc. In support of this, they found that the antitryptic power of serum or caseous tubercular material was actually diminished by incubation with iodine or iodide; that full doses of iodide, administered to man, greatly lower the anti-ferment index of the serum, which, however, recovers with the outbreak of iodism; and that the administration renders caseous tuberculous material digestible, explaining the appearance of tubercle bacilli in the sputum. They assume that gummas would be similarly digested, thus also exposing the spirochetes to the germicidal action of mercury or arsenic. It will be seen that the theory, although attractive, involves some unproven assumptions.

Circulatory Action.—Heinz, 1899, described increased leucocytosis and lymph flow, and assumed increased permeability of the blood vessels. Hirsch, 1914, however, did not find the phagocytic removal of tubercle bacilli hastened by daily KI administration.

Iodides and the Colloid Equilibrium.—It was pointed out, under the salt-actions of iodides, that the surface-relations of the blood are altered in life by intravenous injections of iodides; and that these produce edemas, which may be due to altered colloid-water affinity. Bancroft states that albumen in weakly alkaline solution is precipitated by sodium chloride, and not by iodide, whilst the relation is reversed in acid solution.

This suggests that iodide would alter the colloid characters according to the local hydrogen ion concentration, which is apt to be more acid in tissues with restricted circulation.

Treatment of Iodism.—It is often claimed that iodism does not occur with certain compounds or preparations; but this is mainly because they introduce less iodine. If adequate quantities of iodine are absorbed by susceptible individuals, iodism results, no matter what compound is used. There is therefore little hope in this direction for avoiding or treating iodism. It has been claimed that the catarrhal phenomena can be suppressed by large doses of calcium lactate (4 Gm. per day, Velden, 1913). This has not been tested extensively; but the long continued use of such doses of calcium might be inadvisable.

If the phenomena become too severe, the iodide may be intermitted, when they generally improve rapidly; and since the susceptibility varies at different times, the administration may perhaps be resumed later, with less trouble. More commonly, however, the iodide is continued with little regard to the iodism, unless this is unusually severe.

IODIDE AGAINST SYPHILIS

The use of iodides in syphilis was introduced by Wallace, 1836. Large doses are administered in the various tertiary and late secondary manifestations. They give marked relief, largely by leading to the absorption of gummatous formations. They are not curative, and do not affect the Wassermann reaction or spirochetes. The mechanism of their action is not proven, but is perhaps analogous to the irritant phenomena of iodism. It may be assumed that the provocation of an active inflammatory reaction breaks down the devitalized tissue, exposes the focal parasites to the antisyphilitic metals (Longcope, 1914) and to the immune substances of the blood, and starts repair and healing. Although these effects would be analogous to iodism, they would not necessarily require the occurrence of iodism in the skin or other tissues, which would quantitatively have a different susceptibility. Experimental syphilis of rabbits is also mitigated and shortened by the daily administration of quite small doses of potassium iodide, 0.3 to 6 mg. per Kg. corresponding to $\frac{1}{8}$ to 6 grains for man (L. Pearce, 1925). On the other hand, the iodide ion is not toxic to spirochetes, nor are they unusually susceptible to free iodine (Akatsu, 1917).

Administration of Iodide for Systemic Effects.—Potassium iodide is usually preferred, although it probably has no advantage over sodium iodide. It is best administered freely diluted with water or milk, an hour after meals. The dosage for non-syphilitic conditions is from 0.3 to 2 Gm., three times daily. In lues, this is often raised to 5 Gm. or more. It may be started with 5 drops of the saturated solution, increasing each dose by 1 drop (1 gr.) each day, reducing the dose if iodism becomes severe. In syphilis, one may begin with doses of 1.5 Gm., increasing by 0.3 Gm., every second day. Infants tolerate large doses (in meningitis, to 2 $\bar{5}$ per day; A. Jacobi).

Use in Circulatory Diseases.—Iodides are extensively employed in arteriosclerosis, coronary sclerosis, angina pectoris, aortic aneurism (Bouillaud, 1858), etc. In the lighter grades of these conditions their continued administration seems to give gradual relief to the functional phenomena, especially the pain; but probably without effecting a cure. The effects are not due to any change in the blood pressure, but probably to structural

alterations in the vessel walls, perhaps absorption of cellular exudates; analogous to the effect on syphilis. In many cases, a syphilitic factor is directly concerned.

Direct Action on Circulation.—Potain and others supposed that the iodides lower blood pressure by depressing the heart or blood vessels. This applies to fatal doses of KI, but is then a potassium effect. Ordinary doses have no effect on the blood pressure in normal men or animals (Stockman and Charteris, 1901). The slight circulatory changes in intravenous injection, described by Lehnndorff, 1914, and Macht, 1914, seem practically insignificant. Salant and Livingston, 1916, observed no effects on the circulation of frogs or mammals, even with fairly high concentrations of NaI. (The intravenous injection of free iodine markedly depressed the circulation in cats, not in dogs.)

The blood pressure in arterial hypertonus is also unaffected acutely, and probably even with continued administration (Hewlett, 1912). On the other hand, some clinicians claim a definite fall (*f.i.* Rutkewitch, 2 Gm. daily). There is also a fall in lead poisoning, probably indirect (Capps, 1912). Guerwitsch, 1907, frequently observed increase of pulse rate with iodide administration. This may have been a thyroid effect.

Isolated Heart and Arteries.—Macht, 1914, investigated the effects of replacing part of the NaCl of Locke's solution by NaI or KCl. The results can not, of course, be transferred to intact animals, or man, since they involve different concentrations. He concludes that the iodide and Na ion stimulate the heart and constrict the vessels; the cardiac stimulation being strong for iodide, weak for Na. The K ion depresses the heart and relaxes the vessels. Very weak solutions of metallic iodine are also stimulant; stronger concentrations are toxic.

Decreased Viscidity of the Blood.—Iodides and thiocyanates decrease the viscosity of colloids (Pauli, 1903; the other haloid ions have a similar but weaker effect; Gazzeti, 1913). O. Mueller and Inada, 1904, claimed diminished viscosity of the blood from therapeutic doses, and advanced this as an explanation of the circulatory effect. This could not be confirmed by Determann, 1908; Determann and Broeking, 1912; Lanza and Vergano, 1912, Tscheboksarow, 1913, and Partunier, 1917. Chistoni, 1910, found more positive results. The changes are evidently inconstant, and perhaps even accidental; they are so small that they would have no significance.

Epinephrine Atheroma.—Koranyi, 1906, claimed that this could be prevented by iodides; but this has been disproven (Biland, 1906; L. Loeb and Fleisher, 1907; Hedinger and Loeb, 1907; Klieneberger, 1907).

Trench Foot.—Sweet, Norris and Wilmer, 1918, claim that potassium iodide, 4 Gm. per day, gives decided relief to the pain within 24 hours. The observations and the theory on which they are based would need confirmation.

Miscellaneous Conditions.—Iodides are administered in a variety of obscure conditions to produce "absorptive" effects. These are often difficult to judge. So far as they exist, they may be analogous to iodism; not infrequently they include a syphilitic factor. These uses comprise: The absorption of nonluetic hyperplastic tissue; of fibroses and other chronic inflammatory lymphatic swellings; gout and chronic rheumatism; neuralgias; asthma, etc. The action on bronchial muscle is doubtful (Titone, 1913). Iodides are also used in chronic mercury, lead and other metallic poisoning with the hope of promoting the excretion of the stored metal by converting it into more soluble compounds, but this is hypothetical.

Tuberculosis.—Iodides tend to arouse irritative reactions of the tubercle lesions, similarly to tuberculin. This may sometimes be beneficial, but it may also convert dormant tuberculosis into an active disease. They are therefore dangerous. They have an analogous effect in *leprosy* and produce febrile reactions in a variety of *infections*. They are useful in *actinomycosis*.

Sorel, 1909, found that iodide hastens death in experimental tubercular infection of guinea pigs, but the direct toxicity of iodide is not greater for tuberculous guinea pigs than for the normal (Nicolau and Naota, 1916).

Actinomycosis, oidiomycosis, sporotrichosis and blastomycosis may be treated clinically by moderate doses (Tr. iodine, $\frac{1}{4}$ to $\frac{1}{2}$ c.c. in a half cup of milk, three times daily (Chitty, 1926).

Experimental sporotrichosis of rats responds promptly to iodides, and is suggested for the investigation of iodide action (D. J. Davis, 1919).

PREPARATIONS—IODINE

The principal incompatibilities of iodine are: alkaloids; alkalies and carbonates; tannin; turpentine and volatile oils.

Iodum, U.S.P., B.P.; Iodin, I.—Bluish black, friable scales, of distinctive odor and acrid taste. Very slightly sol. in water (1:2,950); sol. in alc. (1:12.5), or glyc. (1:80); freely sol. in fat solvents or aqueous solutions of iodides. *Dose*, 0.01 Gm., $\frac{1}{16}$ gr., U.S.P., diluted; maximal, 30 mg., $\frac{1}{2}$ gr.

**Tr. Iodi*, U.S.P.; Tincture of Iodine.—7 per cent. iodine; 5 per cent. KI; in alc. *Dose*, 0.1 c.c., $1\frac{1}{2}$ minims, U.S.P., diluted; maximal, 0.3 c.c., 5 minims. The KI in the tincture makes it miscible with water and insures against loss of strength on keeping (Wetterstroen, 1908). (When iodine is administered in milk, it is largely converted into iodide and albuminates.)

Eighteen per cent. of water may be added to saturated alcoholic solution of iodine before precipitation occurs (Schoorl and Regenbogen, 1919).

**Tr. Iodi Fort.*, B.P.—10 per cent. iodine, 6 per cent. KI.

Tr. Iodi Mil., B.P.—2.5 iodine, 2.5 per cent. KI. *Dose*, 0.12 to 0.3 c.c., 2 to 5 minims, B.P. diluted.

**Liq. Iodi Co.*, U.S.P. (Lugol's Solution).—5 per cent. iodine, 10 per cent. KI, in water. *Dose*, 0.2 c.c., 3 minims, U.S.P., diluted.

Ung. Iodi, U.S.P., B.P.—4 per cent. each of iodine and KI, in glycerin and woolfat, U.S.P.; in glycerin and lard, B.P.

When free iodine is rubbed with fat, it combines almost immediately and completely; but when KI and glycerin are added, as in the official ointment, this combination is restricted; these ointments contain permanently about 3 per cent. of free iodine (Pallen, 1912; Fried, 1912; Warren, 1917).

The most stable ointment is made with yellow petrolatum (Ewe, 1920). Iodine is soluble in liquid petrolatum to 1.4 per cent., practically without combination (A. M. Clark, 1919).

IODIDES

Incompatibilities.—Iodides should not be used with calomel or hydrogen peroxide, even in separate prescriptions. They precipitate heavy metals and some alkaloids (strychnine). They are incompatible with mineral acids and oxidizing agents. Salts or solutions which have become yellow by liberation of iodine should not be dispensed.

Acid Hydriod. Dil., U.S.P., B.P.; 10 Per Cent. of HI.—Colorless or pale yellow, odorless liquid; strongly acid taste. Should not be used if colored more than pale yellow. *Dose*, 0.5 c.c., 8 minims, U.S.P.; 0.3 to 0.6 c.c., 5 to 10 minims, B.P.; diluted.

Syr. Acid. Hydriod., U.S.P., B.P.—About 1.4 per cent. of HI, U.S.P.; 1 per cent., B.P. *Dose*, 4 c.c., 1 drachm, U.S.P.; 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

**Syr. Ferr. Iod.*, U.S.P., B.P.—Each cubic centimeter is equivalent to 0.0525 Gm., 0.85 gr., of iodine; see Iron Preparations. For strumous children, it is administered in doses increasing gradually from 0.3 to 1.2 c.c., 5 to 20 drops per day (Marine, 1911 and 1912).

**Potassi Iodidum* (Pot. Iod.), U.S.P., B.P.; KI.—Colorless cubical crystals, or white granular powder, faint iodine odor, sharp saline taste. Very sol. in water (1:0.7); sol. in alc. (1:22); freely sol. in glyc. (1:2). *Dose*, 0.3 Gm., 5 gr.; antiluetic, 2 Gm., 30 gr., U.S.P.; 0.3 to 1.2 Gm., 5 to 20 gr., B.P. A 1:1 solution (1 minim = 1 grain) is convenient for dispensing: Dissolve 1 $\frac{3}{5}$ in $5\frac{1}{2}$ $\frac{3}{5}$ of water, and make up to a fld. $\frac{3}{5}$.

Liq. Pot. Iod. C. Sap., B.P.—12 per cent. of KI.

Ung. Pot. Iod., B.P.—10 per cent. of KI.

**Sodii Iodidum*, U.S.P., B.P.; NaI.—Properties and dose similar to KI. Very sol. in water (1:0.5); freely sol. in alc. (1:2) and in glyc. (1:1).

ORGANIC IODINE COMPOUNDS

Calcii Iodobehenas. (Calc. Iodobehen.), U.S.P. Calcium Iodobehenate, Sajodine, Calioben.—Consists principally of calcium moniodobehenate, $(C_{21}H_{42}ICOO)_2 Ca$, and contains not less than 23.5 per cent. of iodine. White or yellowish powder; odorless or of a slight fat-like odor. Insoluble in water, very slightly soluble in alcohol and ether, freely soluble in warm chloroform. *Dose*, 0.5 Gm., 8 grains, U.S.P.

THYROID

**Thyroidium* (Thyroid.), U.S.P., B.P.; Thyroid.—The dried and powdered healthy thyroid glands of sheep (and other animals used for food, U.S.P.). One part of the dried corresponds approximately to 5 parts of the fresh gland. The U.S.P. requires 0.17 to 0.23 per cent. of thyroid iodine. *Dose*, 0.06 Gm., 1 gr., U.S.P.; 0.03 to 0.25 Gm., $\frac{1}{2}$ to 4 gr., B.P. Raw or broiled glands ($\frac{1}{8}$ to $\frac{1}{3}$ gland) have also been used, but have no advantage.

Thyroxinum (Thyrox.), U.S.P. *Thyroxin.*—An active principle $C_8H_5ONI_3 \cdot C_2H_4COOH$, obtained from the thyroid gland. Contains not less than 63 per cent. of iodine. White needle-like crystals or powder, soluble in water, practically insoluble in other agents. *Dose*, 0.5 mg., $\frac{1}{120}$ gr., U.S.P.

IODOFORM

Uses.—This is obtained by the action of iodine on alcohol, acetone, etc., in the presence of alkalis. It has been known since 1832 and was introduced as antiseptic about 1879. It acts probably by liberating iodine; but this shows some peculiarities, due to the manner in which it is produced. Iodoform itself is practically insoluble and probably inactive. It is also quite stable outside of the body; but in contact with tissues or their extracts, and particularly with diseased tissues and with bacteria, it slowly *evolves iodine* (Altenburg, Schmidt, 1901). This occurs so slowly that the effects are mild, but sufficient to be somewhat antiseptic to bacteria and stimulant to the cells. It also dries the wound secretions, and is mildly hemostatic and analgesic. Hamburger found that it stimulates phagocytosis. Its injection into dogs leads to persistent leucocytosis (W. Weil, 1913).

These actions make it valuable in treating open wounds, since it promotes healing by stimulating granulation and lessening or preventing infection. It is most widely used as dusting powder; it is also injected into tubercular joints, usually as an emulsion with glycerin (iodoform 10, alcohol and glycerin each 45).

Iodoform has, however, a number of *disadvantages*. The most objectionable feature is the persistent odor, which can not be disguised by any perfume. Iodoform is also apt to develop iodism and irritant phenomena in susceptible individuals, producing particularly *eczemas*, even in minute amounts. It may also cause severe poisoning with narcotic symptoms, different from those of other iodides.

General Intoxication.—This may occur when iodoform is applied over a large area, or when it is injected. The symptoms consist in diuresis, nausea and anorexia, lassitude and somnolence, headache, confusion, apathy or marked irritability, striking pallor, hallucinations, diminished reflexes, light convulsions, and paralyses. The temperature rises, then falls. Death occurs through general paralysis of the central nervous system (P. Mulzer, 1905; M. Grossman, 1920). Sodium bicarbonate is said to be antidotal. *Chronic poisoning* is also characterized by paralytic phenomena. The heart, liver and kidneys exhibit fatty changes. Iodoform dermatitis is sometimes seen. It resembles ivy poisoning (Bryan, 1903). The idiosyncrasies are not analogous to anaphylaxis, for they can not be transferred positively (Stropeni, 1912). Fatal poisoning from intrapleural injection is reported by v. Bonsdorff, 1916.

Excretion.—Iodoform is not excreted as such, either by the kidneys or lungs. It appears in the urine as iodide and iodate, and as unknown organic compounds (Angiolani, 1903; Harnack and Gründler, 1883).

Iodoform Substitutes.—The disagreeable qualities of iodoform justify the search for efficient substitutes. A number of odorless iodine derivatives were tried, especially *thymol iodide* (*aristol*), but their popularity was short-lived, since they do not seem to possess the peculiar activity of iodoform.

PREPARATIONS

***Iodoformum** (Iodof.), U.S.P., B.P. (Tri-iodo-methane), CHI_3 .—Contains 97 per cent. of iodine. Usually obtained by the action of iodine upon alcohol or acetone, in the presence of an alkali. Fine, lemon-yellow powder, or crystals; peculiar, very penetrating and persistent odor; unpleasant, slightly sweetish taste suggestive of iodine. Nearly insol. in water; sol. in alc. (1:60), in glyc. (1:80), or olive oil (1:34); freely sol. in eth. (1:7.5). *Dose*, 0.25 Gm., 4 gr., U.S.P.; 0.03 to 0.2 Gm., $\frac{1}{2}$ to 3 gr., B.P.; in pills or capsules. *Maximum dose*, 0.25 Gm., 4 gr.

Supp. Iodof., B.P.—0.2 Gm., 3 gr.

Ung. Iodof., U.S.P., B.P.—10 per cent. in wool fat and petrolatum, U.S.P.; lard, B.P.

Iodoform (and other loose iodine derivatives) are *incompatible with starch*. They are generally *decomposed by heat*, and can therefore not be sterilized in this manner. Since they become antiseptic when applied to wounds, sterilization is usually superfluous.

"B.I.P.P." (Bismuth-iodoform-petrolatum paste).—This ointment has been used as a dressing for infected wounds. It is a mixture of one part of bismuth subnitrate and two parts of iodoform, with sufficient liquid petrolatum to make a paste (Morison, 1916). A similar mixture was used by Calandra, in 1908.

The *iodoform substitutes* are also injured by heat and light. They are all insol. in water and are used like iodoform.

Thymolis Iodidum (Thymol. Iod.), U.S.P. (Dithymol-diiodide; *Aristol*); $(\text{C}_6\text{H}_5\text{CH}_3\text{C}_3\text{H}_7\text{OI})_2$.—Contains at least 43 per cent. of iodine. Chocolate-colored powder with slight aromatic odor. Insol. in water or glyc.; slightly sol. in alc., readily in oils, eth., etc.

THIOCYANATES (SULPHOCYANIDES, RHODANATES)

These produce actions resembling the iodides; but their use has not become popular. They are not dissociated into cyanides, and are relatively non-toxic. Their normal occurrence in the saliva is interesting, but without much practical significance.

Iodide Effects.—NaSCN influences the aggregation of colloids in the same way as the iodide ion, being even somewhat more solvent. This analogy suggested a therapeutic trial. In the limited number of cases in which it has been tested, it was found to affect neuroses, arteriosclerosis, and syphilis in a manner analogous to the iodides, (Pauli, 1903 and 1910). It also hastened the elimination of metals—perhaps by rendering the metal-protein compounds more soluble. It resembles the iodides further in producing coryza, acne, and other symptoms of iodism. Corper, 1915, observed no results in tuberculosis. Nerking, 1913, reports many disagreeable effects, especially in gastric hyperacidity. A conspicuous difference from iodides lies in the fact that it does not act on the thyroid gland. It was used as the *sodium sulfocyanide*, in the maximal dose of 1 Gm. (15 gr.) per day. This salt is quite soluble in water. The potassium salt could probably be used in the same dose.

Toxic Actions.—The earlier authors (Cl. Bernard, etc.) considered the sulphocyanides as relatively non-toxic; and as mentioned, they have been used therapeutically in gram-doses. F. Franz, 1912, confirms that no cyanide is split off in the animal organism. Intravenously, very large doses, 0.08 Gm. per kilogram, produce no toxic symptoms. Even 0.36 Gm. per Kg. intravenously, produces practically no effect on the circulation or respiration or bile and urine flow (Gies, Lieb, and Kahn, 1914). No effects resulted in man from the continuous administration of $\frac{1}{2}$ to $2\frac{1}{2}$ grains per day. The minimal fatal dose by vein for rabbits is placed by Corper, 1915, as 0.4 to 0.6 Gm. per kilogram. By mouth there were only the local salt actions. Lodholz, 1905, described toxic effects from KSCN, which must have been due either to the potassium or to impurities.

The recorded deaths to 1916, attributed to ammonium sulphocyanide are abstracted in *Am. Journ. Pharm.*, 88:571; *Journ. Pharm. Chem.*, 14:87.

Skeletal Muscle.—Immersion of a frog's gastrocnemius in a 2 per cent. solution of sodium thiocyanate (in Ringer's solution) produces a strong primary contraction, followed by gradual increase of tonus, slow waves of contraction and intermittent twitchings (Worthington, 1912; Langley, 1916). At first these are arrested by curare, *i.e.*, they are of nervous origin. As the concentration in the muscle rises, however, the muscle substance is also involved, so that curare becomes ineffective (Langley, 1916).

Occurrence in Saliva.—Thiocyanate is found in the human parotid and submaxillary saliva, but not in all individuals; also in the saliva of many animals, not in dogs and horses. It is absent in new-born infants (Rittershain); also in suppurative middle-ear disease (Juergens, 1901). It is found in other mucosae (nasal, conjunctival, gastric). It is excreted quantitatively in the urine and feces (Pollak, 1902; A. Meyer, 1904), generally in the proportion of 1:2 (Gies and Kahn, 1912). In dogs in which it is absent from the saliva, it occurs in the blood, liver, intestines and urine (Kahn, 1912). In normal dogs, it is present in the urine to the extent of 0.001 per cent.; in the blood, 0.003 per cent.; in the bile, from nothing to 0.033 per cent. (Gies, Lieb and Kahn, 1914). Its quantity depends on the available supply of CN radical. It is formed when HCN is administered, constituting a chemical disintoxication mechanism. Its quantity is increased by tobacco smoke, which contains HCN. It is also increased by feeding amino-acids (alanin) and acetonitrile; not by sulphur, sulphide, thiourea or taurin. It is probably produced from the protein in the liver (Kahn), the saliva being merely an excretory channel (Souza, 1907).

Dezani, 1918, confirms that the excretion in dog's urine varies with the nitrogen intake, so that it is apparently derived, at least in part, from the food.

Its content in the saliva has no relation to tooth decay (Lothrop and Gies, 1911). The quantities present in the mouth could not have an antiseptic effect (Gies and Kahn, 1912 and 1913); although thiocyanate is toxic to higher plants, and in greater concentrations also to bacteria. Sulphocyanic acid (0.3 to 0.4 per cent.) inhibits the gastric digestion of fibrin (Cavazzani, 1915). A comprehensive review of the literature is given by Kahn, 1912.

NITRATES

Potassium nitrate, Saltpeter, was formerly used as a cardiac depressant in fevers, etc.; it is now recognized that ordinary doses do not possess this action. Its effects are simply those of a neutral salt; somewhat more irritant to the gastro-intestinal tract, and somewhat more diuretic than sodium chloride. It has practically gone out of use in therapeutics, but has some reputation as anaphrodisiac. This is not based on scientific data.

Toxicology.—Accidental poisoning from large doses is not uncommon. It presents the phenomena of gastro-enteritis, similar to those of all other soluble indifferent salts. These may be serious, especially if it is swallowed undiluted. The symptoms consist in great abdominal pain, vomiting, frequently bloody stools; irregular pulse, convulsions, and collapse; suppression of urine, or that passed is albuminous and often bloody. The gastroenteritis may be so violent as to lead to an early fatal ending. Of the salt so far studied, the potassium nitrate is by far the most violent; 30 Gm. (1 $\frac{1}{3}$) may be fatal if taken in concentrated form. Smaller doses, long continued, cause a hemorrhagic tendency, edema, and fatty heart (Fackelmann, 1898).

The *treatment* consists in dilution. Large quantities of water should be drunk and the stomach washed. Demulcents—milk, egg white, acacia—are also useful. The symptoms should be met as they arise.

Fate and Excretion.—Nitrates are readily absorbed. Their excretion is similar to that of the halogen ions, and shows the usual mutual relation (Sollmann). Practically the entire quantity is excreted unchanged (Abderhalden and Hirsch, 1913); but a small proportion may be reduced to nitrites. This reduction takes place so slowly, in the case of the inorganic nitrates, that no nitrite action can ordinarily be seen; but very

large doses may cause methemoglobin formation (Binz and Gerlinger, 1901). Metabolism studies have given contradictory results (Grafe and Wintz, 1913).

Normal urine contains 0.1 to 0.4 per cent. of KNO_3 . This is considerably more than is ingested with the food, so that a part must be formed as an end-product of metabolism (H. H. Mitchell, Shonley and Grindley, 1916).

Nitrates provoke the *lueini reaction* (Cole and Paryzek, 1917).

Excised Ureter.—Non-toxic concentrations are slightly stimulating (Macht, 1917).

PREPARATIONS

Potassii Nitras (Pot. Nitras), U.S.P., B.P. (Niter, Saltpeter), KNO_3 .—Colorless, transparent prisms, or white, crystalline powder; saline, cooling taste. Freely sol. in water (1:2.8); very slightly sol. in alc. *Dose*, 0.3 Gm., 5 gr., U.S.P.; 0.3 to 1.2 Gm., 5 to 20 gr., B.P.; diluted.

Sodii Nitras (Chili Saltpeter), NaNO_3 .—Freely sol. in water (1:1.1); sol. in alc. (1:100). *Dose*, as Pot. Nit.

POTASSIUM CHLORATE

A saturated (1:16) solution is used as an antiseptic and astringent mouth wash in stomatitis, especially mercurial and ulcerative; and as a gargle in pharyngitis and tonsillitis. It often seems to be effective, but its action is unexplained. It was introduced with the idea that it would act as an oxidizer, and thus be antiseptic. However, it does not easily part with its oxygen in the body, being excreted practically unchanged.

It should not be employed internally, since this has repeatedly led to serious toxic effects (A. Jacobi, 1879), especially by the production of methemoglobin and destruction of the corpuscles, thrombosis, etc. Patients should be cautioned against swallowing the gargles. The popular tablets are to be condemned.

Excretion.—Chlorates are excreted mainly by the urine, but partly also by the saliva. The urinary excretion begins promptly and is completed within forty-eight hours, about 90 per cent. of the chlorate being recovered (Rosenbloom). A great deal of this is reduced to chloride after the urine is voided. It is doubtful whether this reduction occurs ordinarily in the body. *Bromates* are partly reduced in the tissues, and *iodates* intensively, when given by mouth, but not when administered hypodermically or by vein (Crespolani, 1909).

The distribution of fatal doses has been studied by Rosenbloom, 1912.

Blood Changes.—When the chlorates are added to blood, either inside or outside the body, they effect the *formation of methemoglobin*. The chlorate ion is not used up in this process, so that it may convert an indefinite amount of hemoglobin. They differ in this respect from the nitrites (see index), and their action is in consequence more violent and more prolonged. They may produce an actual asphyxia.

In a severe case of human poisoning the blood, examined 13 hours after taking the chlorate, contained both methemoglobin and hematin. Hemolytic icterus developed later. Similar conditions were found in poisoned animals (Feigl, 1916).

In addition to this formation of methemoglobin, the chlorates break up the *blood corpuscles* (Huber, 1912). This may produce embolism; the proteins, etc., which are liberated by the destruction of the corpuscles are irritant to the kidneys and produce interstitial *nephritis*, with the usual phenomena—proteins in the urine, casts, sometimes hemoglobin compounds. Possibly the chlorate ion itself irritates the kidneys.

Fat embolism of the lungs and other organs are also of frequent occurrence, at least in animals. They originate from the bone-marrow. The blood contains numerous normoblasts. Fragmentation of the heart muscle is a frequent cause of death (Winogradow, 1907).

Methemoglobin Formation by Chlorates.—The blood of different animals shows different degrees of susceptibility for the methemoglobin formation. These differences are common with all poisons acting on the blood, especially as between carnivorous and herbivorous animals. The cause is not understood, but is perhaps connected with differences in the alkalinity of the body. The conversion occurs fairly readily *intra*

vitam in man, dog, and cat, while rabbits and guinea pigs are almost immune. But in the test-tube chlorates convert rabbit's blood, although more slowly than dog's. The action is much slower outside of the body, often requiring several hours.

The concentrations that are injurious for the blood have been determined by E. Caesar, 1918.

Iodates and bromates have a similar action on hemoglobin (Heinz, 1898).

Potassium Chlorate Poisoning.—This is fairly common, either by an overdose, since the laity does not generally regard it as a toxic substance; or by the swallowing of some of the solution given for gargling.

Fatal Dose and Course.—The susceptibility varies greatly and this is one of the principal dangers. The variation may be due to differences of absorption and excretion, embolism, etc. In general, 10 Gm. may be considered as toxic, 15 to 30 Gm. as fatal (Lewin). The mortality is about 70 per cent. The symptoms may start at once or be delayed to six hours; death may occur in six hours to seven days.

Symptoms of Poisoning.—These consist in gastritis (nausea, vomiting, gastralgia); methemoglobinemia (cyanosis, collapse, and terminal convulsions); and nephritis (lumbar pain, anuria, albumen, casts, blood, etc.). The postmortem findings correspond with the symptoms.

Treatment.—This consists in gastric lavage, hot drinks, and symptomatic measures.

PREPARATIONS

***Potassii Chloras** (Pot. Chloras), U.S.P., B.P., KClO_3 .—Colorless crystals, or white granular powder; odorless; cooling, characteristic taste. Sol. in water (1:16.5); nearly insol. in alc.; sol. in glyc. *Explosive* when triturated with organic matter (not when in watery solution). *Dose*, 0.25 Gm., 4 gr., U.S.P.; 0.3 to 1 Gm., 5 to 15 gr., B.P.

Troch. Pot. Chlorat., B.P., 0.2 Gm., 3 gr.

Sod. Chloras., NaClO_3 .—Freely sol. in water (1:1); sol. in alc. (1:100). *Dose*, as Pot. Chloras.

BROMATES

These act similarly to chlorates, but are considerably more toxic, mainly by central paralysis (Santesson and Wickberg, 1913). They form methemoglobin *in vitro*, but not as actively as chlorates (v. Mehring, 1885; Cushny, 1908).

IODATES

Macciotta, 1916, found KIO_3 to be tolerated without disturbance, with oral administration of 0.285 Gm. per Kg. The urine contained no trace of iodate, but only iodide. Hypodermically, the above dose was fatal.

METHEMOGLOBIN FORMATION¹

Methemoglobin contains the same amount of oxygen as oxyhemoglobin, but in different combination, so that it is held more firmly (except against certain reducing agents (Haldane). The two hemoglobin compounds therefore differ essentially in certain of their properties:

1. The spectrum (see Fig. 23). The color of methemoglobin has more of a brownish tinge.

2. In the readiness with which they give up oxygen. While the oxyhemoglobin is a very unstable compound, giving up its oxygen and taking it again, with great readiness, methemoglobin is a comparatively stable and unchangeable compound.

¹ For Bibliography, see Benedicenti, *Archiv für Physiologie*, 1897, p. 210.

3. In their behavior to certain reagents. For instance, HCN does not form any characteristic compound with oxyhemoglobin, but with the methemoglobin it gives cyanmethemoglobin. Similar compounds are formed with H_2O_2 , thiocyanates, and many other salts, and also with alkalis.

Methemoglobin may be formed from oxyhemoglobin in quite a number of ways:

1. By oxidizing agents: Potassium chlorate, ferricyanide, permanganate, H_2O_2 , etc.
2. By reducing agents: The nitrites, hydroxylamine, formalin, iodine, chrysarobin, etc.; coal-tar products. (Phenylhydrazine also gives reduced hemoglobin, and destroys some of the hemoglobin absolutely, producing a new compound which, under certain conditions, yields a green pigment, hemoverdin.)
3. In the early stages of putrefaction, and by the action of light.
4. By salts and glycerin.
5. By acids (this has been denied).

The physiologic significance of this methemoglobin formation rests on the stability of the compound and its consequent inability to carry out the functions of oxyhemoglobin. This produces asphyxia of the tissues. Pure methemoglobin solutions may be injected into the blood, without causing any symptoms. Even the urine remains free from albumin or methemoglobin. The compound is in part secreted by the bile, in part deposited in the hematopoietic organs.

Nor is the temporary conversion of a considerable proportion of the oxyhemoglobin into its isomer of great significance; for methemoglobin is not absolutely stable, and as soon as the oxygen starvation of the tissues is carried to a certain degree, they seize upon the methemoglobin and decompose it. The conversion of a third of the hemoglobin into methemoglobin causes only very slight symptoms; and life is still possible when three-fifths of the hemoglobin has been replaced. Life becomes extinct when the hemoglobin has sunk to one-third. The condition can therefore become dangerous only if the methemoglobin-former continues its action. This does not occur with therapeutic doses of any of these drugs, but may contribute to the fatal ending in cases of poisoning. The symptoms are those of asphyxia. There is a peculiar blue tint about the lips and finger-nails, etc. The methemoglobin gradually returns to oxy- or reduced hemoglobin after death, so that an examination after several days may fail to reveal its presence.

Most of these drugs transform the hemoglobin inside of the corpuscles, without injuring the vitality of the latter; but some cause, in addition, a breaking up of the corpuscles, and this greatly increases the danger. Aside from the asphyxia which must be proportioned to it, the proteins and other substances liberated cause injury to the kidney—albuminuria, glycosuria, methemoglobinuria, etc. It is also claimed that it causes the sudden formation of fibrin ferment, which may then cause extensive intravascular clotting. The debris is credited with causing emboli. But these views are not admitted by all investigators. A small destruction, such as may be caused by the subcutaneous injection of glycerin, certainly has no permanent injurious effect.

The specific action of the drug is, of course, joined to these methemoglobin effects, and may entirely overshadow them. Thus, rabbits die of $KClO_3$ before it comes to any methemoglobin formation. Herbivorous animals are, as a rule, much less subject to the formation of methemoglobin during life, although their shed blood does not differ in this respect from that of carnivorous animals.

Alkali-methemoglobin is much more easily converted back into oxyhemoglobin. The injection of alkalis has therefore been suggested in the treatment of methemoglobinemia. Other treatment consists in the administration of oxygen, artificial respiration, and shock treatment.

THE REACTION OF THE BODY (REMOTE EFFECTS OF ACIDS AND ALKALIES)

The $H^{(+)}$ ions of acids and $OH^{(-)}$ ions of bases part readily with their electric charges, and therefore alter the state of colloids. In this way, and also by direct chemic changes, they produce extensive alterations in the functions of cells, which would be rapidly fatal if they exceed a certain degree.

Actual, Potential and Total Acidity and Alkalinity.—These effects are produced only by the dissociated ions, which represent the *actual* acidity and alkalinity. The activity of an acid or base depends therefore not

only on its total concentration, but also on its dissociation. The mineral acids, *f.i.*, which dissociate freely, are much "stronger" than equimolecular solutions of the organic acids or acid salts, which dissociate only slightly. Undissociated molecules do not exert these actions and are practically inert in this respect. They may, however, be drawn upon to neutralize added acid or alkali, in proportion as the free ions become combined, and in *this* respect are equivalent to the dissociated ions. They may therefore be considered as *potential* acidity or alkalinity. This relation was formerly not understood, and this has given rise to much confusion. The ordinary methods of titration measure only the *total* acidity or alkalinity (actual + potential). In complex fluids, like the blood or urine, this bears no relation to the true actual acidity. The *actual* reaction is measured by the electric potential; or by the use of a series of indicators which are only affected by certain concentrations of free $H^{(+)}$ or $OH^{(-)}$ ions (Soerensen); or by determining the velocity of certain reactions (inversion of cane-sugar, saponification, etc.), which depend on the $H^{(+)}$ or $OH^{(-)}$ concentration.

Hydrogen-ion Concentration.—The actual reaction is also termed the *true reaction* or *H-ion concentration*. It is generally expressed in reciprocal logarithms (as the "*hydrogen exponent*," "*pH*" *f.i.*, a solution containing 1 molecule of dissociated $H^{(+)}$ in 10,000,000 L. ($1:10^7$) is said to have the $H^{(+)}$ concentration of 7.0 (also written $pH=7$) etc. This constitutes *neutrality*, since water dissociates at 25° so as to contain $H^{(+)}$ and $OH^{(-)}$ ions, each in the proportion of 10^{-7} . An increase of H ions means, of course, a relative diminution of OH ions and *vice versa*.

This system of notation, although convenient, is at first somewhat confusing. It must be remembered that $pH = 6$ (really 10^{-6}) means a higher acidity than $pH = 7$ (really 10^{-7}). The acidity is therefore inverse to the number. Also, since logarithms are used, $pH = 3$ means an acidity 1,000 times as great as $pH = 6$; not twice as great.

The following equivalents may render the subject clearer:

$$\begin{aligned} pH1 &= \frac{N}{10} \text{ acid;} \\ pH6 &= \frac{N}{1,000,000} \text{ acid;} \\ pH7 &= \text{Neutrality;} \\ pH8 &= \frac{N}{1,000,000} \text{ alkali;} \\ pH14 &= \frac{N}{1} \text{ alkali.} \end{aligned}$$

The older notation is simpler, but less convenient; *i.e.*, $H^{(+)} = 2 \times 10^{-7}$ denotes twice as great acidity as 1×10^{-7} , 0.5×10^{-7} , one-half as great; etc.

Actual Reaction of the Body-fluids.—The normal reaction of the tissues and fluids within the body proper is near neutrality, that of the fluids inclining a trifle to alkalinity (pH =about 7.1 to 7.8). The gastric and intestinal juices and urine are the only fluids in higher animals which depart from this rule. The neutrality of the blood is maintained even in acidosis—although the cells where the pathologic acid is formed presumably develop an increased acidity, which is supposedly responsible for the symptoms. Normal living cells have an alkaline, neutral or very slightly acid reaction, judging by intravital stains.

¹ The local actions of concentrated acids and alkalis are discussed under "Local Irritants;" see Index.

H-ion Concentration of Protoplasm.—This varies not only in different cells, but also in the same cell under different conditions of activity. It also varies in different portions of the same cell, for instance, in large amebae the liquid of the vacuoles has a different reaction from the cytoplasm (Scarth, 1924); and the nuclear reaction presumably is quite different. *Muscle tissue* has a pH of 6.6 to 6.7, which is not altered by changes in the surrounding medium, between pH 5.2 to 8.2 (Schmidtman, 1924). In general, cells preserve their vitality in media ranging from pH 6.9 to 9.0. *Plant cells* may reach the acidity of pH 3, as shown by their colors, which are natural indicators (Haas, 1916).

Reaction of Normal Blood.—The pH of fresh defibrinated blood is very weakly alkaline almost neutral. It is stated, for instance, as 0.3 to 0.7×10^{-7} (Friendenthal, 1904); $pH = 7.45$ for arterial, 7.3 for venous (Hasselbach, 1913); 7.6 to 7.8 for human serum, 7.4 to 7.6 for oxalated blood (Levy, Rowntree and Marriott, 1915), at air temperature; at 37° the alkalinity would be about 0.1 higher. Similarly, excessive ventilation of the lungs with air or oxygen lowers the H concentration of the blood, whereas excessive ventilation with CO_2 increases it (Milroy, 1914). The CO_2 tension has some influence, so that venous blood is a little less alkaline than arterial.

Pathologic Blood.—Levy et al. found the reaction of the serum in sixty miscellaneous medical cases to be normal (pH 7.6 to 7.8); the whole blood was also nearly unchanged (pH 7.1 to 7.3). Even when symptoms of acidosis are present, the alkalinity is but little decreased (pH of serum, 7.2 to 7.5; Levy et al.). Under alkali therapy, this is restored toward normal.

In diabetic coma, Benedict, 1906, records an extreme change to 1.5×10^{-7} . Masel, 1913, and Van Slyke, 1915, found practically no change, except just before death (7.11, Masel); van Slyke, however, observed that the addition of HCl to acidosis blood raises its H concentration much more than when added to normal blood. The essential blood change of acidosis is therefore the diminution of the reserve alkali.

In normal animals, feeding with acids or alkalies has practically no effect on the H concentration of the blood. Intravenous injection of acid into dogs or rabbits produces air hunger when pH 7.65 is reached; death occurs with 6.9 (Levy et al.; 9×10^{-7} , Szili, 1906). At the other extreme, concentrations above pH 8 are probably also fatal (Rowntree).

Other Body Fluids.—With few exceptions these have about the same reactions as the serum (Friendenthal, 1901, Michaelis, 1914). On standing outside of the body, they may become acid (Hanzlik, 1914).

The hydrogen ion concentration of the cells must generally be somewhat higher than that of the blood, since they supply the acid that is excreted by the urine and lungs.

Effusions.—Hanzlik, 1914, found the pH of edema and pleuritic fluids about 7.1; ascitic fluid, 7.42.

Lobar Pneumonia.—The circulation in the pneumonic lung is so greatly restricted (Kline and Winternitz, 1915), that a rather high H-ion concentration may accumulate. That of the press-juice at autopsy has been obtained as pH 6 and even 5.4 (F. Lord, 1919). This may have little significance however, since postmortem changes might have occurred. Lord considers the acidity a possible factor in recovery, since pneumococci are injured by pH 7.8, and killed quite rapidly by 6 to 5.

Bile.—When flowing directly from the liver, bile is nearly neutral (0.07 to 0.2×10^{-7}). That from the gall bladder is more variable (6.98 to 7.18) and may become slightly acid on prolonged sojourn (Okada, 1915; Quagliariello, 1916).

Digestive Fluids.—The following pH figures are taken mainly from Michaelis, 1914: Saliva, 6.9; gastric juice, 1.77; intestinal juice, 8.0.

Actual Reaction of the Digestive Tract.—This may differ materially from the reaction of the digestive fluids, since these tend to be neutralized by each other, as well as by the buffer-action of proteins. Bacterial activity may also introduce modifications.

Stomach.—The resting empty stomach may be nearly neutral. During the first one and one-half to three hours after a meal, the acidity rises rapidly to $pH = 2$ or even 1; depending on the individual. It then remains stationary until nearly all the food has left the stomach (McClen-don, 1915).

Duodenum.—The reaction of the duodenal contents is the resultant of the neutralization of the acid chyme by the slightly alkaline intestinal and pancreatic juice and bile.

The actual pH of the duodenal contents, is usually quite acid. Myers and McClendon, 1920, found the usual reaction in man to be between $pH = 3.2$ and 5.

Small Intestine.—Long and Fenger, 1917, found the reaction of the intestinal contents slightly acid throughout the small intestine; the acidity decreasing somewhat with the distance from the pylorus. In the human jejunum, it ranged from $pH = 3.8$ to 7.8, mean 5.8; in the upper third of the small intestine in hogs, it ranged from 6.6 to 7.4, mean 6.7; in the middle third, 6.5 to 7.6, mean 6.9; in the lower third, 6.4 to 8.1, mean 7.

Similar figures were obtained in calves, lambs and dogs. They have been confirmed by McClendon et al., 1920.

Milk.—This is about 7.

Cerebrospinal Fluid.—Hanzlik, 1914, found this to range between 6.98 and 7.3.

Hurwitz and Tranter, 1916, found the alkalinity constantly somewhat higher than the blood (average pH , fluid, 8.11; blood, 7.66; difference, 0.45). This normal reaction was not changed in any stage of syphilis.

Reaction of Urine.—This usually inclines toward actual acidity, the normal range in man being $pH = 5.12$ to 7.46; the average about 6.03. The acidity decreases during the secretion of acid gastric juice, and fasting and perspiration (Haskins, 1914). It exceeds 5.0 in less than 1 per cent. and 5.3 in less than 10 per cent. In most diseases, the acidity averages distinctly higher; in cardiac diseases, about 4.91. The highest acidity so far reported is 4.7 (L. J. Henderson and pupils, 1914). The reaction is determined mainly by the ratio of phosphates.

The site of the acid production appears to be exclusively in the cells of the proximal tubules, which reach an acidity of $pH \approx 3$ (judged by the liberation of iron ions from the double citrate; A. B. Macallum, 1924). The intracellular acid is probably HCl , its formation being analogous to that of the gastric acid. This observation avoids the need of the older theoretical explanations, *i.e.*, active reabsorption of alkaline ions (Cushny) or more rapid excretion of NaH_2PO_4 than of Na_2HPO_4 (Trevan, 1916).

Therapeutic Acidification of the Urine.—The reaction of the urine may be altered toward the acid side by the administration of mineral acids. However, the usefulness and scope of these is limited by their local actions. Larger changes can therefore be more rapidly produced by the use of acid salts, such as sodium biphosphate, which combine considerable potential with a relatively low actual acidity; or by the administration of ammonium chloride, which leaves an excess of unbalanced Cl ions when the ammonium is dehydrated into urea; or by calcium chloride, which also gives an excess of Cl ions, because part of the calcium is precipitated as carbonate in the intestines. The acidification of the urine does not surpass the normal upper limit. For instance, the administration of the maximal dose of acid sodium phosphate raised the acidity from pH 6.7 to 5.3 (L. J. Henderson and Palmer, 1913); and from 7.2 to 4.85 (Hanzlik and Collins, 1913). Benzoates have a tendency to render the urine acid (Jordan, 1913); also boric acid, 2 Gm. daily (G. G. Smith, 1913); but these are not advised for therapeutic use.

Therapeutic Alkalinization of the Urine.—The administration of alkalis can increase the alkalinity somewhat beyond the normal range; *i.e.*,

20 to 40 Gm. of NaHCO_3 per day produced a maximal alkalinity of pH 8.7 (Henderson and Palmer, 1913); 4 Gm. changed the reaction from pH 6.5 to 7.4 (Hanzlik and Collins, 1913). About 5 to 10 Gm. of NaHCO_3 per day would be required to keep the urine of a normal individual alkaline. The alkalinity is also increased by the administration of the salts of those organic acids which are easily oxidized to carbonate; particularly the citrates and acetates. These avoid the gastro-intestinal actions of the free alkali.

Equivalence of Potential Alkalinity.—The quantities of the official U.S.P. salts (often containing water of crystallization) which are equivalent in potential alkalinity to 1 Gm. of NaHCO_3 are as follows in order of ascending magnitude (in Grams); magnesium oxide 0.24; magnesium carbonate 0.6; calcium carbonate 0.6; sodium carbonate (anhydrous) 0.63; sodium citrate 1.1; potassium acetate, 1.2; potassium citrate 1.3; sodium acetate 1.6.

Regulating Mechanisms.—Metabolism leads to the production of acids (carbonic, lactic, sulphuric, phosphoric, etc.) which would tend to increase the acidity of the body.

The carbonates derived from the combustion of vegetable salts would tend to render it alkaline.

However, the maintenance of the normal, nearly neutral reaction is so highly important that it is regulated with great nicety by the use of several mechanisms. The carbonates and alkaline phosphates of the blood and tissues constitute a stock of potential alkali; and the carbonic acid and acid phosphates of potential acid. These are sufficient to neutralize at once all ordinary attempts to change the actual reaction. The amphoteric character of the proteins permits them to neutralize a limited quantity of either acid or alkali. The administration of acid or alkalis by mouth therefore does not change the *actual* reaction of the blood and tissues, but only the *potential* acidity of alkalinity, *i.e.*, the *alkali reserve*. The ammonium formation, and the excretion by the urine and lungs, finally restore the equilibrium of potential alkali.

Neutralization in the Alimentary Canal.—Neither acids nor alkalis are absorbed unchanged from the alimentary canal. The alkalis (including the carbonates) are *neutralized* by the HCl of the gastric juice. Or if given in larger amounts, they enter into loose alkali-protein combinations before they reach the blood. The acids undergo a similar change, or if they are not entirely absorbed before entering the intestine, they are there neutralized by the carbonates. The immediate effects, then, would consist only in altering the reaction of the alimentary canal.

(Concentrated acids and alkalis produce corrosions by direct chemical actions. These local effects were considered under Irritants.)

Neutralization in the Blood.—It is difficult to alter the reaction of blood even *in vitro*. Friedenthal, 1903, showed that serum requires, to secure a given change of reaction, thirty to forty times as much NaOH, and 327 times as much HCl, as would be needed in water. This stability is due to the presence of the salts of weakly dissociating acids, which limit the liberation of $\text{H}^{(+)}$ ions to practical neutrality. This property is especially marked with phosphates and carbonates, which are important "buffer" constituents of the serum. The proteins act similarly.

If $\text{H}^{(+)}$ ions are added to such a system, they will be expended in liberating the weak acid from its salt; and since the weak acid is not ionized in the presence of its salts, the actual reaction will be practically unaltered.

If $\text{OH}^{(-)}$ ions are added, they will be expended in neutralizing the free weak acid; and thus will also leave the actual reaction unaltered. A notable change in the true reaction can occur only after enough acid or alkali has been added to neutralize or liberate *all* of the weak acid—*i.e.*, there will be no material change of reaction until not only the free, but also the potential acidity or alkalinity has been overcome. This would require quantities of strong acids or bases much greater than it would ordinarily be possible to introduce into the living body.

So far as this neutrality regulation is concerned, the blood may be considered as a solution of $\frac{\text{N}_2\text{CO}_3}{\text{NaHCO}_3}$ and $\frac{\text{NaH}_2\text{PO}_4}{\text{Na}_2\text{HPO}_4}$. All these dissociate so weakly that in solutions of the concentration of blood, their $\text{H}^{(+)}$ and $\text{OH}^{(-)}$ concentration, separately or together would be practically that of neutrality; *i.e.*, in the close neighborhood of 10^{-7} .

If an acid (HCl) were added to the mixture, it would react with the salts, producing:

This would increase the ratio of H_2CO_3 and NaH_2PO_4 ; but these dissociate so weakly that they practically leave the actual reaction unaffected. The $\text{H}^{(+)}$ concentration would therefore not be increased materially until all the NaHCO_3 and Na_2HPO_4 are used up.

If an alkali (NaOH) were added to the mixture, it would react as follows:

This would reduce the ratio of the free acids, H_2CO_3 and NaH_2PO_4 ; but since these acids were practically neutral, this does not affect the actual reaction materially, until all the carbonic acid and acid phosphate are used up.

The pH is of course not entirely unaffected by changes of the $\frac{\text{H}_2\text{CO}_3}{\text{NaHCO}_3}$ ratio. In a pure solution it varies with this fraction, multiplied by the constant 5×10^{-7} ; for instance, if the ratio rose the $\frac{1}{11}$ the pH would be 6.3; if it rose to $\frac{1}{9}$, the pH would be 5.3. In the body, however, changes of this magnitude cannot occur; the ratio being more nearly $\frac{1}{20}$. For $\frac{\text{NaH}_2\text{PO}_4}{\text{Na}_2\text{HPO}_4} = \frac{1}{1}$, the pH is 6.8 (review, van Slyke, 1921). Michaelis and Garmendia,

1915, state the normal ratio of the phosphates in bloodplasma as $\frac{\text{NaH}_2\text{PO}_4}{\text{Na}_2\text{HPO}_4} = \frac{1}{5.1}$ (molecules).

The theory of "buffer salts" has been elaborated especially by Sørensen and L. J. Henderson. Tables are contained in the books of W. M. Clark and of Michaelis.

The next step in the regulation of the neutrality is the exchange between the plasma and the corpuscles and tissues at large: The hydrogen ions diffuse into or out of the tissues, and these react with the phosphate and proteins, just as they do in the plasma. The alkalinity of the tissues is thus made available. The hemoglobin of the corpuscles plays a particularly important role (Van Slyke, 1921).

Restoration of the Potential $\text{H}^{(+)}$ and $\text{OH}^{(-)}$ Ions.—The regulating mechanism of the blood is important for protecting the body against sudden changes, for meeting temporary emergencies. However, this impairs the stock of potential $\text{OH}^{(-)}$ and $\text{H}^{(+)}$ ions, and therefore would not furnish a permanent protection. Other mechanisms are called into play to restore the normal ratio of these potential ions; mainly by regulating the excretion of CO_2 through the lungs; by varying the reaction of the urine; and by the more or less complete conversion of NH_3 into urea.

Regulation by Excretion of CO_2 .—Addition of acid to the blood liberates CO_2 from the bicarbonate. This increases the CO_2 tension, and thus its excretion by the lungs. The increased CO_2 tension stimulates the

respiratory center, and thus hastens the elimination. This restores the normal ratio of $\text{H}_2\text{CO}_3 \div \text{NaHCO}_3$. Conversely, the addition of alkali diminishes the tension of CO_2 and thus its excretion.

Regulation by Combustion of Organic Acids.—The organic acids arising in metabolism are normally oxidized to CO_2 and H_2O , and excreted by the lungs and urine. This mechanism is disturbed in disease, starvation, etc., and then gives rise to acidosis.

Conversely, the injection of alkali materially increases the excretion of unoxidized lactic acid by the urine (Macleod and Knapp, 1918).

Regulation by the Urine.—The urine like the blood contains a mixture of acid and neutral phosphates (Orth found a mean of 60 per cent. as MH_2PO_4 and 40 per cent. as M_2HPO_4). When acid is introduced, the ratio of acid phosphate is increased; alkalies increase the proportion of alkaline phosphate. This elimination of the excessive acid or alkali ions rapidly restores the potential acidity or alkalinity of the tissues. The flow of urine is also increased, so that acids and alkalies act as effective *diuretics*. The administration of acids first increases the PO_4 excretion; later, this decreases with the available supply of these ions (Fitz, Alsberg and Henderson, 1907). The influence of nephritis was studied by Palmer and Henderson, 1915.

Under normal conditions, the human kidneys free the body from 60 to 70 c.c. of normal acid per day. In diabetic coma, this quantity may be increased ten times (Henderson and Palmer).

Acid on Alkali Excretion.—Secchi, 1914, reports that the administration of HCl to man or dogs on a meat diet increases the elimination of ammonium persistently; that of K and Na temporarily. The Ca and Mg are not materially affected in the urine, but increased in the feces, especially Ca. The calcium of the tissues may thus be diminished.

Stehle, 1917, confirmed the increased excretion of Ca and Mg with dogs. Givens and Mendel found the urinary excretion of Ca increased more than the Mg. However, the alterations of the total balance of N, Ca, Mg or P were not material (in dogs).

With rabbits on a cabbage diet (rich in Ca) administration of acid markedly increases the elimination of Ca and Mg, less that of K and Na. The Ca excretion is mainly by the urine. The tissue Ca is greatly decreased (Stehle, 1914).

Feeding with HCl may cause arterial changes (Adler, 1914).

Mineral Metabolism in Experimental Acidosis of Rabbits.—Goto, 1918, administered 25 to 75 c.c. of N/4 HCl daily for 1 to 4 weeks. Most of the animals that received more than 25 or 30 c.c. per day died within 1 to 2 weeks. The major alkali reserves were utilized in the following order: first the plasma bicarbonate; then the alkaline carbonate and phosphate of the muscles; and the calcium carbonate of the bones.

The plasma bicarbonate was reduced. The urinary phosphates were first increased, then diminished. The fecal phosphate also decreased. There was also marked loss of phosphate and potassium from the muscles. The sodium was not diminished. The skeleton lost 10 per cent. of its weight, mainly as calcium carbonate, thus increasing the ratio of calcium phosphate.

Regulation by Ammonium Metabolism.—In man and in the carnivorous animals the more or less complete conversion of the ammonium ion, which is a potential alkali, into the neutral urea also serves as an important means of regulating the alkali-balance. If the acidity tends to rise, a larger part of the ammonium is left unconverted, and is used to neutralize the excessive acid. If the alkali tends to rise, more of the ammonium is converted, leaving its anion to neutralize the alkali. The ratio of unconverted ammonia (reflected in the ratio of NH_4 to total N of the urine) is therefore also an index of the acid or alkali tendency of the body. It rises if acids are introduced (Walter, 1877); or formed in the organism (acidosis); and is lowered when alkalies are administered (Janney, 1911).

After large doses of alkali, ammonium disappears completely from the urine (Davis, Haldane and Hennaway, 1920).

Different forms of acidosis however do not affect the ammonium excretion equally, although there tends to be a definite relation in man (Hasselbach, 1916). In man, the ingestion of hydrochloric acid produces a parallel increase of ammonium excretion and titrable acid; but sodium biphosphate increases the titrable acidity without increasing the ammonium excretion (Marriott and Howland, 1918). Clinically, increase of ammonium excretion occurs especially in ketonic acidosis, but is absent in certain nephritic acidoses. The ammonium quotient of the urine is therefore not an infallible guide of acidosis, but requires confirmation by other tests.

The administration of ammonium chloride increases the acidity of the urine, since the formation of urea releases unbalanced Cl^- ions, which would convert Na_2HPO_4 into NaHPO_4 (Haldane, 1921).

Ammonia Regulation in Man.—In man, also, there is a close relation between the ammonia and excretion of acid by the urine (Hasselbach, 1916).

Acidosis in Infancy.—Infants and young children develop acidosis readily, presumably because they have a relatively low alkali reserve. They also form acetone substances easily.

Gastric Secretion.—During stimulation of gastric secretion by food or water, the absorption of the acid chyme from the intestines leads to increased ammonium output in the urine (Ivy, 1918).

Efficiency of the Regulating Mechanism in Different Animals.—The protection against acids is conspicuously more perfect in carnivora, both as concerns the NH_4 and the elimination (Spiro, 1901)—probably because these are accustomed to ingest a certain amount of acid with their food. It is impossible to lower the alkalinity of the blood of a dog to such a degree as to produce symptoms, by introducing acid into the alimentary canal, unless corrosion be produced. But if an acid or acid salt be injected into a vein, it will cause very pronounced symptoms. In herbivorous animals, these may also be produced if large quantities are given by the mouth. They will result in death even before the reaction of the blood has become neutral. So that it is not strictly correct to speak of an "acid action," but rather of the effects of diminished alkalinity (Kettner, 1902).

Influence of Diet on Ammonium Conversion.—The ammonium regulation is not entirely absent in herbivora. Cows and calves use it quite efficiently when acid is fed (Hart and Nelson, 1913). Eppinger, 1906, claimed it to be influenced by diet: viz., that a vegetable diet renders dogs susceptible to acid poisoning; and that a meat diet, or injection of amino-acids, evokes the ammonium mechanism even in rabbits, and thus protects them against acid. However, later observers were unable to confirm this (Pohl and Muenger, 1906; G. Bostock, 1913).

Acid-base Content on the Diet.—This has not been worked out in detail. Proteins and fats tend to predominance of acid; and salts of vegetable acids tend to alkali. Meat or grain diet is therefore acid producing; fruits, carrots, etc. tend to alkaline.

Effect on Nephritic Poisons.—Acid producing diets render rabbits more susceptible to mild nephritic poisons; for instance to oils (Salant and Bengis, 1917).

Alkalosis.—Vegetarian diet would tend to increase the alkalinity of the body. This is prevented by the retention of carbonic acid; by the conversion of NaH_2PO_4 into Na_2HPO_4 ; by more complete oxidation of ammonium; by neutralization of proteins, and by increase of unoxidized organic acid, especially lactic acid.

Lactic Acid Excretion in Alkalosis.—Injection of sodium carbonate or oral administration of the bicarbonate produces a distinct increase of the urinary lactate. However, the excreted acid would neutralize only about $\frac{1}{20}$ of the alkali (Macleod and Knapp, 1918).

Nature of Acidosis.—Acidosis or acid-intoxication means a depletion of the alkali-reserve of the body; but not necessarily a change in the actual reaction. It arises when acids or acid salts are introduced in excessive

quantity, or when the organism fails to dispose promptly of the acids that are formed in metabolism. So long as there is an adequate store of potential alkali, the actual reaction of the blood is not materially changed, although it contains less carbonate. The acidity and the ammonium of the urine will also tend to increase. If the acidosis is due to faulty metabolism, oxybutyric acid and acetone substances will appear in the urine.

True and Compensated Acidosis.—Rowntree, 1916, proposes the term "Compensated Acidosis" for diminution of reserve alkali (decreased alveolar CO_2) without material change in the actual reaction of the blood; and "True Acidosis," when the alkalinity falls below $p\text{H} = 7.4$. This occurs only when the respiration fails to remove the excess of CO_2 ; *i.e.*, only as death approaches. A true acidity of the blood ($p\text{H} =$ above 7.0) is not seen clinically.

Symptoms of Acidosis.—The chief clinical sign of moderate acidosis is the hyperpnea, required to eliminate the liberated CO_2 . When the actual reaction of the blood becomes noticeably changed, the vasomotor and other medullary centers are also stimulated; especially if the change is acute, as with intravenous injection of acid. With further rise of the H-ion concentration, the nervous centers become depressed, as also the cardiac muscle. The effects agree with those of excessive CO_2 tension, asphyxia and oxygen deprivation, and diabetic coma, which are really forms of acidosis.

The final symptoms consist of coma, convulsions, depressed respiration and fall of blood pressure, etc. Death takes place by respiratory paralysis, generally before the blood becomes actually acid. The symptoms are at once removed—even in the last stages—by injection of Na_2CO_3 (F. Walter, 1877).

The *toxicity of acids* varies greatly according to conditions. In cattle, for instance, Berg, 1915, sometimes found considerable tolerance (0.87 Gm. of HCl as 0.9 per cent., vein, per kilogram).

Respiratory Center.—This is inhibited by decreasing the H ion concentration of the blood, and stimulated by increased H ion concentration (Douglas and Haldane, 1901, Winterstein, 1915). For instance, the intravenous injection of 0.5 c.c. of normal lactic or other acid per kg. of dog produces a marked increase of the rate and amplitude of respiration (S. J. Cohen, 1918). The effects on the respiratory center do not appear until the H ion concentration lies beyond $p\text{H}$ 7.2 and 7.8. The same phenomena occur on perfusion of the medullary centers (Hooker and Wilson, 1917); and by direct application of acids to the medulla of frogs.

Role of H-ion Concentration and Carbon Dioxide.—In general, the respiratory stimulation is proportional to the H-ion concentration (Winterberg; T. B. Robertson, 1912). However, carbonic acid stimulates more than would correspond to its acidity (Kopaczewski, 1914). This holds also for the perfused center (Hooker and Wilson). R. W. Scott, 1918, finds that excess of CO_2 stimulates respiration even if the blood is made distinctly more alkaline ($p\text{H} = 7.65$), as by sodium carbonate injection. The greater efficiency of carbonic acid is probably due to more rapid penetration into the cells.

The *apnea* following on excessive respiration is due to deficient CO_2 tension and therefore lowered H-ion concentration. *Cheyne-Stokes respiration* is attributed to alternate accumulation and oxidation of acids (Y. Henderson, 1910).

Hemoglobin.—Increased acidity diminishes the affinity of hemoglobin for oxygen (or carbon monoxide). For instance, with a carbon dioxide tension of 40 mm., the oxygen percentage must be doubled to secure the same degree of saturation (Barcroft, 1914).

Permeability of the Corpuscles.—Under the influence of CO_2 , the erythrocytes take up chloride from the serum, and increase its alkalinity. Similar changes occur in hemolysis (Rohonyi and Lórant, 1916).

Dyspnea in Cardiac Disease.—This is probably partly due to acidosis, the metabolic acids being imperfectly burned by the inadequate blood supply (Peabody, 1916).

The actual H concentration is not much altered, but the diminution of reserve alkali may result in a local acidosis of the cells of the respiratory center, since the gas metabolism of nerve cells is nearly a hundred times as great as that of muscles (Alexander, 1912). This must also render every increase of CO_2 much more effective; for instance, the respiration is doubled in decompensated patients by 2 to 3 per cent. of CO_2 in the air, while normal individuals require 4.5 to 5.5. per cent. Alkali treatment restores the response to normal (Peabody, 1915).

Nephritic Dyspnea.—This is often but not always associated with acidosis. In the latter case, it is not relieved by alkali. Such cases probably involve direct changes in the threshold of the respiratory center (Christian, 1916).

Circulation: Vasomotor Center.—The stimulation (reflected in the rise of blood pressure) has been studied by Mathison, 1911. Pilcher and Sollmann, 1915, found moderate and temporary stimulation, independent of blood-pressure changes.

Circulation Rate in Man.—This shows a close parallelism with the H-ion concentration of the arterial blood, and therefore with the oxygen consumption (Boothby, 1915, nitrous oxide method of Krogh and Lindhard).

Peripheral Action on Vessels.—Gaskell, 1880 to 1882, showed that weak acids tend to relax, and alkalies to constrict. This has been confirmed by the subsequent workers (Schwarz and Lemberger). However, the pH changes necessary for these effects seem to lie far outside of the variations that can occur in the living body. For instance, in the frog mesentery, the minimal effective concentrations are: for dilation, pH_3 ; for constriction, pH_9 to 11. Excised arterial rings do not respond satisfactorily to acid. They are constricted by pH_{12} (I. Adler, 1916). Atzler and Lehrmann, 1921, however, claim that the greatest dilation of frog vessels occurs about pH 6. *Capillaries* are also dilated, but this also requires concentrations that are not reached in life (Krogh).

Frog's Heart.—The automatic contractions continue only within certain ranges of H concentrations, which differ for the various portions of the heart (Dale and Thacker, 1913). The sinus requires the highest H^+ concentration ($\text{H}^+ = 4$ to 9.5); the ventricles the lowest ($\text{H}^+ = 6.5$ to 11).

Perfused Terrapin Heart.—Hydrogen-ion changes within the physiologic range produce definite effects. *Increased alkalinity* (pH 7.6 to 7.8) increases tonus, especially of the auricles, and diminishes the excursions. *Diminished alkalinity* (7.3) increases the output, by increasing the amplitude of the beats, and diminishing the tonus (Andrus, 1919).

Isolated Mammalian Heart.—The effects of oxidizing substances, acids and alkalies, are described by Loevenhart and Eyster, 1913. Yanagawa, 1916, finds the coronary vessels constricted by increase of alkalinity, dilated by acidity.

Smooth Muscle.—Increase of acidity depresses, relaxing the tonus, and weakening and slowing the rhythmic contractions. Higher concentrations produce death in the relaxed state. Increased *alkalinity* quickens the rhythm, but may diminish the excursions. The effects are independent of the innervation, and are therefore directly muscular (Evans and Underhill, 1923).

Hydrogen-ion Concentration of Perfusion Solutions.—Distilled water, if carelessly prepared or if stored, becomes very distinctly acid (pH about 6.3); and imparts this acidity to sodium chloride or glucose solutions that are prepared from it (J. R. Williams and Swett, 1922). The balanced solutions contain sufficient alkali to overcome this. The pH of Locke's solution is about 7.5, but it has a low buffer value. That of Tyrode's solution is 8 to 8.1 (G. G. Roth, 1917).

Intestines.—In excised intestines, increase of OH^- produces stimulation, increase of H^+ relaxation (Hammett, 1922). In intact dogs also, intravenous injection of sodium bicarbonate (50 c.c. of 2.5 to 6 per cent. solution) produced stimulation (King and Church, 1922).

Excised Ureter.—The movements are depressed by acid, stimulated by alkalinity (G. B. Roth, 1917).

Striped Muscle.—According to the currently accepted views of Meyerhof, A. V. Hill (Review, 1922) and others, muscular contraction is due to the production of lactic acid, presumably from glycogen (without the use of oxygen). This results in the development of tension, through osmosis (Wacker, 1917 and 1921), imbibition (v. Fuerth), surface tension, etc.; the mechanism being in dispute. Following the contraction, about $\frac{4}{5}$ of the lactic acid is reconverted into glycogen, and $\frac{1}{5}$ is oxidized to CO_2 and water; and this furnishes the potential energy of the process. During strenuous muscular exercise the oxygen supply becomes insufficient for the complete oxidation of the lactic acid. This accumulates in the muscle and so is mainly responsible for fatigue. A part of the acid may also diffuse out of the muscle, into the plasma, and temporarily diminish the potential alkali.

Immersion of excised muscle in acid solutions, or perfusion, does not produce normal contraction; but if the concentration is excessive, it results in fatigue or paralysis (Ranke, 1865; Burridge, 1910) and rigor (Verzar, Bogel and S'zanyi, 1922). Alkalinity beyond the physiological limit ($\text{pH}=9$) increases the excitability of the myoneural junction, in frogs (M. H. Grant, 1920).

Sensory Irritation.—Acids produce prompt stimulation of sensory nerves. They are often used to test reflex excitability, as for instance in Turck's method. With earthworms, the retraction time is influenced not only by the H-ion concentration but also by the power of the acid to penetrate cells (Crozier, 1918).

Lymph-flow.—Yanagawa, 1916, found the thoracic lymph-flow unaffected by the intravenous injection of acids, to the point of toxicity. Alkalies acted only like neutral salts.

Ureter Flow.—In excised kidneys of rabbits, perfused with sodium chloride solutions, the ureter flow varies inversely to the H-ion concentration (Isaacs, 1917). In life, however, the conditions are much more complex.

Penetration.—Living tissues resist the entrance of all acids, except salicylic. Dead cells are permeable to all (Harvey, 1914).

Acid Edema.—Dilute acids increase the swelling of fibrin. M. Fischer has proposed this as an explanation of edema, but the deductions are not convincing (see Index, Colloids and Edema).

Metabolism.—Acid intoxication lowers gas metabolism and heat production (Chostek, 1893).

The administration of non-toxic doses of acids and bases (to dogs) does not materially alter the balance of N, Ca, Mg or P (Givens and Mendel, 1917).

The effects of *lesser changes in the reaction of body tissues* must be rather limited, since these are so promptly brought back to normal. While it can not be doubted that such changes must have an influence upon metabolism, the nature of this can not be stated, because it is complicated by the actions of these substances on the alimentary canal. The latter is different in the case of acids and alkalies. Some of the other actions also require separate consideration. *Organic acids* and their salts are rapidly burned to carbonate after their absorption; so that they act as acids only in the alimentary canal, but the salts act as alkalies after they are absorbed and oxidized (Buchheim, 1888).

Disintoxication of Acids by Salts.—Neutral salts diminish the toxicity of acids for the fish *Fundulus*. CaCl_2 is considerably more efficient (J. Loeb and Wasteneys, 1911). The effects of electrolytes on the penetration of acid into *Fundulus* ova are discussed by J. Loeb, 1915.

Effects of Increased Alkalinity.—Slight increase stimulates many physiologic processes; a few are depressed.

The injection of *lethal doses* of alkali produces tremors, rigidity; finally vomiting, convulsions, relaxation of sphincters; sometimes edema and ascites (Rowntree, 1916).

An excessive intravenous injection of bicarbonate, in a human subject, was followed by tetany, with recovery (Harrop, 1919).

Virchow, 1854, showed increased motion of *spermatozoa*; Gaule, 1878, increased *cardiac activity*; Bethe, 1909, diminished rhythmic movements of medusæ. Packard, 1906, found that sodium bicarbonate increases the resistance of fundulus to lack of oxygen.

Occurrence of Clinical Acidosis.—Acidosis is not a primary disease or a clinical entity. Accumulation of acid, or rather, diminution of the bases of the body, may occur in many pathologic conditions, *i.e.*, whenever the elimination of acid fails to keep step with its production. This may happen through faulty absorption or unusual loss of alkali; or diminished excretion of acid, as in some nephrites; or by increased production of acid, especially in disturbances of metabolism associated with deficient oxidation. The most striking examples of this form occur in diabetes; but minor degrees are present in fasting, especially with low carbohydrate and high fat income; in poisoning by P, As and other metals; in narcosis, etc. Except in diabetes and uremic coma, the acid does not usually rise sufficiently high to produce symptoms other than dyspnea.

Pathologic Conditions Associated with Acidosis.—Among the most important are (Rowntree, 1916; Frothingham, 1916): Diabetes, starvation or other conditions in which the combustion of fats is disproportionate to that of carbohydrates; fevers, pregnancy, eclampsia, nephritis, renal insufficiency, cardiorenal and cardiac diseases; post-operative and post-anesthetic conditions, especially shock; decerebration operations of animals (Macleod, 1918); cholera and other severe diarrheas.

Minor or occasional acidosis has been described in cardiac dyspnea; in cachexia, anemia, cancer, Addison's disease, hepatic cirrhosis, etc. In normal pregnancy there is only a negligible and compensated acidosis.

Acidosis is ordinarily absent in Graves' disease; epilepsy, lung abscess, syphilis; subacute nephritis; chronic cardiac lesions.

Chemical Criteria of Acidosis.—The hydrogen-ion concentration of the blood has only a limited value, since it is not materially altered until the bicarbonate concentration of the blood has fallen greatly, *i.e.*, only in the most severe cases. The determination of minor degrees of acidosis depends on the direct or indirect estimation of the bicarbonate of the blood; or of the elimination of ammonium or acetone substances by the urine. The urine furnishes only qualitative data at best, since it can indicate only the excretion, and not the retention of acid. In nephritic acidosis it would be entirely deceptive (Peabody, 1915; Van Slyke, 1916).

Indeed, the different acidosis tests often do not go parallel in different diseases (Frothingham, 1916). For instance, acetone substances are prominent in diabetes, in starvation conditions, and especially in children; they are generally absent in the acidosis of nephritis, of cholera, and of diarrheas. The ammonia excretion varies as do the acetone substances.

Most Useful Tests of Acidosis.—These are the determination of:

1. The Reserve Alkali of the Blood by the estimation of (a) its CO₂ content (Van Slyke), or (b) the Marriott factor; or (c) the alkali tolerance test (Sellards).
2. The alveolar CO₂ (Plesch-Levy).
3. The H-ion concentration of the blood (Frothingham, 1916; Howland, 1916).

Estimation of the Bicarbonate Content of the Blood.—This furnishes a quantitative index of the potential alkali store, and its diminution is therefore the earliest sign of acidosis and the most accurate gauge of its severity and progress. The bicarbonate can be determined directly by measuring the CO₂ liberated by acidulation of the plasma. Normally, this is 55 to 75 per cent. volume.

It is not easily altered beyond these limits. If it is reduced fixed acids must be present, constituting acidosis in the sense of Van Slyke. A level of 30 volume per cent. of CO₂ indicates dangerous acidosis, 20 per cent. is fatal.

Hydrogen-ion ÷ Bicarbonate Equilibrium.—Hydrogen ion concentration and bicarbonate are normally practically constant. Either may, however, be changed independently of the other, giving the following conditions (adapted from Henderson and Haggard, 1919):

Bicarbonate low, *cH* (hydrogen ion concentration) normal: This is acidosis through the production of fixed acids, compensated by increased elimination of CO₂ through the normal response of the respiratory center.

Bicarbonate low, cH high: Uncompensated acidosis by production of fixed acids (ordinary uncompensated acidosis with exhaustion of reserve alkali).

Bicarbonate normal or high, cH high: Inefficient response of the respiratory center to CO_2 , leading to accumulation of CO_2 (for instance in morphine poisoning).

Bicarbonate high, cH low: Excess of alkali reserve or "alkalosis" (alkali injection).

Determination of "Buffer Value" of Blood.—R. L. Levy and Rowntree, 1916, express this in c.c. of $\frac{\text{N}}{50}$ HCl or NaOH that can be added to blood without changing

its pH ("simple buffer value"), or without changing it beyond the normal ("reserve buffer value"). The simple buffer value is clinically the more important. The sum of the acid and alkali values give the "total buffer value." The simple buffer value averages 0.18 for normal blood; serum averages 0.11 for acids, 0.05 to 0.3 for alkalies.

Determination of Alkali Reserve of Plasma.—This is stated by Marriott, 1916, as $\text{R}_\text{p}\text{H}$, i.e. the H-ion concentration after removal of the CO_2 (by aeration). It appears to be a very delicate index of acidosis.

The normal value of $\text{R}_\text{p}\text{H}$, viz. 8.5, corresponds to an alveolar CO_2 tension of 38 to 45 mm. Moderate acidosis ranges between 8.0 and 8.3 (28 to 35 mm. CO_2); dangerous acidosis = 7.7 (20 mm. CO_2); coma = 7.3 (11 mm. CO_2). An $\text{R}_\text{p}\text{H}$ 7.9 can be controlled by the oral administration of alkali; $\text{R}_\text{p}\text{H}$ 7.7 requires alkali intravenously.

Alkali Administration on Alkali Reserve.—With normal man, the oral administration of sodium bicarbonate, 20 Gm. every 2 hours for 8 doses, increases the reserve alkali of the plasma by 74 per cent. The effect was well marked within 40 minutes after each dose, and was still fairly marked 10 hours after the last dose (Gettler and Lindeman, 1917).

Alveolar Carbon Dioxide.—Indirectly, the carbonate content of the blood may be judged by the alveolar CO_2 tension, and by the "alkali-tolerance test." The volume percentage of CO_2 in the alveolar air is generally about one-tenth of that which can be liberated from the plasma. This relation holds for normal individuals and for diabetic coma, where it has been utilized by Beddard, Pembrey and Spriggs, 1915; and Poulton, 1915. It does not apply, however, to conditions in which the respiration or circulation are seriously disturbed (Van Slyke); as in pulmonary insufficiency and cardiac dyspnea (Peters, 1917). It is also not very delicate in nephritic acidosis (Peabody).

Alkali Tolerance Test.—When the bicarbonate of the blood is lowered, a larger dosage of alkali is required to change the reaction of the urine to alkaline than is the case normally. This increased tolerance for alkali is a delicate and reliable index of decreased potential alkalinity of the body, and therefore of even slight degrees of acidosis, including renal acidosis; and an equally reliable criterion of the progress of the acidosis and of the need of alkali therapy (Sellards, 1912; Palmer and Henderson, 1913; Peabody, 1915; Frothingham, 1916). However, it is useless or misleading if there is marked renal insufficiency.

The test is carried out by giving orally, between meals, 5 Gm. of sodium bicarbonate (in water) every two hours, until the urine becomes alkaline to litmus. Normally, this occurs with the first or second or at most with the third dose (the pH of the urine being reduced to an average of 7.6, sometimes to 8.3, within an hour, Palmer and Henderson).

Renal Acidosis.—Light grades of chronic nephritis, with normal phenol-s-phthalein output, usually show little or no acidosis. In severer grades, the kidneys fail to excrete acid properly, and thus an acidosis (diminished potential alkalinity) develops, which is fairly proportional to the degree of phenolsphthalein retention.

The alkali-retention test shows this much earlier than the alveolar CO_2 ; the latter generally diminishing only when the phthalein output falls below 10 per cent. in two hours. The actual reaction of the blood is not materially altered except in the extreme stage; so that even in uremia, the symptoms are not commonly attributable to acidosis (Peabody, 1915). The acidosis of infancy is frequently connected with diminished output of urine (Howland and Marriott, 1915).

M. Fischer, 1915, refers to acidosis both the edema and the Cl retention. His theories have been discussed in another place.

The toxicity of uranium is associated with acidosis, and can be diminished by administering alkali. This also protects the uranium kidneys against anesthetics (MacNider, 1916).

Phosphates and Acidosis.—Nephritis is often accompanied by phosphate retention, and this diminishes the acid excretion of the kidneys. This would not be relieved efficiently by alkali administration. Calcium salts may be useful by eliminating phosphates through the intestines (Marriott and Howland, 1916).

Low Blood Pressure.—Reduction of the blood pressure below a certain critical level, exhausts the alkali reserve, presumably by deficient oxidation, and thus produces acidosis. This occurs especially when the blood corpuscles have been diminished by hemorrhage. If the pressure is restored, for instance by the injection of gum-saline, the acidosis is diminished.

In man, the plasma-bicarbonate CO_2 does not begin to fall below the normal (50 c.c. per 100 c.c.) until the systolic blood pressure is below 80 mm. At 70 to 80 mm., the CO_2 averages 43 c.c.; at 60 to 70 mm., 35 c.c.; below 60 mm., it falls to 27 c.c. (Cannon, 1919).

Cannon attributes the acidosis of low blood pressure to deficient blood flow (Gesell, 1919) and consequent tissue asphyxia, resulting in production of fixed acid (Araki, 1891).

Anesthetics during the Acidosis of Low Blood-pressure.—Animals in this condition are hypersensitive to chloroform, ether and asphyxiant concentration of nitrous oxide. Nitrous oxide with plenty of oxygen is said to be safe.

Rebreathing in Shock.—This was advocated by W. T. Porter to increase the aspiratory action of the thorax; and by Y. Henderson, to prevent acidosis and increase the alkaline reserve. Neither the theories nor the published data are convincing.

Acid-base Regulation During Anesthesia.—Surgical anesthesia tends to diminish the alkali reserve; probably mainly by the partial asphyxia. Reimann, 1919, found compensated acidosis in 30 to 85 per cent. of routine operative anesthesia; and 15 to 20 per cent. of uncompensated acidosis.

Asiatic Cholera.—This disease results in a considerable loss of reserve alkali, with the production of acidosis. It is benefited by the early administration of sodium bicarbonate, 0.5 Gm., increasing the dose with the severity of the symptoms (Sellards, 1914).

According to Brouardel ("Les Asphyxies," p. 11) alkaline saline intravenous infusions were successfully used in algid cholera by Lorain, 1866).

Diabetic Coma.—Diabetic coma is essentially a manifestation of acidosis (Stadelmann, 1883). There is not only a close resemblance in the symptoms; but the increased elimination of beta-oxybutyric acid discovered by Stadelmann (1883), and of ammonium (Boussignault, 1850), and the great diminution of carbonates in the blood (to 10 per cent.; Minkowski, 1888; Kraus, 1889) furnish direct evidence of increased acid production. Accordingly, the administration or injection of alkalies has proved fairly successful in preventing and meeting this condition (Magnus-Levy, 1899). It usually relieves the dyspnea, produces diuresis, and often more or less mental improvement.

The success is not so striking as in experimental acid-intoxication; mainly because the acid, in diabetic acidosis, is primarily within the cells, and therefore is not so readily reached by the alkali. The details of this treatment will be discussed under Sodium Bicarbonate.

The alkali could also be furnished by the administration of the salts of organic acids (Folin, 1906; Lichtwitz, 1911), or by Ca or Mg; but probably not in sufficient quantity. Eppinger, 1906, suggested increasing the formation of ammonia by the administration of amino-acids; but his results have been challenged by Pohl and Muenzer, and by A. Loewy, 1906.

Ehrmann, Esser and Loewy, 1911, claim that the injection of neutral oxybutyric salts also produces coma, so that the diabetic coma would not be a pure acidosis.

Acetone Type of Acidosis.—The acidosis of starvation conditions, notably diabetes, fever, especially in children (Howland and Marriott), severe dysentery and some hepatic derangements (phosphorus poisoning) are associated with the appearance in the blood and urine of beta-hydroxybutyric acid, aceto-acetic acid and acetone (the so-called acetone substances, ketone substances or acidosis substances). These do not occur in some other acidoses; for instance, they are absent in nephritis, in the summer diarrhea of infants (Howland, 1916), etc.

They are essentially due to the abnormal metabolism of fats; *i.e.*, they arise whenever the combustion of fats is out of proportion to the combustion of glucose.

The appearance of acetone-substances in the urine signifies the production of abnormal acids; but is not a quantitative index; for considerable quantities of oxybutyric acid may be present in the blood when the urine shows only traces of acetone substances (Frothingham, 1916; R. Fitz, 1917). On the other hand, acetone substances may be excreted in the urine when the alkali reserve has not yet been noticeably depleted; *i.e.*, when there is no acidosis.

Their appearance is generally associated with increased ammonium excretion.

Toxicity of Acetone Substances.—Hurtley and Trevans, 1916, find that the neutral salts of aceto-acetic acid produce respiratory changes.

Source of Acetone Substances.—These arise in the catabolism of fat; but may also be formed from leucine and tyrosine, and therefore from protein; but not from carbohydrates. (The agents that may give rise to the ketone substances are called *ketogenetic*; those that tend to prevent it are *antiketogenetic*.)

Origin from Fat.—The acetone substances are formed in the course of the combustion of the fatty acids with an even number of carbons (the combustion of the odd-carbon acids results in glucose; A. I. Ringer, 1913).

Marriott, 1914, believes that oxybutyric acid is normally formed by the successive steps of fatty acid—butyric acid(?)—aceto-acetic acid $\begin{cases} \text{D. oxybutyric acid (readily burned)} \\ \text{L. oxybutyric acid (difficultly burned)} \end{cases}$. It may also be derived from the amino-acids (leucine and tyrosine) of protein burned).

but not from carbohydrates. Normally, the oxybutyric acid is completely burned. This seems to require the simultaneous combustion of a certain quantity of glucose (at least one molecule of glucose to three molecules of the higher fatty acids). It is conditioned on the aldehyde group of the glucose, analogous to glycuronic acid formation. Ringer, 1914, assumes the formation of a glucosidal compound, which facilitates oxidation.

When the ratio of the glucose is insufficient, the oxybutyric acid is not completely burned; a part is excreted unchanged, and a part as aceto-acetic acid and acetone (G. Lusk, 1909).

Quantity of Oxybutyric Acid in Blood and Tissues.—Since this acid is an intermediary product of normal metabolism, traces are normally present in the blood and tissues, especially in the liver; but much less than in acidosis. For instance, in normal subjects, 100 c.c. of blood contains less than 1.5 mg. of aceto-acetic acid, and less than 4 mg. of oxybutyric acid. In acidosis, the proportion may rise to 28 mg. of acetone and 45 mg. of oxybutyric acid (Marriott, 1914). The quantity in the liver and other organs also is greatly increased in phlorhizin acidosis, and especially in diabetic coma (Sassa, 1914).

Conditions Leading to Oxybutyric Acidosis.—These arise whenever the rate of carbohydrate metabolism is inadequate, relative to the fat catabolism. The most important are starvation; diabetes; and hepatic anomalies (Woodyatt, 1916).

Fasting.—This may result in acidosis, or not; according to whether the subject has fat to burn or must live on his protein. In very severe diabetes, increased protein intake may increase the acidosis (through the amino-acids); but in phlorhizin acidosis, when the organism can still burn sugar, the feeding of protein diminishes the acidosis (Benedict and Osterberg, 1914).

Diabetic Acidosis.—This corresponds exactly to the starvation acidosis; the impaired utilization of sugar furnishing the condition for the faulty fat metabolism.

Hepatic Anomalies.—The acidosis substances are mainly regulated by the liver. It is therefore natural that hepatic derangements should give rise to acidosis. Mottram,

1915, indeed, refers all acetone-conditions to enforced over-activity of the liver, since he finds them constantly associated with fatty infiltration of the liver cells.

Lactic Acidosis.—Lactic acid appears in the blood after violent exercise, strychnine spasms, and phosphorus poisoning. It has also been found in the urine after cocaine convulsions (Underhill). The lactic acid is derived from glucose, for it does not occur in glycogen-free animals (Lusk, 1916).

Lactic Acid Excretion in Alkalosis.—Macleod, 1918, finds that the injection or administration of alkalis increases the elimination of lactate, sufficient to neutralize about $\frac{1}{2}$ of the excess of alkali.

Creatine Elimination.—This appears to be connected with acidosis. In rabbits, Underhill, 1916, finds that acid-producing foods (oats and corn) cause the appearance of creatine in the urine, and this is removed by base-producing foods (carrots).

Creatine Excretion in Starvation.—This also appears to depend largely on the acidosis. It may be abolished by alkali administration in the early stages of starvation; much more difficultly later. However, carbohydrate deficiency may cause creatinuria even in the absence of acidosis (Underhill, 1916).

DILUTE HYDROCHLORIC AND OTHER ACIDS

General Statement.—These are used mainly for their local action on digestion in gastric hypoacidity, etc. The sparingly soluble acid salts (acid potassium tartrate) extend their action into the intestines, and produce catharsis. After absorption, the mineral acids and their acid salts increase the acidity of the urine, and are employed, usually with methenamine, against ammoniacal fermentation of the urine. They are further used as antidote to alkali poisoning; as local astringents against excessive perspiration; and as local hemostatics.

Action on Digestion.—The reaction of the gastric and intestinal contents modifies the activity of the motor and secretory functions, and of the digestive ferments. These effects may give rise to digestive disturbances, or be utilized for the correction of digestive disorders. The results depend on the condition of the alimentary canal, and therefore on the time of administration, as well as on the dose and concentration of the acid.

Action in the Mouth.—Acids have a characteristic "*sour*" taste, and are slightly astringent in the mouth. This taste determines their use as flavors. They soften the enamel of the *teeth*, and should therefore be taken through a glass tube. They also reflexly increase the flow of *saliva*, but this is of little practical importance.

Use in Fevers.—The addition of acid makes it easier to take larger quantities of cold water than could conveniently be taken without. They are therefore of therapeutic value in *fevers*, when one wishes to obtain at the same time the refrigerant action of cold and the diuretic effect of large quantities of fluid. It was believed that the alkalinity of the tissues is raised in febrile conditions, and that this is counteracted by acids. The modern ideas render this doubtful.

Action in the Stomach.—The presence of acid is important for the digestion of proteins and connective tissue; for the control of the pyloric sphincter; and for its antiseptic properties.

Gastric Acidity.—Pure human gastric juice, pathologic as well as normal, is secreted with about 0.4 to 0.5 per cent. of free HCl (Koeder, 1905; Rehfuess and Hawk, 1914; Carlson, 1915) the same as in dogs or cats. This corresponds to $pH = 0.95$ to 1 (Menten, 1915).

The acidity, however, is not normally maintained in the stomach, the acid being rapidly neutralized by the saliva, the mucus and the reflux of duodenal contents, to 0.15 or 0.2 per cent. HCl (Boldyreff). The breaking down of this mechanism appears to be the basis of "hyperacidity," in which the acid remains at the same concentration

(0.5 per cent. HCl) at which it was secreted (Carlson, 1915). The curve of the acidity during normal digestion has been studied in man by McClendon, 1915. He also determined the hydrogen-ion concentration of human *duodenal contents*, viz., $H^{(+)} = 2 \times 10^{-8}$.

Liberation of HCl.—The mechanism by which HCl is liberated is not fully established. Koeppe, 1896, supposed that it is formed in the stomach from NaCl: assuming that the epithelium is permeable to Na and not to Cl ions, the sodium would diffuse out of the stomach, and H ions would diffuse into it. The theory requires further proof. Bechhold assumes a selective colloidal adsorption of the anions as the probable explanation of the acidity. Hammett, 1915, confirms Fitzgerald that the acid exists in the bodies and canaliculi of the parietal cells.

Pyloric Control.—Free acid in the stomach increases the pyloric peristalsis; it closes the cardiac and opens the pyloric sphincter. However, the presence of free acid in the duodenum closes the pyloric sphincter until the acid is neutralized by the intestinal juices. Moderate gastric acidity therefore hastens the discharge of food from the stomach, but excessive acidity prolongs the sojourn because it can not be promptly neutralized in the duodenum (Cannon, 1911). Peristaltic waves, cyclic tone changes, and nervous reflexes also play important parts in the pyloric control (Carlson; Whelan and Thomas, 1921).

The controlling influence of acids on the emptying of the stomach appears to be exerted mainly from the duodenal side: clinically, the time of discharge is often normal in achylia; and gastric stasis often exists in hyperchlorhydria. In fasting anesthetized dogs, water is discharged from the stomach more promptly than with any degree of acidity; acids causing a delay, proportional to their concentration. *Duodenal regurgitation* begins with 0.2 per cent. HCl (W. E. Morse, 1916).

Foods also act on the acid regulation of the pylorus: proteins by binding the acid, prolong the sojourn; so do fats, by binding the duodenal alkali. Carbohydrates are indifferent.

Relation of Gastric Pain to Acidity.—The pain of gastric ulcer has been attributed to direct irritation by the free acid. However, it appears to be indirect, due sometimes to the increase of gastric peristalsis and tone, and pyloric spasm; or more often to hyperesthesia to these motor activities.

In human subjects with normal stomachs, Lowenthal, 1892, found no sensation from 250 c.c. of 0.3 per cent. HCl. With 0.5 per cent. there was sometimes a warm sensation, but no pain. Other observers report absence of any sensation with 0.5 per cent. J. E. Schmidt, 1909, found no symptoms with 0.5 to 2 per cent. With 5 per cent., Boring reports a sensation similar to hunger-pains.

The results on patients with gastric ulcer are more variable. Pain was sometimes, but not always present, after 0.1 to 0.4 per cent. HCl. Ginsberg et al., 1916, find that the pain is always accompanied by strong contractions, indicating that it is due to tension. This was relaxed by alkalies or amyl nitrite; strengthened by pituitary.

L. L. Hardt, 1918, found that ulcer pains occurred in the absence of free acid, and may sometimes even be relieved by 0.3 per cent. HCl.

Gastric Tetany.—In gastric obstruction, the gastric juice which cannot pass into the duodenum is vomited. This results in a material loss of acid (Bennet and Dodds, 1921) and tends to shift the equilibrium so far toward the alkaline side as to produce fatal tetany (McCann, 1918; MacCallum et al., 1920; Hastings, Murray and Murray, 1921).

Digestive Action.—*Pepsin* acts only in the presence of free acid. While any acid may answer for this purpose, hydrochloric seems to be the best, and is most efficient in the concentration existing in the gastric secretion; it also aids in the *solution of the connective tissue* of meats; and it determines the *antiseptic* qualities of gastric juice.

The ingestion of dilute acid also increases the secretion of gastric juice. This effect is partly reflex, for it is observed in Pawlow's separated stomach (Bickel, 1905) but only when it is given with food (Heinsheimer, 1906).

Salivary Digestion in the Stomach.—Very slight acidity accelerates the action of all diastases, but somewhat stronger concentrations depress. However, the bulk of the food remains for an hour or more in the cardiac pouch, with only the surface layer impregnated by acid (Heyde and Gruetzner). Salivary digestion proceeds practically undisturbed during this time (Cannon, 1911).

Digestive Leucocytosis.—This may be produced by the introduction of dilute HCl into the empty stomach, and therefore need not involve the digestion of proteins (Cathcart, 1923).

Pancreatic Juice.—The flow is increased by acids. This action is perhaps partly reflex, but it has been shown (Bayliss and Starling, 1902) that the presence of acid in the jejunum leads to the production of a chemic substance, "secretin," the intravenous injection of which stimulates the pancreas to increased secretion.

Bile.—The secretion of bile, and the contraction of the gall-bladder are increased by the introduction of acid into the duodenum (Okada, 1915). (Kless and Kneupfel, 1914, claimed that the evacuation of the gall-bladder is not hastened by injection of acid or soap into the duodenum.)

Use in Indigestion.—Acids are administered in dyspepsias in which the secretion of acid is deficient; in the achylia of pernicious anemia; in putrefactive fermentation; and in infantile diarrheas due to this cause. All mineral acids act alike. Dilute Hydrochloric Acid (1 c.c., diluted, just before or after meals) is generally preferred. It is often combined with bitter stomachics.

It has been objected that doses much greater than the ordinary would be required to restore the normal acidity. However, when taken after meals the acid would be confined to the surface of the food-mass and would therefore suffer little dilution.

The increased flow of pancreatic juice and of bile is probably too small to be of any value.

Acids are contraindicated in catarrhal conditions, in which there is a hypersecretion of mucus. Even in normal individuals the prolonged administration of large quantities of acids is apt to prove too irritant, and interferes with digestion. This is the explanation of the popular use of vinegar to reduce *obesity*. A direct limitation of diet would seem a more rational means for this purpose.

Lactic Acid Organisms.—These were introduced with the object of supplying the antiseptic action of acids to the intestines, in infantile diarrheas, etc.; but they have not fulfilled these expectations very satisfactorily. They are discussed in N.N.R.

Combined Acid.—In order to avoid the irritant effects of free acid, loose acid compounds have been administered to liberate their acid gradually; such are Acidol (betaine hydrochloride) and Oxyntin (acid protein). However, they are therapeutically useless. Long and Hull, 1915, showed that the quantity of acid bound by proteins is quite definite and does not depend simply on the H-ions; but it is so small that it barely suffices for the digestion of the combined protein. Betaine hydrochloride is more active, but still below therapeutic efficiency (Long, 1915).

Action on Urine.—The administration of acids increases the acidity of the urine. This leads to *increased irritability of the mucous membranes* of the urinary passages, so that inorganic acids are to be avoided in all

inflammatory conditions of these organs. They must also be avoided where there is a tendency to the formation of uric acid or oxalate *calculi*. On the other hand, they are indicated with phosphatic calculi. They are used especially to enhance the action of methenamine (see Index). It may be repeated that they increase the ammonia of the urine at the expense of the urea.

Acid Irrigation of Phosphatic Renal Calculi.—These dissolve, although very slowly, in 0.06 per cent. HCl. Since this strength would be harmless, Gesinger et al., 1918, suggest its use by continued irrigation, for stone in the renal pelvis or ureter.

Effects upon Metabolism.—Outside of the change in the ratio of ammonia and urea, these are quite small, as far as our present means allow us to judge. The excretion of nitrogen seems to be pretty constantly slightly increased.

Applied directly to *excised organs*—muscle, nerve, etc.—the result is an increase and subsequent diminution of function.

Styptic Action.—The local application of dilute acid is fairly efficient (Hanzlik, 1918).

Organic Acids.—The local actions are along the same lines as those of the inorganic acids, but present important differences in detail. They are little used in digestive disorders. Their systemic actions are quite different, since they are for the most part burned in the body. They are therefore more conveniently discussed in connection with their salts.

PREPARATIONS—DILUTE MINERAL ACIDS

These have a uniform strength of 10 per cent. They are colorless, odorless liquids, of strongly acid taste; miscible with water, alcohol or glycerin. They are *incompatible* with alkalies and the salts of weak acids (carbonates, salicylates, sulphides, sulphites, etc.). *Dose*, 1 c.c., 15 minims U.S.P.; 0.3 to 1.2 c.c., 5 to 20 minims, B.P.; in one-half tumbler of water after meals.

**Acidum Hydrochloricum Dilutum* (Acid. Hydrochl. Dil.) U.S.P., B.P.—*Incompatible* also with salts of Ag and Pb.

Acidum Nitricum Dilutum (Acid. Nit. Dil.), B.P.

(*Acid. Nitrohydrochl. Dil.*—See Index.)

Acidum Phosphoricum (Acid. Phos.), U.S.P.; *Acid Phosph. Conc.*, B.P.—87 per cent. of H_3PO_4 , U.S.P.; 66 per cent. B.P. Colorless, odorless, syrupy liquid.

Acid. Phos. Dil., U.S.P.; *Acid. Phosph. Dil.*, B.P.

Acid. Sulph. Dil., U.S.P., B.P.

Acidum Sulphuricum Aromaticum (Acid. Sulph. Arom.), U.S.P., B.P.—An alcoholic dilution of sulphuric acid, flavored with ginger and cinnamon. Contains free sulphuric acid and ethylsulphuric acid equivalent to about 20 per cent. of H_2SO_4 , U.S.P.; about 14 per cent., B.P. A clear, reddish-brown liquid; pleasant aromatic odor; intensely acid. *Dose*, 0.5 c.c., 8 minims, U.S.P.; 0.3 to 1.2 c.c., 5 to 20 minims, B.P., diluted.

It is doubtful whether it possesses any advantage over other acids. Ethyl-sulphuric acids acts simply as a mineral acid (Uyedo, 1910).

Inf. Ros. Acid., B.P.—1.25 per cent. Acid. Sulph. Dil., 2.5 per cent. dried rose petals. *Dose*, 15 to 30 c.c., $\frac{1}{2}$ to 1 ounce, B.P.

SODIUM BICARBONATE AND OTHER MILD ALKALIES

General Statement.—Sodium and potassium bicarbonates are used as liquefying expectorants, and to dissolve mucus in other catarrhal conditions. Sodium bicarbonate is particularly useful for neutralizing hyper-

acidity in digestive disturbances. Magnesium oxide, or magnesium or calcium carbonate, act more persistently, but less promptly and efficiently. Excessive doses of alkalis disturb digestion and produce diarrhea.

The systemic effects are utilized for combating acidosis. Smaller doses, especially in the form of potassium bicarbonate or citrate, are used in rheumatism and gout. Their action, if they have any, is not understood.

The administration of alkalis increases the flow of urine and reduces its acidity or renders it alkaline. This is useful for decreasing the irritation in cystitis, and to prevent the formation of urate calculi.

Sodium carbonate is too irritant for internal use.

Effect on Mucus.—Mucin is more soluble in alkaline media, so that the alkalis dissolve accumulations of mucus or render them more fluid. At the same time they increase mucus secretion through a mild irritation.

Use in Catarrhs.—Mild alkalis, especially bicarbonate and borate, are useful as washes or gargles (1 to 4 per cent.) in all kinds of catarrhal conditions; as expectorants; in cystitis, dysentery, etc.

Removal of False Membranes.—The false membranes of diphtheria, croup, etc., are also composed largely of mucus, and may be broken down by alkalis. These may be applied by inhaling the vapors produced by slaking lime in the sick-room.

Use on the Skin.—Alkalis are also employed to soften the crusts in eczema; as a soothing lotion in dermatitis and burns; to relieve itching, etc.

Action on Normal Digestion.—Strong alkalis, including sodium carbonate, produce local irritation and gastritis. The weaker alkalis, such as the bicarbonates, would also tend to interfere with normal digestion. They tend to inhibit the secretion of digestive juices; the activity of pepsin; the gastric peristalsis and the opening of the pyloric sphincter (Cannon 1911); the protective action of the mucus and the antiseptic action of the gastric acid. They might be conceived to aid the digestion of fats; but the intestines are normally sufficiently alkaline.

In fact, however, these detrimental actions are very slight, and the utilization of the food is practically perfect (unless excessive doses are taken), because moderate quantities are rapidly neutralized and absorbed.

Secretion of Gastric Juice.—It was formerly claimed that this is stimulated; but practically all of the later experiments indicate that it is rather diminished both in quantity and acidity (Pawlow, 1897; Bickel, 1905; Heinsheimer, 1906; Rosenblatt, 1907; Wilbrand, 1914; Chiari, 1915).

The subject is not, however, finally settled. It is claimed, for instance, that the administration of alkali during digestion (in man) produces only a temporary decrease of acidity, followed by a rise above the previous level. Pimenow also claimed that the sodium bicarbonate, while it inhibits gastric secretion if given before a meal, increases secretion if administered during the meal. If this is actually the case, it might be due to the liberation of free CO_2 by the acid contents; for Pavlov observed that gastric secretion tends to be increased by the presence of CO_2 in the stomach and inhibited by HCl.

King and Hanford, 1917, found in a dog with a Pavlov stomach, that one per cent. sodium bicarbonate excites some flow of gastric juice, but rather less than distilled water. The total acidity of the "alkali juice" was a little lower than the "water juice." The peptic activity was about the same.

Pancreatic Secretion.—This is diminished by the oral administration of bicarbonate (Wilbrand, 1914).

Ferments.—Diastases are hindered by free alkali, being very sensitive. Pepsin is also inhibited or destroyed (Hamburger, 1915; see under Sodium Chloride). Trypsin can act in a weakly alkaline medium.

Uses of Alkalies in Digestive Disturbances.—While alkalies are either indifferent or disturbing to normal digestion, they are very useful to restore the normal conditions in digestive diseases.

Gastric Catarrh and Dilatation.—The alkalies dissolve the excessive mucus which lessens the permeability of the walls of these organs, preventing at once the pouring out of digestive juices and the absorption of the digestive products. This mucus forms a similar impermeable coating about the masses of food. Further, the mere presence of a large amount of indigestible material—and tenacious mucus must be regarded as such—is in itself irritating. Lavage with 1 per cent. bicarbonate is the most efficient treatment of these conditions; but the alkali may also be given with an emetic or cathartic.

Intestinal Catarrh and Catarrhal Jaundice.—The alkalies are similarly useful. (They do not increase the secretion of bile; Rutherford, 1879.) In intestinal affections, the slowly soluble alkalies, magnesium oxide or magnesium or calcium carbonate, may be preferred, so that they will not be neutralized before reaching the intestines. A saline cathartic enhances their usefulness. This combination exists in several mineral waters (*e.g.*, Carlsbad). For infants, lime-water is generally preferred to the other alkalies.

Gastric Ulcer.—Alkalies are useful by diminishing the quantity and acidity, and therefore the irritation, of the gastric juice. They also permit the destruction of the pepsin through sodium chloride. Bismuth subcarbonate is preferable, because its action is more prolonged, and because it adds a mechanical protection.

An efficient routine for continuous alkali treatment for gastric ulcer is described by Sippy, 1915: Soft food is given every hour. Midway between the feedings, the patient receives an alkali, alternating between (1) magnesia and sodium bicarbonate, each 0.65 Gm., 10 grs., and (2) bismuth subcarbonate, 0.65 Gm., 10 grs., with sodium bicarbonate, 2 Gm., 30 grs. The progress is controlled by the reaction of the stomach contents, which should not be allowed to become acid.

Gastric Hyperacidity; Functional Dyspepsias, Heart-burn; Gastric Flatulence, Etc.—In these conditions, the soluble alkalies (sodium bicarbonate or aromatic ammonia) are commonly used and effective. They neutralize the excessive acid, relax the spasmodic pylorus (Enriquez, Binet and Gaston Durand, 1914), and thus empty the stomach and lessen the pain and irritation. The CO_2 which is liberated stimulates the gastric movements (Schierbeck, 1891), and promotes the expulsion of the gas. It acts perhaps also as a mild local anesthetic. The bicarbonate is usefully combined with an aromatic carminative (peppermint) and cathartic (rhubarb).

Time of Administration.—This has given rise to much theoretical and unproductive discussion. The alkalies should evidently be given when the digestive conditions call for them. This is better recognized by the symptoms than by rules. The soluble alkalies (bicarbonate, 1 Gm.; aromatic ammonia, 2 c.c.; for infants, lime-water) should be administered whenever they are indicated by gastric distress, and repeated as often as needed; also at bedtime and on arising. For intestinal effect, they should be given on an empty stomach.

Obesity.—Alkalies are sometimes used. Their effects are probably due to disturbance of digestion.

Use in Arterial Hypertension.—Full doses of alkalies temporarily lower the arterial pressure, probably as a result of the nausea. The benefit is doubtful. Scheffer, 1908, advocated sodium silicate, but bicarbonate accomplishes the same result.

Alkalosis and Scurvy.—Hess and Unger, 1919, describe the occurrence of minor scurvy on alkalized milk, in guinea pigs; and also in infants fed on malt soup formulas which contain potassium carbonate. The condition yields promptly when antiscorbutics are added.

Use of Alkalies in Acidosis.—Their rationale has been discussed. The alkali must be administered in large quantity. This can best be accomplished by sodium bicarbonate. It has the advantage over the carbonate, and especially the hydroxide, in that its actual alkalinity (OH^- ions), and therefore its local action and toxicity are much lower; while its potential alkalinity, and therefore its neutralizing power is not very much inferior.

In view of the lower toxicity, considerable larger amounts of alkali can be introduced as bicarbonate.

The carbonate can take up more carbonic acid than bicarbonate, but this advantage is illusory; for the ratio of carbon dioxide and carbonate is immediately adjusted in the lungs to the normal equilibrium (Sellards).

Neutralizing Power of Alkalies.—To neutralize 100 parts of 10 per cent. HCl requires the following quantities of the official sodium salts: acetate¹ = 37.3; citrate¹ = 32.6; bicarbonate = 23.3; carbonate = 15.3; calcium carbonate = 13.8; sodium hydroxide = 12.2; magnesium oxide = 5.5.

To neutralize a given quantity of acid therefore requires about 52 per cent. more of NaHCO_3 than of Na_2CO_3 (absolute). On the other hand, a given quantity of NaHCO_3 gives about 27 per cent. more of CO_2 than the same quantity of Na_2CO_3 ; or, in other words, it requires about 27 per cent. more of Na_2CO_3 to obtain a given quantity of CO_2 , than would be required of NaHCO_3 .

Administration and Dosage in Acidosis.—The use of the bicarbonate should not be delayed until coma has set in, for it may then be too late. It should be begun as soon as the acidosis is recognized. The initial daily dose by mouth may be 30 to 45 Gm., 1 to $1\frac{1}{2}$ ounces, in divided doses and freely diluted, best between meals. This may be raised to 100 Gm. or more.

It should be continued at least until the pH of the plasma is normal; and if possible, until the reserve-alkalinity of the plasma has been restored.

These large doses generally produce a cathartic effect. This purging may not be entirely useless. At all events, plain purges have been found useful in such cases, and so has pilocarpine, originally used on the theory that it helps the elimination of the "toxins."

After coma has set in, the oral administration may be continued, and "drop enemas" of a 4 per cent. solution may also be given. However, these can not be relied upon to secure sufficient absorption; and sterilized bicarbonate solution should be injected slowly by vein.

The heat of sterilization drives off some of the CO_2 , and thus converts part of the bicarbonate into the carbonate. This is highly corrosive to the subcutaneous tissue. The ordinary solutions must therefore never be injected hypodermically, or even allowed to escape into the skin from the intravenous injections; for serious sloughing may result.

Intravenous Dosage of Sodium Bicarbonate.—It may be injected as 5 per cent. solution. As a prophylactic, 3 to 5 gms. may be administered

¹ After combustion.

every 2 to 3 hours until the reaction of the urine changes. In developed acidosis, much more must be given; generally 500 c.c. of the 5 per cent. injected slowly (in half an hour), is a safe maximum (Sellards).

Hypodermic Injection of Pure Bicarbonate Solution.—If the solution is freed from Na_2CO_3 by saturating it with CO_2 until it is colorless to phenolphthalein, it does not cause necrosis and only very slight irritation. Magnus-Levy, 1913, and Czapski, 1914, advocate the hypodermic use of a liter of a 2 per cent. solution of this kind to follow up the intravenous injection; or if the latter presents special difficulties (sometimes the flow becomes arrested).

Alkalies and Acids on Sugar Metabolism.—Aside from the neutralization of acidosis, alkalies are probably further useful in diabetes by promoting the utilization (combustion) of sugar. Acidosis, on the other hand, tends to produce hyperglycemia. There is thus, in diabetes, a vicious circle of hyperglycemia and acidosis, which may be broken by the alkali. However, the experimental data are somewhat contradictory, probably depending on accessory conditions that are not understood.

Alkali on Glucose Metabolism.—Pavy and Godden, 1912, observed that the injection of alkali prevents ether and chloroform acidosis. Elias, 1913, found that feeding alkali removed hunger glycosuria and diminished pancreatic diabetes.

Underhill, 1916, found that alkali also lowers epinephrine glycosuria. In a case of severe human diabetes, large doses of alkali markedly decreased the sugar excretion and raised the carbohydrate tolerance.

Fulk and Macleod also confirmed the tendency of alkalies to diminish the sugar of the blood. This is not due to a change in the glycogen formation, so that the sugar must be more rapidly destroyed. This is reflected by an increased lactic acid content of the blood, lactic acid being a product of glucose combustion (Macleod and Hoover, 1917). The injection of acids conversely diminishes the lactic acid.

The injection of dextrose, in large amounts, in itself increases the hydrogen-ion concentration of the blood (Macleod and Fulk, 1917), perhaps by leading to incomplete combustion of lactic acid. If dextrose was injected with sufficient alkali, the liver removed the sugar more actively from the blood (Macleod, 1917).

On the other hand, Beard, 1918, found no constant influence of sodium bicarbonate administration on the carbohydrate tolerance in diabetes.

In normal rabbits, the blood sugar is not lowered by the injection of sodium bicarbonate (McDanell and Underhill, 1917).

In normal dogs, alkali injection does not increase the respiratory quotient, but tends to inhibit glycogenolysis (Kramer and Marker, 1916), and increases the deposition of injected dextrose in the liver (Macleod, 1916).

Murlin and Kramer, 1916, confirmed that the injection of alkali suppresses the glycosuria of depancreated animals, or at least lowers the $D \div N$ ratio. The respiratory quotient rises, and the blood-sugar and the glycogen are not increased, so that there must be an increased combustion of sugar.

The retained glucose is not deposited as glycogen, nor excreted by the saliva, stomach or intestines (Kramer, Marker and Murlin, 1916). When the pancreas has not been completely removed, there is distinct improvement in sugar combustion. After complete excision, however, the combustion is not improved, and nevertheless the sugar is retained.

Prophylaxis of Anesthetic Acidosis.—W. H. Morriss, 1917, recommends the administration of 15 to 30 gm. of sodium bicarbonate in the 36 hours preceding the anesthesia—sufficient to render the urine alkaline.

MacNider, 1918, confirmed that intravenous injection of sodium carbonate protects naturally nephropathic animals against anesthetic acidosis and renal injury. Intravenous saline does not confer this protection. The injection of glucose prior to anesthesia tends to stabilize the acid-base equilibrium of pregnant animals. This is more effective in early than in late pregnancy, and in younger than in older animals (MacNider, 1926).

Acids on Glycosuria.—Elias, 1913, showed that the injection of acid produces hyperglycemia. However, the acid was too strong ($\frac{1}{4}$ normal HCl) to make the results available for human diabetes. Watanabe, 1917, concluded that acid administration to rabbits does not have any definite effect on the blood sugar. Jensen, 1917, found no effect on the sugar tolerance of a dog that had been highly sensitized by partial excision

of the pancreas; but in another animal, that had been rendered glycosuric by the operation, the administration of acid produced a distinct rise in the sugar excretion.

Intravenous Bicarbonate in Shock.—This often gives better results than plain saline infusion; the rise of blood pressure being more sustained and the respiration deeper (Seelig, Tierney and Rodenbaugh, 1913). The bicarbonate, 0.5 per cent., may be added to the normal saline (Dawson, 1905); or 1.5 to 5 per cent. bicarbonate may be used as such. The 1.5 per cent. is isotonic with blood. These solutions should not be boiled.

Sodium Carbonate on Epinephrine Output.—Intravenous injection of concentrated solution increases the epinephrine output temporarily, presumably by the hypertonic stimulation of the bulbo-spinal centers (G. N. Stewart and Rogoff, 1919).

Alkali Injection in Nephritis.—Energetic alkaline therapy was advocated by M. H. Fisher, who conceives nephritis and edema as acidosis. The clinical results in the hands of others have often been unfavorable and sometimes dangerous (Wyss; Weiland; Newburgh, 1913). Bogert, Underhill and Mendel, 1916, found that the restoration of the blood volume after injection of saline solution was not hastened by the addition of 0.4 per cent. of sodium carbonate, either in normal or in nephritic animals.

Renal injury (spontaneous glomerular nephritis of dogs) renders the acid-base equilibrium unstable, so that it is easily upset by anesthesia, especially by chloroform. This results in more severe nephritis, anuria or failure to respond to diuretics (MacNider, 1918).

Bicarbonate Edema.—Large doses of sodium bicarbonate (about 20 Gm. per day) may lead to the retention of water and eventually to edema, in proportion to the dose (Hayem, 1890). This may occur in diabetic as well as in normal individuals (Widal, 1911; Levison, 1915; Beard and Rowntree, 1917). It is probably analogous to salt edema.

Alkalies and Salicylates.—The administration of sodium bicarbonate with inorganic salicylates tends to prevent the precipitation of the irritant salicylic acid in the stomach. It has been affirmed that it would also prevent the albuminuria and acetone that sometimes follow salicyl administration (Glungen, 1911); but it is ineffective for this purpose (Hanzlik).

Alkalies and Cinchophen. These are often prescribed together, with the view of preventing the precipitation of the increased uric acid in the urine.

Metabolism.—The direct effects of alkalies are not important. Perhaps the only certain action is the increase of urea at the expense of ammonia. The indirect effects of digestive disturbance may be more serious.

It is known that *alkalies favor oxidation*; and it has been found that they lead to an increased oxygen consumption and CO₂ excretion (Lehmann, 1884). This effect is not, however, very large—probably because the alterations in the reaction of the body are never very great. Experiments made to determine the effect on *nitrogen metabolism* have given somewhat variable results, and these were certainly not greater than might be expected from the pure salt action, or from the interference with digestion which would result from large doses. (Doses as large as 13 Gm. sodium carbonate, 20 Gm. of sodium bicarbonate, or 40 Gm. sodium citrate do not influence the total nitrogen excretion.) Macleod and Haskins, 1906, found increased elimination of endogenous *uric acid* and purines. Abl, 1913, attributes this to the intestinal derangement.

The effect upon carbon metabolism is equally small and uncertain.

Increase of alkalinity is said to heighten the *bactericidal power* of the serum and tissues; but further evidence is needed.

Use in Rheumatism, Gout, Etc.—The alkalies, especially potassium bicarbonate, acetate, and citrate, have considerable reputation in acute and chronic rheumatism, gout, etc. It is difficult to estimate their efficiency. There is no good foundation for the assumption that they increase the oxidation of uric acid or its solubility in the tissues. Explanations of their actions are purely speculative.

Actions on Urine.—Alkalies increase the flow and alkalinity of the urine. These effects are utilized especially in catarrhs of the urinary

passages, and to prevent the formation of urate calculi. To secure this alkalinity requires about 7 Gm. of sodium bicarbonate or 15 Gm. of sodium acetate or citrate, per day. The organic salts are preferred, to avoid disturbance of digestion.

Sodium bicarbonate slows the excretion of intravenously injected lactose, and decreases the chloride output (Hertz and Goldberg, 1914).

Use in Vesical and Urethral Catarrh.—Alkaline urine is less irritant to the inflamed mucous membranes, and helps to dissolve the mucus and pus. The dilution of the urine, and the flushing of the urinary passages by the diuresis are similarly useful.

Use against Urate Calculi.—Alkalies and diuretics can not dissolve these calculi; but they prevent the precipitation of uric acid and acid urates, which can occur to a serious extent only in acid urines. The alkalies (potassium or sodium citrate or acetate) must be given in sufficient quantity to keep the urine alkaline to litmus. Care must be taken that this does not lead to the precipitation of phosphates, since these might be deposited on the calculus.

In a few instances, it has been observed that alkalies caused the breaking up of large stones into small fragments. This can not be attributed to solution of the uric acid. Probably the calculi were composed originally of small fragments glued together by fibrin and the alkalies caused the solution of the latter.

The alkalies can exert no effect on the condition of the uric acid in the tissues, since the reaction of these is not altered. This will be discussed further in the next section.

Cystinuria.—Alkali has a solvent action on cystin; its administration in sufficient quantity to keep the urine alkaline prevents the deposition of cystin crystals (Smillie, 1915).

PREPARATIONS—BICARBONATES

**Potassii Bicarbonas* (Pot. Bicarb.), U.S.P., B.P.; KHCO_3 .—Colorless crystals; odorless; saline and slightly alkaline taste; permanent in the air. Freely sol. in water (1:2.8); practically insol. in alc. *Dose*, 1 Gm., 15 gr., U.S.P.; 0.3 to 2 Gm., 5 to 30 gr., B.P.

**Sodii Bicarbonas*, U.S.P., B.P. (*Baking Soda*); NaHCO_3 .—White powder; odorless; cooling, mildly alkaline taste. It is permanent in dry air, but slowly decomposes in moist air. Sol. in water, 1:10 at 15°C., practically without decomposition. When heated, it loses CO_2 , and is converted into normal carbonate. Practically insol. in alc. *Incompatible* with acids and acid salts; and with the salts of most alkaloids, metals and earths; not with magnesium salts in moderately dilute solutions. *Dose*, 1 Gm., 15 gr., U.S.P.; 0.3 to 2 Gm., 5 to 30 gr., B.P.

"*Soda mini*" tablets generally contain 5 gr., with $\frac{1}{8}$ minim oil of peppermint.

URATE SOLVENTS

URIC ACID AND ITS SALTS

Acid urates occur in solution in the blood and tissues; and as the peculiar sodium biurate deposits in gouty tophi, etc. In the urine, acid urates also occur in solution. When the urine is scanty or acid they may be deposited as free uric acid or "quadriurate," *i.e.*, a mixture or compound of free uric acid and acid urate. These deposits may concrete into urinary calculi.

Uric Acid, $C_5H_4N_4O_3$, is a weak dibasic acid, which under proper conditions, can form three series of salts, namely:

Neutral Urates.— $C_5H_3N_4O_3.Na_2$; also named dibasic, normal or secondary urates. These are formed only by strong alkalis, and can not occur under natural conditions, being decomposed by CO_2 and even water. They need not be considered further.

Acid Urates.— $C_5H_3N_4O_3.Na$; also named monobasic or primary urate or biurates. They are neutral to litmus.

Quadriurate.— $C_5H_3N_4O_3.Na + C_2H_4N_4O_3$; also named hemibasic urate or tetraurate. It is a mixture or solution of uric acid and acid urate. The quadriurate forms the sedimentum lateritium in cooling acid urines. On standing, it separates uric acid crystals. Water dissolves out the acid urate, and leaves the uric acid.

There has been much discussion as to the nature of the combination. Kohler, 1911, considers it a simple mixture. Ringer and Schmutzer, 1912, regard it as a "solid solution" of uric acid in acid urate; which can be formed at body temperature, but which is unstable on cooling and thus separates the uric acid.

Other Urate Deposits in Urine.—These may consist of uric acid in acid urines; of acid urates in acid or neutral urines; and ammonium urate in neutral or ammoniacal urine. The acid urate is generally amorphous; but may be crystalline in neutral urine.

Urinary Calculi.—The consolidation of urinary precipitates into calculi involves the cooperation of a "colloidal mortar," presumably fibrin (H. Schade).

Urate Tophi.—These consist always of acid urates (Ritter, 1897); so do the uratic deposits in animals, even when free uric acid is injected (Loghem, 1907).

Actions of Urates.—The importance of these lies in the fact that they may be formed or retained in excessive amounts in pathologic conditions, when they first produce inflammatory necrosis of cells, and are then deposited in insoluble granular form. This, becoming crystalline, acts as a powerful mechanical irritant, producing the phenomena of gout. These can be simulated in animals by the injection of suspensions of acid sodium urate, and in birds by the subcutaneous injection of chromates, or even by ligation of the ureters. The cause of the abnormal appearance of the uratic deposits in gout, etc., is not understood.

Solubility and Precipitation.—Free uric acid is very little soluble. The acid urates also have a limited solubility. They behave therefore as colloids, and as with colloids in general, their solution may be favored or hindered by a variety of conditions, some little understood. It would often be desirable to increase their solubility, *fi.*, to prevent urate deposits in the tissues and urine; if possible, to dissolve these deposits when formed; and perhaps to favor the elimination of the urates in gout, etc. Many attempts in these directions have failed, because they were based on imperfect understanding of the chemical data. Alkalies dissolve a limited amount of free uric acid, by converting it into the more soluble acid urates. This is the only direction in which some success has been found, and this is confined to the urine.

The study of the solubilities is greatly complicated by the small quantities going into solution, the polyvalence, formation of colloidal solutions, supersaturation, the influence of small quantities of impurities, decompositions, etc. (His and Paul, 1900).

Uric Acid.—Pure water dissolves at 18°C. only 25 mg. of uric acid per liter = 1:40,000 (His and Paul). At 40° the solubility is probably doubled. *Alkalies*, even the bicarbonate or phosphate, transform part of the uric acid into acid urate, and therefore increase its solubility. *Free acids* diminish the solubility, since they decrease the ionization; undissociated uric acid being less soluble, (His and Paul). Addition of *free uric acid* to urine may precipitate a part of the uric acid originally in solution (Voit), presumably by acting as a crystallizing nucleus. The solubility in *serum* is much greater (500 mg. per liter) than in water (Bechhold and Ziegler, 1906). This is probably due to the *colloids*; and it is probable that the colloid constituents of the urine also contribute to the solubility of the uric acid and urates (Lichtwitz, 1910). Ruedel, 1892, claimed that *urea* has an important solvent action; but Ritter, 1897, finds this very limited.

Acid Urates.—The solubility of the different urates in water is about as follows (Allan and Bensch, 1889, etc.): Li, 1:350; K, 1:800; Na, 1:1,000; NH_4 , 1:6,000; earths, 1:4,000 to 6,000. Excess of the alkali or other salts decreases the solubility, by "salting out," in proportion to their concentration (Roberts; Ritter). The salts of the plasma,

f.i., reduce the solubility to one-tenth of that in water (His and Paul). Bechhold and Ziegler found the solubility of sodium acid urate in water as 1:665; in serum it was 1:1,925 when formed by the neutralization of added uric acid; but only 1:40,000 when added as sodium urate. The difference illustrates the influence of conditions; the formation of urate in the serum is more favorable to colloidal solution.

Solid sodium acid urate occurs in two forms: when freshly precipitated, it is gelatinous, colloidal or amorphous; later, this becomes crystalline. The colloidal form is more easily soluble (Benschl). Gudzent, 1908 and 1909, claims two forms, the ordinary more soluble lactam, which is gradually converted into the less (two-thirds) soluble lactim.

There is some reason to believe that uric acid exists in the blood in two forms (S. R. Benedict, 1916).

Influence of Phosphates on Acid Urines.—The acid NaH_2PO_4 liberates and precipitates uric acid; this is counteracted by the presence of the alkaline Na_2HPO_4 ; but excess of the latter precipitates the acid urate by "salting out" (Ritter).

Alkalies on Urate Deposits in Tissues.—The solvent action of the alkalies extends only to free uric acid. When all the uric acid exists as acid urate, as it does within the body, the addition of alkali can have no further solvent action. On the contrary, *excess* of alkali or other salts tends rather to decrease the solubility of the urates. It is evident therefore that no direct solvent action can occur on the urate tophi (Ritter). This inefficiency has been confirmed by clinical experience. If alkalies have any effect, which is doubtful, it would be due solely to their diuretic action.

Loghem, 1907, even claimed that hydrochloric acid is more useful for preventing the formation of urate deposits in animals, presumably by lessening the "salting out." Ritter had a similar idea. This has not been confirmed (Staal, 1908).

Uric Acid Retention in Disease.—The older notions were based on faulty analytic methods. According to the more reliable determinations of Folin and Denis, 1913, and 1915, and Pratt, 1913 and 1915, normal human blood contains 1 to 2.5 mg. of uric acid per 100 c.c. The proportion is notably increased (2.5 to 4.7 mg.) in gout (average 3.7 mg.); in lead poisoning, leukemia, and some cases of arthritis and nephritis.

Injected uric acid remains in the blood of gouty patients longer than with the non-gouty (McClure and Pratt, 1917).

Relation of Uric Acid to Gout.—The occurrence of urate tophi is a striking proof of disturbed uric acid conditions in this disease, but need have no causal connection. As has been said, the uric acid of the blood is very generally increased, but this may be even higher in other diseases and non-gouty arthritis. In gout, however, this is not accompanied by retention of non-protein nitrogen (Folin and Denis, 1915). It was formerly believed that definite changes in the uric acid content of the blood occurred during the acute gouty attacks. The modern results indicate that this is not correct; but that the urate concentration is the same during as between attacks; and that the attacks occur also when the urate concentration has been lowered by cinchophen (Daniels and McCrudden, 1915).

The urate deposits are not due to simple over-saturation; for the solvent power of serum for uric acid is much higher than the concentration in gout. Presumably it is caused by alterations, local or general, of the colloidal equilibrium (Lumiere).

It may be noted, in passing, that Hippocrates (Aphorisms, VI, 28) affirmed that eunuchs are not subject to gout (also Celus, Lib. IV, Cap. XXIV).

Increased Elimination of Uric Acid by Drugs.—This has been discussed under Cinchophen. The elimination is also increased by diuresis, (J. H. Robertson, 1914). The increase, on intravenous injections of NaCl or sodium chloride or sulphate solutions, is nearly proportional to the increased volume of urine, and is about the same (per volume of urine) for NaCl and Na_2SO_4 , and for isotonic and hypertonic solutions. The influence of saline diuresis is greater on uric acid than on total nitrogen; for instance, when the uric acid output was increased 52 per cent., the total nitrogen was increased only 12 per cent. (J. L. Morris and Rees, 1923).

Alkalies on Urates in Urine.—The conditions for the solvent efficiency of alkalies are much better in the case of acid urine. This contains not only acid urates, but also free uric acid, often in saturated solution.

When the urine cools, becomes more acid, or under other conditions, the solution may become supersaturated. The uric acid will then precipitate alone, or in combination with part of the acid urate (quadriurate). This can be prevented either by making the urine more dilute (diuresis), or by making it less acid. Alkalies act in both directions (Buchheim, 1853). The greatest solvent action can be obtained by administering adequate doses of sodium citrate or bicarbonate, together with plenty of water (Haskins, 1916). Too high a concentration of alkalies, as of other salts, would render the acid urate less soluble; but in practice, the administration of alkalies does not raise the total concentration of the urine, especially if water is taken freely. Alkaline urines would also dissolve actually precipitated uric acid; for the urine, after the administration of alkalies, is able to dissolve more uric acid than before (Haskins, 1916). With the practical limits of the alkalinity of the urine, however, this solution is so slight that it has little effect on formed calculi. The injection of alkaline solutions into the bladder has not been more successful (Buchheim).

Solvent Power of Urine for Uric Acid.—Haskins, 1916, found that this varies with its reaction and concentration. Urines of acidity $pH = 6.1$ and over can not dissolve any added uric acid; those that are less acid or alkaline take up more and more, according to their alkalinity. Concentrated urines dissolve more (though not in strict proportion) than do dilute urines of the same reaction.

Destruction of Uric Acid.—Basham, 1870, claimed that alkalies increase the destruction of uric acid; but further experience showed this to be uncertain and really negative (Severin, 1868; lithium, Bosse and Buchheim, 1862). The destruction by more concentrated alkalies has been studied by Stevens and May, 1911.

Difference in Bases.—The acid urates of different bases differ somewhat in solubility. The solubility of sodium urate, *f.i.*, is about one-fourth that of potassium urate, one-seventh that of lithium urate, etc. It might seem therefore that the solubility could be improved by the administration of K or Li salts. This is true of pure solutions (or when sodium urate or urate stones or tophi are treated with lithium carbonate); but it can not occur in the presence of an excess of Na; for according to ordinary chemical mass laws, when several bases compete for an acid, it is the least soluble salt which is always formed (*e.g.*, $BaSO_4$ in a mixture of H_2SO_4 , NaOH and $Ba(OH)_2$). Since there is always an excess of Na ions in the blood and urine, the Li and K would have no chance to exert their solvent action. The very slight superiority of lithium could exist only with very large doses, and these are unsafe (Haskins, 1916).

Organic Bases.—The same reasoning applied to these (ethylenamines, piperazine and piperidine). These also would be unable to compete against the Na. Moreover, they are excreted imperfectly, so that their alkaline efficiency in the urine is probably inferior to that of the ordinary alkalies. However, in some unexplained manner, large doses of piperazine (2 Gm.) do seem to confer a somewhat greater solvent action than exists in normal urines of the same reaction. The difference is not sufficiently great to be significant (Haskins, 1916).

Piperazine.—This is diethylen-diamine, $H_2N \begin{array}{c} \diagup CH_2 - CH_2 \diagdown \\ \diagdown CH_2 - CH_2 \diagup \end{array} NH_2$. It produces no

symptoms and is practically non-toxic. The solvent power for uric acid, in pure solution, is said to be higher than that of Li_2CO_3 (Mayert and Schmidt, 1890; Plugge, 1895; Stevens and May, 1911), but still insufficient to make much impression on a urate stone (Penzoldt). In the presence of Na salts, and therefore in the blood and urine, it is not

* The literature on organic urate solvents was reviewed by Hanzlik, 1916.

superior to other alkalis (Mendelsohn, 1892; Meisels, 1893); and since a part is oxidized, and therefore only a fraction appears in the urine, its effect on the alkalinity, and therefore on the solvent power, is less than that of NaHCO_3 . The clinical results have been inconstant and indefinite.

These limitations apply also to the derivatives of piperidine (dimethyl-piperazine = *Lycetol*, Wittzack, 1894; ethylen-ethenyldiamine = *Lysidine*, Ladenburg, 1894). Eczema has been reported from lysidine (Ortner). Piperidine, $\text{CH}_2(\text{CH}_2)_4\text{NH}$, was introduced by Tunncliffe and Rosenheim.

Organic Bases on Elimination and Destruction of Uric Acid.—The attempt to attribute the supposed clinical effects to these mechanisms is also without foundation (Waucomont, 1911), although piperidine does somewhat increase the elimination of uric acid, probably by increasing its formation through intestinal irritation (Abl, 1913).

Methenamine on Uric Acid.—This and the related compounds (Citatin, etc.) have a solvent and destructive action on uric acid, even in acid urines (Stevens and May) 1911; Haskins, 1915). This is due to their formaldehyde. They were therefore advocated as urate solvents (Bardet and Laquers). The action, however, is imperceptible with the ordinary doses (Nicolaier; Haskins, 1915; review, Hanzlik, 1916). Doses of 4 Gm. make the urine distinctly more solvent; but an equal effect can be secured by rendering the urine alkaline to pH 7.1 to 7.4, through the administration of bicarbonate, etc. (Haskins).

ORGANIC ACIDS AND THEIR SALTS

Local Action of Organic Acids.—Free citric and tartaric acid are relatively mild acids, used mainly for flavoring and for producing effervescence with carbonates. Acetic acid is somewhat more active. Lactic acid is employed as a mild caustic for the solution of false membranes, and in laryngeal tuberculosis. Formic acid is used as a counterirritant. The fatty acids are discussed under the Oils.

Fate and Systemic Actions.—The organic acids are mostly oxidized in the tissues to CO_2 and H_2O . Their salts therefore are converted into the bicarbonates, potassium acetate into bicarbonate ($\text{KC}_2\text{H}_3\text{O}_2 + 4\text{O} = \text{KHCO}_3 + \text{CO}_2 + \text{H}_2\text{O}$); sodium citrate, into NaHCO_3 , etc. and thus exert an alkaline action after absorption; although before combustion they may be neutral or acid. Their systemic action is thus identical with the administration of alkalis, but the local action is absent. This is sometimes of material advantage, as in rendering the urine alkaline with potassium acetate or citrate. They are also diuretic, and are often used in catarrhal cystitis.

Before the oxidation is completed, they may exert ion actions. These are small for acetates and formates. Oxalates, citrates and tartrates inactivate calcium. The tartrates are but poorly absorbed, and hence act as saline cathartics. Citrates share this to a less degree.

ACETATES

Potassium and sodium acetates are used mainly as alkaline diuretics and to counteract acidosis. The toxicity of sodium acetate is very low, even on intravenous injection. Free acetic acid acts locally simply as a feeble acid. The nutrition of rats is not impaired by the free consumption of concentrations up to $\frac{1}{4}$ per cent. When $\frac{1}{2}$ per cent. of acid was taken as drink, the nutrition was impaired (Sollmann, 1921). This explains the effect and danger of the use of vinegar in obesity.

PREPARATIONS

Acidum Aceticum Glaciale (Acid. Acet. Glac.), U.S.P., B.P.; Glacial Acetic Acid—90 per cent. of $C_2H_4O_2$. Congeals about $14.5^{\circ}C$.

Acid. Acet., U.S.P., B.P.—About 36.5 per cent., U.S.P., 33 per cent., B.P.

**Acid. Acet. Dil.*—6 per cent., U.S.P.; 5 per cent. B.P. Clear, colorless liquid, characteristic vinegar-like odor, acid taste. Miscible with water or alcohol. *Dose*, 2 c.c., 30 minims, U.S.P.; 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Acetum. Vinegar.—Corresponds in strength to the preceding.

Liq. Ammon. Acet.—See Index.

**Potassii Acetas* (Pot. Acet.), U.S.P., B.P., $KC_2H_3O_2$.—White powder or crystalline masses; odorless; saline taste. Deliquesces, and hence should not be dispensed in powders. Very sol. in water (1:0.5); freely sol. in alc. (1:2.9). *Dose*, 1 Gm., 15 gr., U.S.P.; 1 to 4 Gm., 15 to 60 gr., B.P.; diluted.

Sod. Acet., U.S.P., $NaC_2H_3O_2 + 3H_2O$.—Colorless crystals or granular powder; odorless; saline taste. Efflorescent. Very sol. in water (1:0.8); sol. in alc. (1:19). *Dose*, 1 Gm., 15 gr., U.S.P.

CITRATES

General Statement.—These are used especially as alkaline diuretics, Sodium citrate can be administered, *f.i.*, in diabetic coma, in large doses. 30 to 50 Gm. per day, without digestive disturbance or diarrhea (Lichtwitz, 1911). Citric acid (about 1 per cent.) is used as a refrigerant drink in fevers, etc; often as lemon juice, which contains about 8 per cent. A large lemon contains about 4 Gm., ordinary lemonade about 0.5 per cent. The syrup is a useful flavor.

Fate.—If sodium citrate is fed to cats and dogs, the blood and urine contain only traces.

When injected into a vein, the citrate disappears rapidly from the circulation. None escapes into the urine with intravenous injection, up to 0.5 gm. per Kg.

After hypodermic injection in rabbits, about 12 per cent. is excreted in the urine; with cats, 30 per cent.; with dogs, 40 per cent. (Salant and Wise, 1916).

Normal Occurrence in Urine.—Normal human urine contains about 0.5 gm. per day (Amberg and McClure, 1917).

Action on Calcium.—The citrates form double salts with calcium, which do not liberate Ca ions. Their intravenous injection (not oral administration) produces the typical effects of Ca deprivation (Sabbatani, 1901; Vietinghoff-Scheel, 1902; Martin, 1904; see Calcium). The injection of minute quantities into the brain produces convulsant effects. Repeated hypodermic injections of increasing doses create considerable tolerance (Robertson and Burnett, 1912).

Coagulability of the Blood.—Citrates, like other Ca inactivators, render the blood non-coagulable *in vitro*. When moderate doses (10 to 50 c.c. of 10 per cent., for man) are injected intravenously, however, the coagulation time of the circulating blood is definitely shortened (Weil, 1915); returning to normal within 24 hours (Lewisohn, 1917). The mechanism has not been explained. It has been attributed to injury of the platelets, leading to liberation of thromboplastin (N. Rosenthal and Baehr, 1922). With oral administration of 1 to 2 Gm., Coleman, 1909, describes a doubtful delay in coagulation.

Use in Transfusion.—Weil, 1915, introduced the use of "citratated blood," the blood of the donor being kept uncoagulated by the addition of sodium citrate. This may be injected at once, or preserved for a time. Wassermann, agglutination, hemolysis, etc., tests must be made as usual.

The technic and advantages of citrate perfusion are discussed by Sydenstricker et al., 1917; Lewisohn, 1917; Bernstein, 1917; etc.

Dosage.—Lewisohn, 1915, 1916, advised 0.25 per cent. of sodium citrate, and that the total dosage should not exceed 5 Gm. Within this limit, the citrate produces no systemic disturbances.

The addition of 0.2 per cent. of citrate to shed blood prevents coagulation completely, even for 48 hours; whilst 0.1 per cent. dose not hinder it at all. 1 per cent. of citrate, (1 c.c. of 10 per cent. citrate per 10 c.c. of blood) keeps the blood non-coagulable for two weeks; but this injured the corpuscles and with large transfusions in children, the total dose may approach rather close to the dangerous limit.

Acute Toxicity.—In animals, the intravenous toxicity varies with the rate of injection. The oral toxicity is low (Salant and Wise, 1916).

"Reactions" Following the Transfusion of Citrated Blood.—Somewhat over half of the citrated-blood transfusions are followed by a fairly severe chill and fever of about 2.5°F ., in half an hour, returning to normal in 4 to 8 hours. This reaction has little practical importance, and is apparently due to alterations produced in the corpuscles (Drinker and Brittingham, 1918).

In this series, 200 to 900 c.c. of the blood was drawn into 35 per cent. sodium citrate, corresponding to 2.8 Gm. of the citrates, as 0.3 to 0.45 per cent.

The febrile reactions have no relation to the purity of the citrate. They are not produced by the plasma, so that the corpuscles must be the toxic element. They are seen with the injection of washed citrated corpuscles, thus excluding immunologic "incompatibilities."

Apparently the citration causes a change in the corpuscles, and perhaps in the platelets, which renders them more toxic. Presumably this is due to a change in permeability by the calcium deprivation.

Preservation of Erythrocytes.—Centrifugation of blood injures the corpuscles mechanically, resulting in immediate or delayed hemolysis. This is especially marked with dogs, less with rabbits or sheep. Human corpuscles are quite resistant. Protection is afforded by viscid solutions, such as plasma, or better gelatin ($\frac{1}{8}$ per cent.). Human corpuscles do not require this protection. The resistance to mechanical injury is not related to the osmotic resistance. Drawn blood gradually hemolyses, even on ice. Gelatin does not protect against this. Preservation is best secured by sugars (2 per cent. of dextrose or 5 per cent. of dextrose). This preserves blood suitable for injection for over two months (Rous and Turner, 1915).

Sodium Citrate in Hemophilia.—Intravenous injection produces an immediate and marked shortening of the coagulation-time. This is followed in one to two days by return to the original, or even by a slower coagulation. Intramuscular injection has no effect (Ottenberg, 1916).

Other Anticoagulants.—In laboratory experiments, the coagulability of blood can easily be diminished or abolished. Leech extract and heparin have this effect, whether they are injected, or added to shed blood; albumoses, only when injected; citrates, oxalates, fluorides, concentrated solutions of other salts, formaldehyde, hydrocyanic acid, etc., only on shed blood (by removing the calcium or inhibiting the fibrin ferments). None of these drugs can be used effectively on patients, except by local application.

Clinical Danger of Intravenous Hirudin.—Enychmann claimed to have used 0.3 Gm. intravenously with 14 patients, without toxic symptoms. Lewisohn, 1915, however, obtained alarming symptoms after 0.1 Gm. of Hirudin-Sachsse.

Coagulation of Milk.—The inactivation of calcium by citrates also prevents the clotting of milk. Their addition to cows' milk, produces a looser curd in the stomach. This is utilized in infants (1 to 3 gr. of citrate per ounce of milk), when ordinary milk is not well borne (curds in vomits and stools). It should be reduced or omitted as soon as the need is passed (Cotton, 1906; R. Curtis, 1916).

Effects on Circulation.—As used clinically, this is practically unaffected. Larger doses, 30 mg. of sodium citrate per Kg. depress the heart muscle and stimulate the vasomotor center, in dogs. The renal vessels may be dilated (G. R. Love, 1923).

Excised Intestines.—Strong solutions depress all portions of the intestines; weaker concentrations stimulate the small and depress the large (Salant et al., 1917).

Rabbits' large intestines are depressed by all concentrations. With cats, the small and large intestines are both depressed (Salant and Schwartz, 1917).

When injected intravenously into dogs, small doses of sodium citrate stimulate the gastric and intestinal movements feebly. Larger doses, 100 mg. per Kg. rapidly injected cause a temporary depression of the stomach and intestines, and a sympathetic stimulation similar to epinephrine (G. R. Love, 1923).

Fruit Acids.—The acidity of fruits is due mainly to citric acids; other acids occurring only in small quantities. Tartrates are important only

in grapes (Bigelow and Dunbar, 1917). The drinking of *orange-juice* turns the urine alkaline; the oxidation was complete even when very large quantities were taken, *i.e.*, 2,400 c.c., containing about 48 Gm. of acid, in a day (Blatherwick and Long, 1922).

Infantile Scurvy.—The antiscorbutic effects of orange and lemon juice are not due to the citric acid; for citric acid itself is ineffective (Chick and Hume, 1917; Hess, 1918); whereas scurvy is cured by decoctions of orange peel (Hess, 1918), which are practically devoid of citric acid, or by orange juice from which the citric acid has been removed (Harden and Zilva, 1918).

Adult Scurvy.—This is probably analogous to the infantile form, and at least is relieved by the same dietary measures. The antiscorbutic factors exist only in fresh foods, and are destroyed by canning, pickling or drying, and greatly weakened even by cooking (Stefansson, 1918).

PREPARATIONS

Acidum Citricum, U.S.P., B.P.; Citric Acid, $C_3H_4(OH)(COOH)_3 + H_2O$.—A tri-basic organic acid obtained from the juice of limes or lemons. Colorless, translucent prisms or a white powder; odorless; having an acid taste; efflorescent in warm air. Very sol. in water (1:0.5); freely sol. in alc. (1:1.8). *Dose*, 0.3 to 1.2 Gm., 5 to 20 gr., B.P.

(**Syr. Acid Cit.*—See Index.)

Liq. Ammon. Cit., B.P.—*Dose*, 8 to 24 c.c., 2 to 6 drachms, B.P.

**Potassii Citras* (Pot. Cit.), U.S.P., B.P., $K_3C_6H_5O_7 + H_2O$.—Transparent prisms or white granular powder; odorless; cooling saline taste. Very sol. in water (1:0.6); very slightly sol. in alc. *Dose*, 1 Gm., 15 gr., U.S.P., 1 to 4 Gm., 15 to 60 gr., B.P.

Potassii Citras Effervescens (Pot. Cit. Eff.), U.S.P.—20 per cent. of potassium citrate. The effects would presumably be due mainly to sodium tartrate, which is formed by the effervescence. *Dose*, 4 Gm.; 1 drachm.

Liq. Pot. Cit., U.S.P.—8 per cent. of the anhydrous citrate. Must be recently prepared. *Dose*, 15 c.c., 4 drachms, U.S.P.

Sod. Cit., U.S.P., $2Na_3C_6H_5O_7 + 11H_2O$.—White granular powder; odorless; cooling saline taste. Efflorescent. Freely sol. in water (1:1.3); insol. in al.

Dose, 1 Gm., 15 gr., U.S.P.

Sod. Citro. Tart. Eff., B.P.—*Dose*, 4 to 8 Gm., 1 to 2 drachms, B.P.

MALATES

Fate.—These are mostly destroyed, even on hypodermic administration, but from 3 to 40 per cent. escapes into the urine. They produce much less damage than tartrates or citrates (Wise, 1916).

SUCCINATES

Leucocytes.—Hypodermic injection of 0.1 c.c. of 1 per cent. sodium succinate in man is said to increase the leucocyte count of the blood by 20 to 70 per cent. (Hammett, Kessler and Browning, 1917).

Heart.—Direct application of concentrated solutions depresses the heart, similar to tartrates (Salant and Livingston, 1917).

LACTATES

These are but slowly absorbed and therefore act as saline cathartics. They are completely burned in the organism, and have no other action (Faust, 1910). However, the drinking of 2 liters of lactic acid milk (with about 2 per cent. of organic acids) resulted in strongly acid urine, due to increase of acid phosphate, although paradoxically the organic acid of the urine was apparently not increased (Blatherwick and Long, 1922). It has been claimed that lactates somewhat limit nitrogen metabolism, after the manner of fats. For Lactic Acid, see Index.

FORMATES

Local Action.—Free formic acid occurs in several animals (ants, etc., Faust, 1910) and plants (nettles), and is partly responsible for their irritant effects. (Berchart, 1915, concludes that the effects of nettles are not due to formic acid.)

Formic acid resembles acetic acid, but is more volatile, more irritant, more antiseptic and more resistant to oxidation. It has a popular reputation as a counterirritant, but is probably not superior to other irritants. It is usually employed in the form of the *Spiritus Formicarum*, etc., corresponding to 1 per cent. of the absolute acid in two-thirds alcohol (this was formerly obtained by macerating ants). Its antiseptic action has been utilized for the preservation of food; 0.1 to 0.15 per cent. of free absolute acid suffices (Lebbin, 1906). The formates are not antiseptic.

Systemic Actions.—Formates act essentially like equal doses of acetates.

Formic Acid on Oral Administration.—Even formic acid behaves quantitatively like acetic acid. Water containing 0.001 to 0.25 per cent. of either formic or acetic acid, administered to rats for many weeks, in daily dosage up to 0.2 c.c. of acid per Kg. of body weight (equivalent, in man, to 6 liters of 0.2 per cent. acid per day) produced no effects whatever; not even diuresis. Twice this dosage interfered materially and progressively with growth and appetite; both acids again behaving alike (Sollmann, 1921). Lebbin also found formic acid practically harmless.

Formates by Mouth.—The toxicity is low, so that 6 to 10 Gm. of sodium formate may be taken daily for some time (Fleig).

Eppinger, 1913, administered sodium formate, 3 to 4 Gm. daily, to three patients. Two felt no discomfort; the other developed albuminuria and hematuria, persisting for five days; but this must have been a coincidence.

Action after Absorption.—The formates again act practically as indifferent salts. The general circulation is not affected by quite large doses. Enormous doses depress the heart (Livierato, 1906). They are said to produce methemoglobinuria (Croner and Seligmann, 1907). Diuresis may result (Fleig); doubtless due to simple salt action. Stimulant effects of various kinds have been claimed, but shown to be absent (Fleig, 1907, literature).

Therapeutic Uses.—At one time, formates were exploited rather fantastically as a sort of elixir of youth, destined to confer on man the vigor and indefatigability of insects; and to cure various ailments, mainly of the neurasthenic type (Garrigue; Clement; Huchard, 1902; H. Stern, 1906). Fleig exposed the uncritical nature of the evidence and showed the results were due solely to suggestion.

Fate.—Formates are oxidized less readily than other organic salts, so that a greater proportion (up to two-thirds) appears unchanged in the urine. With smaller doses, the destruction may be more complete (Pohl). The oxidation occurs mainly in the liver (Fleig, 1907).

Normal Occurrence.—A small quantity of formates occurs normally in mammalian tissues. In man, the normal daily urinary excretion is 13 to 120 mg. This indicates that considerable quantities are formed in intermediate metabolism, probably of all classes of foods. It is also formed from formaldehyde and methyl alcohol, not from ethyl alcohol (Dakin, Janney and Wakeman, 1913).

Acidum Formicum.—The acid official in foreign countries contains 25 per cent. of HCO_2H . The dose is stated as 1 to 20 drops.

METALS AND THEIR SALTS

The different metallic salts have many features in common. They combine with proteins, and therefore act locally as astringents, irritants, corrosives and antiseptics. After absorption, their effects are chiefly circulatory, especially on the blood vessels, but also on the heart. Changes in the capillaries are characteristic, and lead to phenomena analogous to those of inflammation. Their excretion by the kidneys results in nephritis. Being slowly excreted, they readily produce chronic poisoning, resulting in nervous and metabolic disturbances.

The toxicity of the different metals depends largely on their absorbability, which varies greatly. Iron salts, *f.i.*, are ordinarily non-toxic because only traces are absorbed. Metallic poisons are generally more

toxic to herbivora than to carnivora—probably because they remain longer in the alimentary canal of herbivorous animals, allowing greater absorption.

Relative Absorbability of the Metals.—Arsenic, mercury, and uranium are the only metals the absorption of which is of an extent sufficient to cause acute systemic poisoning with non-corrosive doses. Phosphorus, which behaves pharmacologically in many respects like metals, is absorbed still more readily. Other metals are absorbed much more slowly. To this class belong lead, silver, tin, and iron. Any metallic salt, if given in strong solution, will cause *corrosion* of the mucous membrane of the alimentary canal and will then be absorbed, and would exert its systemic action were it not that the local effects often kill before the systemic can come into play.

Habituation to Local Action.—If the administration of a metallic salt is begun with small doses and gradually increased, it may become possible to administer without local effect doses which would at first have produced corrosion (Hausmann, 1906). Habituation also diminishes the **absorption** of arsenic, but not of antimony (Cloetta, 1906 and 1911).

Habituation of Lower Organisms.—Yeasts, bacteria and protozoa readily acquire considerable tolerance to the various metals. This may be transmitted for generations, and may or may not extend to other metals. The experiments of Neuhaus, 1910, with infusoria, and the trypanosome studies of Ehrlich, 1910, present many interesting facts.

Solubility and Absorption.—To be absorbed, the metal must be in soluble form; but it is to be borne in mind that the solubility in the alimentary canal is not necessarily the same as the solubility in water in a test-tube. The combination of the metal will usually be changed in its passage through the digestive tract. In the stomach it will be converted largely into the chloride, in the intestines into the carbonate and sulphide. The metallic salts also enter into double combinations with proteins, and these are often soluble in an excess of the latter. In these ways such insoluble compounds as mercuric oxide, mercurous chloride, lead sulphate, and silver chloride, may be brought into solution.

Absorbability through Intact Skin.—Lead, copper and zinc oleates are said to be absorbable through the skin (C. Voegt and Burchardt, 1916).

Ion-action.—The characteristic effects of the metals are produced only when they are ionized. The uncombined metals and molecular organic compounds (for instance, the organic arsenic derivatives) do not produce the typical actions of their metallic ions directly. They may cause effects of their own, differing from those of the ions; or they may be inactive. Eventually, however, they are usually transformed into ionized compounds, and therefore gradually develop the ordinary actions, but much more slowly. The non-ionized compounds are often differently distributed in the body, so that their actions may differ from those of the ordinary salts, even when they are subsequently dissociated. The organic arsenic compounds are important examples.

Intravenous Injection of Metallic Salts.—The systemic actions of most metals are studied mainly by injecting them intravenously, since the slow absorption and the strong local actions would obscure the remote effects, if the metals were given by the ordinary channels. For the intravenous injection, such metallic salts must be chosen as will not precipitate the blood. Double salts (such as iron-ammonium citrate, etc.) or metallic albuminates may meet this requirement. In some cases it is

necessary to have recourse to some non-ionic compounds of the metal, from which the ionic metal is liberated in the body.

Delayed Action.—When a non-precipitant preparation is injected directly into the blood the symptoms in many cases do not arise at once, but are *developed quite slowly*, sometimes only in the course of several days. This is due to the fact that the metals do not act in the blood, but only after they have been absorbed into the cells; and this absorption is so slow that it may take several days to accumulate sufficient metal to produce any action. The metal may by this time have disappeared entirely from the circulating liquids (White, 1880).

It would appear also that the symptoms do not arise immediately even after the poison has reached the cells. Tartar emetic, when injected in appropriate doses into a vein, disappears from the blood in ten minutes, but the first symptoms may be seen only after some twelve hours. This corresponds with the behavior of toxins and of many other poisons.

Storage in Cells.—The metals enter into firm combination with the protoplasm, and accumulate in the cells, especially of the liver, until these contain much larger quantities than the surrounding medium (Bokorny, 1905).

Cumulative Action.—The *excretion* of the metals is usually even slower than their absorption. They have therefore often a cumulative action; doses too small to produce any immediate effect cause serious poisoning if long continued. Pb, Hg, and As are prominent examples. A single large dose may, on the other hand, produce chronic poisoning.

Excretion.—The metals are excreted by the kidneys, by the bile, and by the intestinal epithelium, especially in the large intestines. The relative share of these channels differs for different metals, for different individuals and even day by day in the same individual (Cole et al., 1926).

A *gastroenteritis* may result even when the poison has been given intravenously.

Metal Nephritis.—The amount of the metals excreted by the kidneys is often sufficient to cause a marked nephritis, characterized by albuminuria, casts, etc. The nephritis begins usually in the epithelium of the convoluted tubules and spreads from here to the glomeruli. If the poisoning is chronic, the nephritis may become interstitial and lead to renal cirrhosis.

Nephritis has been described in poisoning by the following metals: Ag, Al, As, Au, Be, Bi, Cd, Ce, Co, Cr, Cu, Hg, Mn, Ni, P, Pb, Sb, U, W, Zn. There may also be renal *glycosuria*, *i.e.*, the appearance of sugar in the urine without hyperglycemia (Luzzato, 1914).

Circulatory Effects.—Severe acute intoxication from the systemic action of metals generally results in progressive fall of blood pressure. With most metals this is due to injury of the capillaries. A few metals may also depress the heart directly.

The metals, aside from silver, may be divided into *two principal groups*; the first group acting mainly peripherally on the *blood vessels*, the second group acting peripherally on the *heart*. To the first group belong arsenic, antimony, uranium, bismuth, iron, manganese, selenium, tellurium, aluminum, tin, nickel, cobalt, gold, and platinum (Wohlwill, 1907), to the second group, lead, phosphorus, copper, zinc, cadmium, mercury, vanadium, cerium, and thallium.

In the perfused heart, all metals (in the form of lactates) produce block and diastolic standstill (Voegtlin, 1915).

Nervous Phenomena.—The serious circulatory disturbances lead to central and peripheral nervous symptoms. Direct acute nervous actions are not common in

mammals, except perhaps with silver. Severe chronic poisoning by all metals often produces peripheral neurites and central nervous disturbances (encephalopathia).

Frogs show with most metals a paralysis, preceded by a slight stimulation. The tetanizing action predominates with Ni, Co, and Pt. Whether the metals have any direct effect on *metabolism* can not be decided with our present methods, because of the disturbances introduced by the intestinal and renal irritation, and by the circulatory changes.

Oligodynamic Action of Heavy Metals.—When applied directly or in pure solutions, especially to isolated cells, the heavy metals and their salts may produce marked effects in extreme dilutions. This action is sometimes beneficial, more commonly destructive.

The growth of *moulds* for instance, is markedly favored by traces of Zn and Mn (Raulin, 1870, quoted by Bayliss); the presence of zinc in a dilution of 1:25,000,000 increases the crop of the mould *Aspergillus* by more than 50 per cent. (Bertrand and Javillier, 1912). On the other hand, the alga *Spirogyra* is killed by copper in a dilution calculated as 1:72,000,000 (Naegeli, 1893, who introduced the term oligodynamic action). Similar effects are produced by Hg, Pb, Sn, Fe, and Ag, but Cu is by far the most toxic (Locke, 1895). The addition of metallic Hg, Ag, or Pb to blood gradually produces hemolysis, whilst Cu hardens the corpuscles (Bechhold, Ascoli). If metals are placed in water, the containers, even after rinsing, impart to fresh water considerable catalytic and protein-precipitant properties; the order of efficiency being: (most) Cu, Hg, Ag, Pb, Sn, Zn, Al, Fe, Mn, Pt (Falta and Richter-Quittner, 1921). Touching the His-bundle of the mammalian heart with a rod of clean, polished copper produces instant heart-block (v. Egmond, 1920).

It may be assumed that in these dilute solutions the metals exist first as colloidal metals, but that they pass rapidly into colloidal hydroxides and carbonates (Traube-Mengarini and Scala, 1912) with positive charge, which are therefore adsorbed (and detoxicated) by negatively charged solids (Bayliss).

COLLOID METALS

Colloid metals may be obtained by establishing an electric arc between metallic wires under water; very fine particles of the metal being throw off and forming a colloidal solution. Similar solutions may be obtained from solutions of metallic salts by certain reducing agents. Colloid solutions of Pt, Ag, Hg, Au, Bi, Cd, Pd, and Ir have been prepared by these methods. The metal exists in these solutions, not as ions, but in true metallic conditions; it is, however, so finely subdivided that it remains permanently and evenly distributed through the solution. It is precipitable by salts, in the same way as other colloidal solutions. The chemic reduction gives equally fine particles and can be used to make more concentrated solution than the electric (Voigt, 1914).

Colloid solutions can not produce the ion-actions of the metals directly. The colloid condition, however, gives them *catalytic properties*, *i.e.*, minute quantities may induce reactions in large quantities of other substances (*e.g.*, conversion of alcohol into acetic acid), the metal taking no part in this transformation. This catalysis is hindered by many poisons, just as is the action of true ferments. The metals *pass quite readily from the colloid into the ionic condition*, *e.g.*, by the action of bacteria, and may then exert the ordinary action of the metals. Since this conversion occurs but slowly, these actions will be mainly local, and will produce a minimum of irritation.

Absorption and Fate.—It is questionable whether the colloid metals are at all absorbed unchanged.

The problem has been studied chiefly with colloidal silver. After intramuscular or peritoneal injection, the absorption is quite slow, and not exclusively by the leucocytes (Voigt, 1916). If injected intravenously, they sojourn only a few minutes in the blood (Niculescu, 1912), and are then deposited, especially in the liver and the hemopoietic and excretory organs (Voigt, 1914, 1916).

Protein Stabilizers.—Colloidal metals for clinical use (for instance Collargol) are often "stabilized" by the addition of proteins. These may produce active or passive anaphylaxis (Bottner, 1918; Hanzlik and Karsner, 1920). It is quite possible that the therapeutic and toxic "reactions" are due to the injection of the foreign protein. This would account, for instance, for the erythema observed in a patient by Nagai, 1919.

Pharmacologic Actions of Colloid Metals.—Their gradual transformation into the ionized form will eventually produce the ordinary systemic effects of metals. They have been used, hypodermically and intravenously, for this purpose, but without serious advantage. (Solutions should not be made isotonic with salt, since electrolytes cause precipitation.) They also produce other rather indefinite and inconstant effects, probably attributable to the colloid condition: hyperpyrexia, first hypo-, then hyperleucocytosis, renal and intestinal irritation, and fatal coma (Foá and Aggazotti, 1908 and 1909; Gros and O'Connor, 1911). They may be followed by increased excretion of nitrogen and uric acid (Ascoli and Izar, 1907).

Repeated intravenous injections of colloid metals, or of other foreign colloids, produce marked irritation of the lymphoblastic tissue of the spleen, lymph glands and bone marrow (Nissen, 1922). An interesting effect has been described by Gaudrelet: In a normal animal, the intravenous injection of the dye thionin has little effect; but it exaggerates the hypotensive effect of nigrosin injection. This response fails to occur in animals that were injected with electrocolloid metals, peptone, or other colloids.

Therapeutic Use against Infections.—Colloid silver particularly has been extravagantly lauded as an internal antiseptic in puerperal and other septicemias and infections; but the claims do not stand critical examination (Report, Coun. Pharm. Chem., 1909; de Arric, 1912). Gros and O'Connor found that colloid metals, like charcoal, adsorb poisons, alkaloidal as well as toxins, and therefore decrease their toxicity, but the decrease is insignificant, and does not occur at all unless the poison was treated before being injected. Phagocytosis is perhaps somewhat increased for some bacteria, but not for all (Arric, 1913). Colloid silver or mercury is fairly antiseptic, but not germicidal (Marshall and Killöb, 1915).

The overenthusiastic therapeutic claims for colloidal metals were well criticized by Bayliss ("The Colloidal State," pp. 76–80). He pointed out that the "electrical charges" and the "surfaces" in the dilute solutions of colloidal metals are insignificant in comparison with those that already exist in the protein systems of the blood and tissues; and that many of the effects attributed to the metals are due to the protective colloid (Auld) and others to the acidity of the solutions (Bradley).

Dangers.—Colloid silver preparations are apt to deteriorate rapidly into the insoluble form, and may thus produce embolism (Rittershaus, 1905; H. J. Hamburger, 1909). A number of deaths have occurred probably by vascular embolism from the injection of collargol into the renal pelvis for X-ray diagnosis (Eisendrath, 1914). Buerger, 1914, finds that these injections may penetrate the renal parenchyma to the surface of the kidney, and lead to necrotic and suppurative foci.

Chemotherapy of Cancer.—This started with the announcement of Wassermann, Keysser and Wassermann, 1911 and 1912, that they had succeeded in causing the disappearance of rat tumors by the intravenous injection of selenium-eosin compounds. Since then, similar favorable results were reported for colloidal copper, platinum, sulphur and some other colloids and organic metal compounds (Neuberg and Caspari, 1912; Neuberg, Caspari and Loeb, 1912; L. Loeb and co-workers, 1912 to 1914). Even human tumors seemed to show some retrogression. However, the results do not withstand criticism. Uhlenhuth, 1912, and Walker, 1912, failed to confirm the animal experiments with eosin-selenium. Keysser's further experience (1914) also convinced him that cure of animal tumors by the various methods occurs in only a small percentage of cases; that they are ineffective against visceral or growing tumors; success being confined to large subcutaneous tumors, which they cause to soften and liquefy. Weil, 1915, suggests that they accumulate in the necrotic portions of the tumors, as do iodides and dyes, and there lead to the liquefaction of the necrotic tissue.

The injection of lead will be discussed under that heading.

As to the human cancer, the reported improvement has been essentially symptomatic only, and this has little significance. Weil, 1913 and 1915, points out that the only admissible sign of improvement is reduction of the size of the tumor; and from this standpoint, the clinical reports are negative. Loeb (McClurg, et al., 1915) concedes that a cure can not be expected. Keysser also considers that the effective dose in animals is so near to the fatal, that no results could be expected from a safe dosage.

INORGANIC ARSENIC COMPOUNDS

Arsenical compounds act locally as mild and slow corrosives and have been employed in superficial cancer. Systemically, they relax the capillaries and increase their permeability, thus simulating inflammation.

This change is most conspicuous in the splanchnic area. In acute arsenic poisoning, it results in extreme gastroenteritis, closely resembling cholera.

This dilatation of capillaries introduces changes in the circulation which cause secondary disturbances in the function of more remote organs, particularly in the *nervous system*; and further, *fatty degeneration* of the cells, especially in glands and muscles, with other disturbances of nutrition and metabolism, particularly in chronic poisoning. There may also be a direct paralysis of the *heart*, both ganglionic and muscular.

Milder degrees of the same action may stimulate metabolism beneficially. This might explain the therapeutic uses of arsenic in malnutrition, anemias and skin diseases; but the mechanism of their action, and indeed the results, are somewhat in doubt. There are also characteristic effects on the bones and bone-marrow. Arsenic, especially in the organic forms, is highly effective against protozoan infections.

Arsenous and Arsenic Compounds.—Trivalent As (arsenites) is generally much more toxic for protozoa, bacteria and yeast cells than is pentavalent As (arsenates) (Kionka, 1911). This holds also for the different valencies in organic compounds, and for the corresponding antimony valencies (Friedberger and Joachimglu, 1917). It has been assumed that the 5-valent As is non-toxic until it has been reduced to the 3-valent (Loew, 1887). The occurrence of a partial reduction was demonstrated by Binz and Schulz, 1879.

Relative Toxicity of Arsenic Compounds.—With intraperitoneal injection into guinea pigs, the toxicity decreases in the order of: arsenites, arsenates, colloidal arsenic, atoxyl and cacodyl (Launoy, 1918).

Colloidal Arsenic.—Soreao, 1918, confirms that this has a low toxicity, its conversion into ionic arsenic being very gradual.

The ratio of toxicity of arsenous acid: *arsenic acid* varies for different tissues. With intravenous injection in rabbits, it is as 6:10; for the excised frog's heart, as 300:1. The arsenous is also more toxic for the excised intestine or rabbits. These different ratios indicate that the toxicity of arsenic acid is due to reduction to arsenous acid, which varies in degree for different tissues (Joachimoglu, 1915).

Resistance of Species.—Arsenic is toxic to all animals which possess a central nervous system; also to most of the higher plants, but not to all the lower organisms. Its antiseptic action is comparatively small. It can not therefore be classed as a general protoplasmic poison. New-born salamanders show a very great tolerance. Among *mammals*, the resistance is greatest in mice, then come the hedgehog, rabbit, dog and cat (Willberg, 1913).

The toxicity is the same for splenectomized as for normal mice (Towels, 1916). The *penetration* of various arsenic compounds into living and dead cells has been studied by M. M. Brooks, 1923, 1925.

Oxidation and Reduction Theory.—Schulz, 1884, and Binz, 1897, attempted to explain the arsenic effects as alternating oxidation and reduction of the cells, due to the easy passage of arsenous and arsenic compounds into each other (which Schulz, 1892, demonstrated on organ-emulsions). Husemann, 1892, pointed out that if this were true, both forms should have the same toxicity. The difference is not great for mammals, but very considerable for lower animals and plants (O. Loew). The explanation is therefore not tenable. It is now generally believed that the arsenicals hinder protoplasmic oxidation in an unknown way; although Schaefer and Boehm, 1872, showed that arsenic has little effect on ordinary ferments.

Voegtlin, Dyer and Leonard, 1923, suggest that the trivalent arsenic oxides bind and thus inactivate organic sulphhydryl groups, especially those of glutathione, which Hopkins believes to play an important role in the physiological oxidation-reduction phenomena.

Local Actions.—The arsenicals are not precipitant and therefore irritate only weakly, even on wounds or mucous membranes; but the cells die slowly after prolonged contact. This is sometimes used for killing exposed *dental nerves*; and as salves for superficial *epitheliomas*. Arsenic

is much more destructive to pathologic cells, so that the cancerous tissue may be killed without injury to the surrounding normal tissue. As with all cancer-salves, some of the deeper tumor cells generally escape, leading to inoperable recurrences. Their use is therefore not advisable.

Circulation.—Arsenic poisoning is characterized by pronounced and persistent fall of blood pressure.

Asphyxia or strophanthus injection produce the normal pressor response (the pressure rising, for instance for 60 to 140 mm. through asphyxia; and from 13 to 140 mm. after strophanthus injection; Sollmann). The fall can therefore not be explained by cardiac failure and arterial vasomotor depression. These occur only late in the poisoning, as secondary results of the low blood pressure. The cause must be looked for in a paralysis of the capillaries; or in diminution of the effective volume of blood by transudation of plasma.

Heart.—In the excised (Langendorff) heart the amplitude is first increased, then diminished; the rate may be slowed, quickened or arrhythmic. Arsenites are more toxic than arsenates, and these more than the organic. Of the latter, cacodylate is the most potent; arspenamine and its oxidation products are inactive (Archangelski, 1912). In intact animals the cardiac action of the arsenicals is relatively unimportant, for the heart is able to maintain a fairly high pressure if the aorta is clamped (Boehm and Unterberger, 1874).

Vascular Action.—The vasodilation is most conspicuous in the splanchnic area; but the blood pressure falls even when the intestines are tied off, so that the muscular vessels are also dilated. The dilation can be demonstrated by perfusion of excised organs. It is therefore peripheral. The vessels, however, continue to react to splanchnic stimulation till very late; and to epinephrine even after the splanchnic response is lost (A. Loeb, 1911). The arterioles must therefore still be capable of contracting.

Paralysis of Capillaries.—For this reason it is assumed that structures beyond the arterioles—namely, the capillaries—are the seat of the paralysis. This view is favored by the fact that they have become more permeable. Intravenous injections of large quantities of salt solution will cause edema in animals poisoned with As, but not in the normal (Magnus, 1899; other capillary poisons are discussed by W. Heubner, 1907).

The thoracic *lymph flow* is increased by arsenic, the phenomena being similar to those of peptone (Yanagawa, 1916).

These changes in the capillaries explain partly the therapeutic actions, and the whole course of the poisoning. Since *increased permeability* of the capillaries is one of the essential features of inflammation, the phenomena of arsenic poisoning are similar to those produced by an irritating inflammation, although the primal cause is different.

However, arsenic inhibits the migration of leucocytes in the inflamed mesentery of frogs (Ikeda, 1916).

Gastroenteritis.—The first and principal symptoms of acute arsenic poisoning are those of violent inflammation of the digestive tract. This suggested that arsenic acts as a corrosive. However, the autopsy rarely shows extensive corrosion, and it is known that the corrosive action occurs extremely slowly. Furthermore, the gastroenteritis may be obtained with at least equal readiness if the arsenic is injected into the circulation or subcutaneously. This would not definitely exclude all local action, since some arsenic is excreted into the alimentary canal; but the quantity is not nearly enough to account for the symptoms.

The inflammation is really due to the systemic action on the capillaries, which is strongest in the intestines, no matter how the arsenic has been introduced. The capillary paralysis results in the production of an exudation into the connective tissue. This raises the epithelium (just as would a blister on the skin), and causes it to be thrown off in shreds or false membranes. The exudation is then poured into the lumen of the intestine and largely coagulates. This distention, as well as the circulatory changes, causes increased peristalsis and *watery diarrhea*; and the shreds of mucus and coagulated exudation give to the evacuation the character of "*rice-water*" stools (Boehm and Pistorius, 1882). The pathology of this condition is exactly the same as that of Asiatic cholera, and without a history it is impossible to distinguish between the two conditions except by chemic examination of the dejections.

The extreme distention of the capillaries may lead to their rupture, to the formation of ecchymoses, or possibly bleeding into the intestine or stomach, and consequently bloody vomiting or diarrhea; but this is by no means always the case.

Kidneys.—Arsenic produces nephritis, at first mainly vascular (Schlayer and Hedinger, 1907), but always with more or less involvement of the epithelium (MacNider, 1912; O'Hare, 1915).

The vessels of the kidneys participate in the capillary dilation. The glomerular capillaries are swollen so as to fill the capsule; the urine is albuminous and scanty, and can not be increased by caffeine (Hellin and Spiro, 1897). The retention of nitrogen in the blood is relatively slight (Karsner and Denis, 1914).

The types of nephritis from different arsenic compounds, and the actions of arsenicals on the **adrenals** are described by L. Pearce and Brown, 1915.

Absorption.—This occurs readily, to some extent even from the intact skin. Poisoning may therefore result from the external use of arsenical cosmetic preparations. With hypodermic injections, the diarrhea often sets in within an hour.

Excretion.—This occurs by all the usual channels—urine, feces, sweat (Tachau, 1911), milk, and epithelium of the skin (Heffter, 1905). With oral administration, the main part leaves by the feces; with hypodermic by the urine. The excretion is always slow and incomplete, especially with prolonged administration (Croner and Seligmann, 1907).

Time of Excretion.—The excretion begins in two to eight hours after the administration, but lasts for a long time—three to ten days, after a single dose; to seventy days when it had been given continuously. In rabbits' urine it was found for 120 days, in dogs' for 160 days, after the administration was stopped. The elimination and retention in dogs has been studied by Dutcher and Steel, 1914.

Distribution in Tissues.—The arsenic is stored in all the tissues, but especially in the liver, kidneys and heart; less in the skeletal muscles and brain (Blarez and Deniges, 1907; Eckeley, human, 1913; Schellbach, human, 1922). In the liver of dogs it is found as an arsenical nucleoprotein (Slowtsoff, 1902). The *cerebro-spinal fluid* contains at most traces in normal individuals (Eckeley), more in meningitis (Finel and Leroid, 1913). Arsenic also passes across the placental circulation to the fetus. It is just as toxic when injected into the mesenteric, as by the jugular vein, showing that the liver neither neutralizes nor retains it. It is less toxic on hypodermic injection, since it enters into more slowly dissociated compounds with the tissue elements.

Deposition in Hair.—After the administration of arsenic, the hair contains detectable quantities, in firm combination. The deposition is slow but persistent. Therefore none is found in acutely fatal poisoning, the earliest demonstration being after two weeks. It may then persist for months or years, long after the metal has disappeared from the liver and bones (Heffter, 1915).

Normal Occurrence of Arsenic.—A. Gautier, 1899, found minute traces of arsenic in normal tissues. Its universal presence was confirmed by Bertrand and all those who

worked with sufficiently delicate methods (Fordyce et al., 1923; C. N. Myers and Cornwall, 1925). In man, it occurs especially in the thyroid (0.16 mg.); also in the thymus, brain, and skin. It appears to be in organic combination with the nuclein. None is found in the liver. This arsenic is introduced with the food and especially the drinking water. (According to the Royal Commission, 1903, the quantity of arsenic in food should not exceed $\frac{1}{100}$ gr. per pound, or in liquids, per gallon.)

The quantity of arsenic normally present in the intestinal canal *never* exceeds $\frac{1}{10}$ mg. Larger quantities point to poisoning (Gautier, 1904).

The urine generally contains traces, up to 0.5 mg. per day, depending mainly on the arsenic content of the food (I. Bang, 1916).

Etiology of Arsenic Poisoning.—Arsenic was at one time used very extensively for criminal poisoning, especially in the seventeenth century. An Italian woman, Toffania, carried this art to great refinement, using under the name of "Acqua Toffana" a mixture of arsenic and ptomaines obtained from the putrefied juices of animals poisoned with arsenic.

At the present time arsenic is less used with criminal intent. This may be attributed to the perfection of chemic means of detection, which allow of the discovery of the minutest trace. Accidental poisoning has been lessened to some extent by requiring the preparations of arsenic sold at retail to be colored either with lamp-black or indigo, so that they do not have the innocent appearance of a white powder. This is also of some importance in diagnosing the poisoning, the color of the vomit calling attention to it. But accidental and suicidal poisoning is still very common, since arsenic is so extensively distributed. It is easy to obtain it as a rat and fly poison. It is frequently used in the arts. Paris green is a preparation whose sale is almost unrestricted. Many of the cosmetic preparations on the market contain arsenic and have given rise to accidents. The use of arsenic compounds, such as Schweinfurth green, as *pigments* has been absolutely prohibited; but a great many of the *coal-tar dyes*, which are popular at the present time, employ arsenic in their preparation, and very frequently this is not entirely removed. Formerly *wall paper* dyed with arsenic compounds was a common source of arsenic poisoning, but this has now largely disappeared.

The arsenic is given off from these papers as dust. However, undoubted cases of poisoning have also occurred when the arsenical paper was completely covered by a harmless paper; in these, some volatile arsenic compound must have been formed.

Most modern wall papers still contain minute, but practically insignificant traces (Schulz, 1915). The permissible limit of arsenic in papers is placed at 0.1 gr. per square yard; but this is probably not quite harmless. The Bureau of Chemistry of the United States Department of Agriculture has analyzed a number of papers on the American market (Haywood and Warner, 1904). Over 90 per cent. of these contained less than 0.046 gr. per square yard, and are therefore safe. *Furs, rugs, and fabrics* were less satisfactory. *Black stockings* particularly often contained quantities of arsenic (above 0.01 gr. per square yard), which must be deemed dangerous, considering their intimate contact with the skin.

Fruits, after the use of arsenical insecticide sprays (Bordeaux mixture, lead arsenate), contain arsenic (and lead), for long periods (Sonntag, 1915). The quantities, however, are usually unimportant.

Course of Acute Arsenic Poisoning.—This may be very rapid: In *fulminant cases*, the withdrawal of the blood from the general circulation into the splanchnic area may produce prompt collapse, and death before the enteritis has time to develop (corresponding to "dry cholera"). Usually, however, the symptoms do not appear for from one-half to one hour after the arsenic is taken, and then run through eighteen hours to three days and sometimes four to fourteen days.

Acute Symptoms.—The suspicion of the patient may have been aroused by the sweetish astringent taste of the substance. Almost the first symptoms are vomiting and profuse and painful diarrhea. The withdrawal of water from the body leads to great thirst, dryness of the mouth and throat, and difficulty in swallowing and articulation. The urine is diminished and often bloody and albuminous. The nervous symptoms consist in vertigo, headache, and pain in the limbs. There will be cyanosis and cold extremities. Toward the end occur syncope, coma, clonic and tonic spasms, and a general paralysis. Death usually occurs by exhaustion as a result of the prolonged gastroenteritis, as in cholera.

In the **subacute poisoning** the inflammation of the mucous membrane of the alimentary canal is prominent. Inflammation of other mucous membranes also becomes conspicuous, and shows as conjunctivitis, coryza, stomatitis, salivation, and pharyngitis. Skin eruptions make their appearance if the arsenic poisoning is at all prolonged. In this case there are also symptoms arising from the central nervous system, as well as neurites.

The **diagnosis of acute arsenic poisoning** is made by the violent gastroenteritis. This can usually be distinguished quite easily from that produced by acids and alkalies, by the history of the case, absence of corrosion in the mouth, and furthermore by the lesser prominence of the local symptoms. The very quick onset distinguishes it from other metals.

Autopsy Findings.—The patient appears emaciated from the withdrawal of liquid from the body by the profuse diarrhea, and this even if he retains a fair amount of adipose tissue. The appearance of the alimentary canal with its large amount of fluid and the presence of shreds of mucus and false membrane, with usually no pronounced corrosion, are characteristic. Microscopically gastroadenitis and cell infiltration are often seen.

✎ The body after arsenic poisoning usually putrefies very slowly and may become mummified, which always causes a suspicion, although it is not at all a proof of such poisoning. The positive proof can be furnished only by the chemic examination. It must not be forgotten that arsenic is frequently introduced into the body in the embalming fluid.

Fatal Dose.—This varies, especially with the solubility of the preparation, etc. Of the trioxide, 5 to 50 mg. are toxic; 0.1 to 0.3 Gm. are usually fatal; but recovery may occur after much larger quantities. The mortality is 50 to 75 per cent. (Lewin).

Fineness of Powder.—The dry trioxide or ordinary white arsenic is so slowly soluble that its toxicity is greatly influenced by the fineness of the powder in which it is taken; for instance, it required 500 times more of the coarse powder than of the solution to produce emesis (Schwartz, 1922). The U.S.P. x therefore specifies the maximal size of the particles in powders that are to be administered in solid form.

Treatment of Acute Poisoning.—Acute arsenic poisoning is best treated by emetics, lavage with warm water, or purgation. The chemic antidotes are of doubtful value.

Ferri Hydroxidum cum Magnesii Oxido (see Index) was introduced by Bunsen and Berthold, 1834, and was long considered the best antidote, the ferric hydrate and arsenic forming a compound which was deemed almost insoluble; but experienced pharmacologists (De Busscher, 1902; McGuigan

et al., 1923) found that the antidote at best postpones death for a few hours, and apparently gives a slightly smaller percentage of fatalities; the differences may lie within the experimental error. It is conceivable that this antidote and other colloids may somewhat delay absorption by adsorbing the arsenic (Lockemann and Paucke, 1911), and its administration can do no harm, provided that it is *promptly followed by effective evacuation*.

The hypodermic injection of *magnesium sulphate* has saved animals from fatal doses of arsenic, even when the latter was also injected hypodermically. Presumably, difficulty soluble arsenic-magnesium compounds are formed (Sieber, 1912). However, the antidote must be used very promptly, and the effective dose of magnesium is itself dangerous.

Arseniuretted Hydrogen (AsH_3).—This is an extremely toxic gas, so that a few bubbles may be fatal to man. It is produced in lead-burning; by the action of impure sulphuric acid on metals; from ferrosilicon, etc. It may produce the ordinary arsenic phenomena, but the toxic effects are mainly due to hemolysis. It combines with the hemoglobin (Meissner, 1913), and destroys the corpuscles. The symptoms are often delayed, and start with malaise, collapse, fainting fits, etc. This is followed by bloody urine; icterus, painful liver and kidneys; eventually by anemia (Stadelmann, 1882). Severe cases may die during the earlier stages with convulsions, delirium and coma. The gas has a characteristic garlic odor.

"Ferrosilicon."—This is a mixture of Fe and Si compounds, used in the manufacture of steel. In the presence of water or moist air (as in shipment) it liberates phosphoretted and arseniuretted hydrogen, which have produced fatal poisoning (J.A.M.A., 55:781, 1910). The grades containing 30 to 70 per cent. of silicon are much more subject to the decomposition, and are therefore more dangerous than those containing a greater or smaller percentage.

Garlic Odor with Arsenic.—This is a rather characteristic feature under certain conditions. It is noted when the metal is burned in air to As_2O_3 . Moulds growing on damp wall paper and other arsenicals produce it by forming ethyl arsine, $\text{As}(\text{C}_2\text{H}_5)_2\text{H}$. The odor is sometimes observed in the arsenic vomitus (Gumprecht), and is probably due to reduction products. Garlic breath does not occur, or very rarely, in the therapeutic administration of inorganic arsenic compounds, but is very strong after the use of cacodylates.

Habitation.—The mountaineers of Styria and certain other regions consume arsenic once or twice weekly, as a general stimulant and tonic. There appears to be unimpeachable evidence that they gradually accustom themselves to use with immunity quantities of arsenic trioxide (to 0.4 Gm. per day) which would produce very serious toxic, irritant and cumulative effects in ordinary individuals (Tschudin, 1851; Schaefer, 1861; Knappe, 1875). This tolerance can also be induced in dogs and rabbits. Cloetta, 1906, attributes it to lessened absorption from the alimentary canal; Hausmann, 1906, to increased excretion. The latter also showed that the corrosive action on the intestines is decreased by habituation. Withdrawal does not cause any abstinence symptoms, even if the arsenic has been consumed for years. Joachimoglu, 1916, finds that the absorption of small doses, in dogs is not diminished by habituation; but that it is rather increased in accordance with the larger dose. However, habituation leads to increased resistance of the intestinal mucosa to the inflammatory and necrotic actions of arsenic, which would promote the absorption of toxic doses. For this reason, the absorption of large doses is smaller in habituated animals.

Chronic Arsenic Poisoning.—In this, chronic gastro-intestinal catarrh develops, possibly with ulceration. The less intense but persistent capillary paralysis gives time for widespread fatty and other degenerative changes. These affect first the endothelium of the capillaries, later the intestinal epithelium, and finally the cells of other organs—liver, kidney, heart-muscle, etc. The increased size of the fatty liver may cause pressure on the bile-ducts, consequently reabsorption of bile and icterus. There is a considerable tendency to the development of local effusions; swelling of the eyelids is fairly characteristic.

Impaired nutrition or toxic actions on peripheral nerves give rise to polyneuritis, with atrophy of the muscles, disturbance and paralysis of sensation, and of the special senses (blindness). The voice is frequently

altered, through paralysis of the vocal cords. The skin is also particularly affected. This action results in acne-like eruptions, exfoliation, and in falling out of hair and detachment of finger-nails. Herpes zoster sometimes develops. In a few cases a peculiar cutaneous melanosis may be noticed. This is not due to a deposition of arsenic, but to the formation of organic pigment granules in the epidermis and the exterior layers of cutis (Gans, 1914). The mucous membranes, especially the conjunctivæ, may also suffer.

The *diagnosis of chronic arsenic poisoning* may be somewhat difficult because the symptoms are sometimes quite obscure or resemble very closely those produced by chronic lead poisoning. There is some difference in the electric reaction of muscle and the absence of the blue line on the gums, which are characteristic of lead. But in other cases of the acute or chronic form the chemic examination is the only absolute means of making the diagnosis.

Chronic arsenic poisoning is treated by withdrawing the cause; the same measures may also be used as for chronic lead poisoning.

Causation of Nervous Phenomena.—There are not solely due to ischemia, even in acute poisoning, but must be partly direct; for they occur also in frogs, whose nervous functions are not immediately influenced by the blood supply.

Therapeutic Use in Nervous and Rheumatic Conditions.—Arsenic has been used in chorea, neuralgias, and the various rheumatic and arthritic diseases. Its effects are usually not striking, and may probably be referred to the general tonic action.

Effects on Metabolism.—These resemble phosphorus: *Therapeutic doses* check oxidation, and favor nutrition and growth, even in adults. The bones become larger and more compact. The condition of the skin is especially improved. The blood formation seems stimulated under suitable conditions. Gain of weight under arsenic is not always due to improved nutrition; for it may be simulated by edema. With rats, growth is markedly impaired by the continued administration of "therapeutic" doses of trioxide, *i.e.*, 0.015 to 0.05 mg. per Kg. per day, corresponding to $\frac{1}{60}$ to $\frac{1}{20}$ grain for man (Sollmann, 1921).

Excessive doses, as with phosphorus, lead to increased excretion of nitrogen, loss of weight, lessened gas metabolism, fatty degeneration of tissues, acidosis, decreased functionation of organs, destruction of blood, icterus, inability of the liver to form glycogen.

Hepatic Degeneration.—A further analogy with phosphorus poisoning consists in fatty degeneration of the liver cells, more marked with inorganic than with organic arsenic compounds. With intravenous injection, this is localized around the central veins; with hypodermic, it is more general (Ullmann, 1914).

Tissue Degenerations.—Toxic doses produce degenerative changes also in the kidneys, capillaries and blood. Pathologic tissues—malignant lymphomata, syphilitic gummata, etc.—are more susceptible and may be attacked even by therapeutic doses. Experimental tumors may also be liquefied and destroyed (Neuberg, Caspari and Loebe, 1912).

Factors Concerned in the Metabolic Actions.—The metabolic effect is quite variable, as it depends upon a number of mutually opposed causes. Among these are: the capillary dilatation; supposedly a direct action of arsenic upon the cells; and the action on the gastro-intestinal canal and on the kidneys. Small doses of arsenic increase the *gastric secretion* (Klocman, 1912); larger doses cause irritation, colic and diarrhea. In common with other intestinal irritants, it increases the output of uric acid (Abl, 1913).

The interaction of these factors may produce different results, so that the experimental data must be interpreted cautiously. As with all metabolic effects, only the gross features are known; the detailed actions on special organs would probably be even more important.

Therapeutic Use in Blood Diseases.—Arsenic is employed with limited success in various *leucemias* and *anemias*, especially in pernicious anemia;

and with iron in chlorosis. The results are generally referred to an action on the bone-marrow, but in some cases may be parasiticial. This is the basis of its use in *malaria* and *syphilis*.

Arsenic in Leucemia.—The results are not brilliant, but it usually improves the general conditions somewhat. The early, milder stages are most promising (Hahn, 1914). Sometimes marked rapid improvement occurs, as with radium or x-rays (Thayer); but this is exceptional.

Arsenic in Syphilis.—Arsenic was used in the days of Fallopius, and intermittently since. The difficulty with inorganic arsenicals lies in the toxicity of efficient doses. Herzfeld, 1911, advises the painless hypodermic or intramuscular injection of 1 per cent. sodium arsenite.

Actions on Bone-marrow and Blood Formation.—In normal animals, the effects of arsenic on the marrow are mainly destructive: atrophy of the fat cells, dilation and multiplication of the capillaries; increase of the leucoblastic, but not of erythroblastic cells (in contrast to hemorrhage). Larger doses cause hyaline degeneration and anemia. Similar changes are produced by other metals, organ extracts, peptones, etc. (Stockman and Charteris, 1903).

Saneyoshi, 1913, has also brought evidence that ordinary doses of arsenic do not normally stimulate the production of corpuscles. It is conceivable, but not demonstrated, that it acts more positively in anemia. von Hoesslin, 1913, claims generally restoration of hemoglobin and erythrocytes, decrease of lymphocytes and increase of neutrophiles. Its clinical effects might also be explained by the *antihemolytic action*, which has been demonstrated by Gunn and Fletham, 1911. The viscosity of the blood is sometimes slightly increased (Farmachidis, 1912).

Resistance of Erythrocytes.—As judged by hypotonic hemolysis, this is increased by therapeutic doses of arsenic in anemias. Hill, 1915, suggests this as an explanation of the clinical improvement.

Bones.—Arsenic leads to *thickening of the bones* and filling up of the Haversian canals (Gies, 1877), which may possibly justify its use in *rickets* and *osteomalacia*.

Skin.—Arsenic is extensively used, externally and internally, to improve the nutrition of the skin and hair, and in non-parasitic chronic skin diseases. It should never be used in acute inflammatory conditions. The results are often disappointing.

Hartzell, 1908, considers it most successful in recent, slowly spreading psoriasis; in chronic stationary lichen; and of limited value in pemphigus. Its injudicious use is often very harmful to the skin (pigmentation, etc.). Arsenic is used extensively in *veterinary practice*, to improve the appearance of cattle, by brightening the coat and increasing the subcutaneous (also the peritoneal) fat.

Glycosuria.—Arsenic treatment (not salvarsan) lessens alimentary glycosuria in dogs. It has no effect on epinephrine glycosuria (Begemann, 1912). It has been tried in *human diabetes*, but without much success. Arsenic poisoning causes rapid loss of glycogen from the liver, and leads to the formation of lactic acid. Small doses increase, larger doses retard *autolysis* (of the liver; Lacqueur and Ettinger, 1912). Small doses increase the *catalytic action* of the blood; larger doses have little effect (Duncker and Jodlbauer, 1911).

Cachectic Conditions.—Arsenic is employed as a tonic in a variety of these conditions, especially after malaria; in tuberculosis, and in asthma. Although it is easily understood how it may be of benefit, its actual use must be entirely empirical. We do not know sufficient about the nature of these conditions, nor can we predict the action of arsenic with sufficient certainty, to be able to foretell its results.

Dosage.—The ordinary tonic dose of arsenic trioxide is 1 to 2 mg., $\frac{1}{60}$ to $\frac{1}{30}$ gr.; of the liquid preparations, 2 to 3 drops, three times daily. For more energetic effects, it should be aimed to establish a tolerance by beginning with small doses, and gradually increasing these until some local manifestation of the arsenic appears—usually diarrhea, colicky pains, or conjunctivitis or swelling of the eyelids. As soon as these are seen, the amount must be diminished. The starting dose may be 3 drops of Fowler's solution, or 5 mg. of the oxide, three times daily, increased by 1 drop, or 1 mg., every day. All the official liquid arsenic preparations

contain 1 per cent. They may be given in water; the trioxide in pills, often with iron.

PREPARATIONS—INORGANIC ARSENICALS

**Arseni Trioxidum* (Arsen. Triox.), U.S.P.; *Acidum Arseniosum* (Acid. Arsen.), B.P., Arsenic Trioxide, Arsenous Anhydride, Arsenous Oxide, Arsenous Acid (White Arsenic), As_2O_3 .—White powder, or irregular masses of two varieties; one, amorphous, transparent and colorless, like glass; the other, crystalline, opaque and white, resembling porcelain. Both are odorless. "Powdered Arsenic Trioxide when administered in solid form . . . must consist of particles not greater than 0.0125 mm. in diameter" (U.S.P.x). Slowly sol. in 30 (glassy) or 100 (powdered or porcelain) parts of water; in 15 boiling water; sparingly in alc. Freely sol. in hydrochloric acid and alkalies. *Dose*, 2 mg., $\frac{1}{30}$ gr., U.S.P.; 1 to 4 mg., $\frac{1}{64}$ to $\frac{1}{16}$ gr., B.P., *maximum dose*, 5 mg., gr. $\frac{1}{12}$.

**Liquor Acidi Arsenosi* (Liq. Acid. Arsen.), U.S.P.; *Liq. Arsen. Hydrochl.*, B.P.—1 per cent. of As_2O_3 , 0.5 per cent. HCl. Clear, colorless, acid liquid. *Incompatibilities* (of all arsenic solutions): Salts of iron and of magnesium; lime-water; tannins. *Dose*, 0.2 c.c., 3 minims, U.S.P.; 0.12 to 0.5 c.c., 2 to 8 minims, B.P.

Arseni Iodidum (Arsen. Iod.), U.S.P., B.P.; Arsenous Iodide, AsI_3 .—Orange-red, inodorous, crystalline powder. Sol. in water (1:12), with partial decomposition. *Dose*, 5 mg., $\frac{1}{12}$ gr., U.S.P.; 3 to 12 mg., $\frac{1}{20}$ to $\frac{1}{5}$ gr., B.P.

Liquor Arseni et Hydrargyri Iodidorum (Liq. Arsen. et Hydrarg. Iod.), U.S.P. B.P. (Donovan's Solution).—Represents 1 per cent. each of AsI_3 and HgI_2 . *Dose*, 0.1 c.c., $1\frac{1}{2}$ minims, U.S.P.; 0.3 to 1.2 c.c., 5 to 20 minims, B.P.

**Liquor Potassii Arsenitis*, (Liq. Pot. Arsen.), U.S.P.; *Liquor Arsenicalis* (Liq. Arsen.) B.P. (Fowler's Solution; *Liquor Kalii Arsenicosi*).—Potassium arsenite, corresponding to 1 per cent. of As_2O_3 , colored and flavored with Co. Tr. Lavender. A clear or faintly opalescent liquid with a pink color and a slight odor of lavender. It is slightly alkaline, and therefore *incompatible* with alkaloidal salts (in addition to the incompatibilities mentioned under Liq. Acid. Arsen.). *Dose*, 0.2 c.c., 3 minims, U.S.P.; 0.12 to 0.5 c.c., 2 to 8 minims, B.P. *Maximum dose*, 0.5 c.c., 8 minims.

Sodii Arsenas Anhydrosus (Sod. Arsen. Anhydro.) B.P.—Freely sol. in water (1:3.1). *Dose*, 1.5 to 6 mg.; $\frac{1}{40}$ to $\frac{1}{10}$ gr., B.P.

Liq. Sod. Arsen., B.P.—1 per cent. of Na_2HAsO_4 . *Dose*, 0.12 to 0.5 c.c., 2 to 8 minims, B.P.

ORGANIC ARSENIC COMPOUNDS

Both trivalent and pentavalent arsenic can be readily introduced into a large variety of organic molecules. In this non-ionic condition it does not immediately produce the ordinary arsenic effects; but in the course of the oxidation and reduction and other cleavage which these organic molecules undergo in the body, more or less ionic arsenic is gradually split off, and this produces, the ionic arsenic actions, in a delayed and generally in a milder form. The decomposition is generally slow, and progresses through intermediate stages of simpler organic molecules, so that a considerable part of the arsenic is probably excreted in organic form, before the cleavage is completed. In the meantime, the original compounds and their organic derivatives have the opportunity to exert their distinctive effects. These are much less toxic to the higher animals than is ionic arsenic; they lack particularly the paralyzing action on capillaries. On the other hand, they are much more toxic to protozoan parasites, trypanosomes, spirochetes, amebae, plasmodia etc; so that their administration arrests these protozoan infections, especially syphilis, sleeping sickness and spirillosis. The compounds that are practically useful, however, have very little parasitical action in vitro; they require the cooperation of the host to become effective. This applies also to most of the other anti-protozoan agents. In the case of the arsenicals it is probably due to transformation into more active cleavage products; other explanations may apply to the other agents. The toxicity and efficiency of the organic compounds are determined by a number of complex factors, especially the relation of

absorption, distribution, sojourn and storage; and the rate and course of the decomposition. These are only imperfectly known. The direct administration of the active decomposition products of the arsenicals is not feasible, because they are too toxic when they are suddenly introduced. In the digestive tract also the organic molecules are likely to undergo toxic cleavage, so that they must generally be administered parenterally. The compounds of the arsphenamine type tend to form colloidal solutions, and their intravenous injection may produce colloidal reactions with the blood. These differ for the individual compounds and can be minimized by careful technic in the preparation and injection of the solutions.

Chemical Structure.—The therapeutic organic arsenic compounds may be arranged under two groups:

(1) The *substituted arsenic acids* (with *pentavalent arsenic*) formed by replacing the OH of arsenic acid by alkyl or aromatic groups as follows:

Cacodylic Acid: $\text{O.As}(\text{CH}_3)_2\text{OH}$.

Arsanilic Acid: $\text{O.As}(\text{C}_6\text{H}_4\text{NH}_2)(\text{OH})_2$.

Acetylarsanilic Acid: $\text{O.As}(\text{C}_6\text{H}_4\text{NH.CH}_3\text{CO})(\text{OH})_2$.

(2) The *arsphenamines* (with *trivalent arsenic*) comprising arsphenamine (dioxy-diamino-arseno-benzol) and derivatives formed by introducing

sulphur containing chains into their amine group.

Arsenic Content.—The quantity of arsenic in the compounds is of less importance than the manner in which it is combined.

Arsenic trioxide contains 75.74 per cent. of arsenic; crystallized sodium arsenate, 24 per cent.; sodium cacodylate, 35.6 per cent.; sodium arsanilate (atoxyl) 22 to 26 per cent.; arsphenamine, 31.6 per cent.; neoarsphenamine, about 20 per cent.

Chemotherapy.—This term was restricted by Ehrlich to the parasiticide treatment of infections by chemical agents. Such "specific remedies" had been discovered empirically for several protozoan diseases; namely quinine against malaria; mercury against syphilis; and ipecac against amebic dysentery. Ehrlich 1909, sought systematically to extend this field by the search for substances which would combine a relatively high toxicity for the parasites with a relatively low toxicity for the host; *i.e.*, which would have a favorable "chemotherapeutic index,"

or in other words, a low ratio of $\frac{\text{(Minimal effective dose)}}{\text{(Minimal lethal dose)}}$. He assumed

that the relative toxicity for parasite and host would depend chiefly on the selective affinity of these for the toxic agent, and believed therefore that the therapeutic index would depend on the ratio of "parasitotropism" to "organotropism" (Bechhold and Ehrlich, 1906). It is now recognized that the matter is not so simple; that destruction of the parasite *in vivo* often does not depend on the direct "parasitotropism" of the agent, but that it generally demands the cooperation of the tissues of the

host, through mechanisms which are not clear, and which may vary in different cases; so that "organotropism" may not be a hindrance, in fact that it may be a necessary condition for the therapeutic effect (Dale, 1923, 1924). However, the tropism theory was a mere working hypothesis, and was not directly involved in Ehrlich's work. This took the direction of determining experimentally the therapeutic index of a variety of substances, and culminated in the discovery of the trypanosomicidal dyes and arsenicals, and of the more widely applicable arspenamine; and this in turn led to the introduction of the other parasitocidal metals.

Clinical experience had already shown that protozoan infections, malaria, syphilis and amebiasis, may yield to drugs; whilst no bacterial infection of man had been suppressed *in vivo* by chemicals. Evidently bacteria are more resistant, so that protozoa offer the more promising approach. The trypanosomes which cause the tropical "sleeping sickness" and similar diseases in animals are easily transmitted to white mice, and therefore presented a convenient test of therapeutic efficiency. Ehrlich and Shiga, 1904, studied in this way a great variety of substances. The search was at first haphazard; but when partly successful results were obtained, it was sought systematically to improve these by altering the side-chains so as to increase their specific affinity for the chemoreceptors of the parasites. The effective agents found by Ehrlich and by independent workers belong to four groups: (1) Benzidine Dyes (Trypan red, etc.); (2) Basic Triphenylamine dyes (Malachite Green, Parafuchsin, etc.); (3) Arsenic Compounds; and (4) Antimony and Bismuth compounds.

These investigations were important mainly by elucidating the general principles of chemotherapy; for it was soon found that the detailed results could not be transferred directly to man: Agents which were effective in one species of host were often much less effective in another. Nor can the results for one kind of parasite be transferred to another kind. The dyes in particular were not practically available, since they cause intense coloration of the body, irritation and necrosis of the skin, and severe cachexia. These objections do not hold for the arsenic or antimony compounds; but with these also the efficiency for man can not be deduced from the animal experiments. However, the trypanosome studies, with somewhat refined technic (Voegtlin and Smith, 1920; Dale and White, 1922) are very useful for preliminary orientation. For antisypilitic agents, the results should be checked on rabbits inoculated with syphilitic virus (W. H. Brown and Pearce, 1916; Pearce, L. and Brown, 1922). The final decision must rest with clinical tests on man.

Acquired Resistance ("Fastness") of the Parasites.—The injection of ineffective doses of the chemotherapeutic agents may render the trypanosomes more resistant to the agents of the same group, although they preserve their susceptibility to the other groups (Ehrlich, 1907). The resistance is preserved for many generations, even if the resistant parasites are passed through a succession of hosts, although the passage through different genus of mammals may produce modifications (Voegtlin, Dyer and Miller, 1924). It is not known whether there is a genuine habituation, or mere a selective survival of the more resistant strains; the latter appears more likely. The decision would be one of practical importance; for if ineffective doses really induce tolerance, they would render treatment more difficult; if they only lead to the survival of the more resistant strains, they would not alter the ultimate difficulty of the treatment, but might in the meantime be useful by checking the less resistant strains. Ehrlich,

who took the former view, thought it essential that the parasites must be killed by one single massive dose of the antiseptic ("*Therapia Magna Sterilisans*"). Clinical experience has shown this to be impossible and fortunately also unnecessary. There may be advantage, however, in employing simultaneously or successively agents belonging to different groups; for strains resistant to atoxyl, for instance, need not be especially resistant to mercury (Nierenstein and Todd, 1907). The acquisition of drug resistance by spirochetes has not been demonstrated *in vivo*; it has been induced *in vitro*, *i.e.*, in cultures, but is lost in a few generations, so that it would not be important therapeutically (Akatsu and Noguchi, 1917).

Arsenic in Protozoan Infections.—Arsenic has had some reputation in syphilis since the times of Fallopius (Herzfeld, 1911), and the cacodylate was employed in this disease by Gautier in 1896. Arsenic was also used in malaria with fair success. These instances were, of course, entirely empirical. Experimentally, Laveran and Mesnil, 1902, found that arsenous acid causes the temporary disappearance of trypanosomes from the blood of infected mice. It has also been tried in human cases (Merck's Reports, 21:223) but the really effective dose is too dangerous. A more selectively parasitotropic modification was found by H. W. Thomas, 1905, in arsanilic acid (atoxyl). This compound was first prepared by Bechamp in 1863, and its general actions investigated by F. Blumenthal, 1902. It was then used as an arsenic substitute in skin diseases, anemias, etc. Its toxicity to mammals is much less than that of arsenic trioxide, its acutely fatal dose being some forty times as great. It proved highly efficacious in mice and was tried extensively in human sleeping sickness, especially by Robert Koch, 1907. In man, however, it often causes severe toxic effects, and the clinical results have not come up to expectation.

SODIUM CACODYLATE

The effects of cacodylic acid (dimethylarsenic acid) are essentially those of the inorganic arsenic, to which it is partly reduced in the body. Since this reduction occurs but slowly, the action is more prolonged and less toxic, and the local irritant effects are avoided. It has therefore some advantage. On the other hand, the degree of reduction, and therefore of the effect, is variable; and the cacodylate, especially when given by mouth, imparts a *garlic odor* (from cacodyl oxide, $\text{As}_2(\text{CH}_3)_4\text{O}$), to the breath, sweat, urine, etc. To avoid the more rapid reduction in the stomach, intestines and liver (Heffter, 1901), it is usually administered hypodermically or intramuscularly. Excessive doses produce *toxic symptoms*, due mainly to the ionic arsenic (Schulz, 1879; Heffter, 1901; Dawes and Jackson, 1907), although the cacodyl molecule may conceivably play a part.

Therapeutically it is used in the same condition as inorganic arsenic. The *dosage* is from 0.025 to 0.15 Gm., $\frac{1}{2}$ to $2\frac{1}{2}$ gr. per day, as pills; or hypodermically, as a freshly prepared warm sterile solution; also by enema. In *syphilis*, Oppenheim, 1907, and J. B. Murphy claimed some success (single intramuscular injection of 2 to 4 gr.); but Cole, 1916, showed it to be inefficient even with doses that produced albuminuria and hematuria (intravenous injection of 0.5 Gm. every 3 days for 4 to 6 doses). Brayton, 1917, confirmed its lack of value, and pointed out that it produces fibrosis of the vein in nearly every patient, and is sometimes followed by severe nephritis.

Fate of Cacodylate.—A part is excreted unchanged in the urine (on hypodermic injection, 6 to 10 per cent., Dawes and Jackson); but the greater portion undergoes reduction, first to the volatile cacodylic acid, and a small part finally to inorganic arsenic.

A bibliography of cacodylate is given by de Biehler, 1907. It was introduced into therapeutics mainly by Gautier, 1899. The clinical side actions are discussed by Seifert, Nebenwirk, 1915, page 172.

PREPARATIONS

**Sodii Cacodylas* (Sod. Cacodyl.), U.S.P.—About 73 per cent. of sodium dimethylarsenate, $\text{Na}(\text{CH}_3)_2\text{AsO}_2$. White, deliquescent prisms or granular powder, without odor or taste. Very sol. in water (1:0.5) freely sol. in alc. (1:2.5). *Dose*, 0.06 Gm., 1 gr., U.S.P. in pills, hypodermically, or by enemas. *Maximum dose*, 0.2 Gm., 3 gr.

ARSANILIC ACID DERIVATIVES

These are related to arsenic and cacodylic acid as follows:

*The commercial product contains a half-molecule of water of crystallization.

SODIUM ARSANILATE (ATOXYL)

General Statement.—This salt, $\text{C}_6\text{H}_4(\text{NH}_2) \cdot \text{AsO} \cdot \text{OH} \cdot \text{ONa}$ (sodium aminophenyl-arsenate), may be derived from sodium arsenate by replacing one hydroxyl by aniline. (It was at first believed to have a different constitution.)

Under the misleading name of “Atoxyl” (for the substance is quite dangerous) this salt has received considerable prominence as an organic form of arsenic, effective in all conditions in which arsenic is indicated; especially in sleeping sickness, in which it is superior to many other arsenicals; and in syphilis and other protozoan affections, in which it is inferior to arsphenamine (Tomaszewski, 1908; Greven, 1910).

In sleeping sickness it causes prompt disappearance of the trypanosomes from the blood, but they may recur, so that the injection must be repeated every seven days (R. Koch, 1907, *Deut. Med. Wochenschr.*, 33:1889. This paper discusses also the details of dosage and administration). Kopke's (1906) clinical results were less favorable. The parasites become gradually resistant. B. Moore, Nierenstein and Todd, 1907, therefore recommended alternation with mercury which acts on another stage of development (Hodges, 1908).

The chief objection to “atoxyl” is the fairly frequent occurrence of toxic effects, especially permanent blindness, from therapeutic doses. These, as well as the therapeutic actions, are mainly due to the reduction products, probably trivalent, which are formed in the organism.

Sodium arsanilate should not be given by mouth, since it would be decomposed and rendered more toxic. The hypodermic dosage is from 0.02 to 0.2 Gm. every other day. The injections are said to be nonirritant.

Toxic Effects of Atoxyl in Man.—Acute symptoms occur especially with doses exceeding 0.5 Gm. They resemble partly those of ordinary arsenic poisoning, and consist in nausea and vomiting; colic, vertigo, general weakness and somnolence; neurites, pain in limbs; deafness, retention of urine, sometimes nephritis; iritis, and not uncommonly permanent optical atrophy (Hallopeau, 1907; Fordyce, 1911). Chronic poisoning presents the ordinary phenomena of chronic arsenic intoxication. The clinical side actions are discussed by Seifert, *Nebenwirk.*, 1915, page 178.

Optic Effects of Atoxyl (and Arsacetin).—The eye symptoms usually appear within a few weeks (in Koch's series only when the dosage exceeded 0.5 Gm.). They begin with scintillation, cloudiness, diminished vision, and contraction of the visual field (Fordyce, 1911). The anatomic changes in animals as well as in man (Birch-Hirschfeld and Koster, 1910) show degeneration of the optic nerve and retinal ganglia, the retina being the more susceptible. The cerebral cells are also injured.

Inorganic arsenic and cacodyl may also cause optic neuritis (of the nicotine type), but only very rarely (Sulzer, 1911). Arsphenamine does not seem to cause the optic injury.

Protein Metabolism.—Boyd, 1911, found in two human cases that arsanilate lessens the excretion and causes the retention of nitrogen.

Toxic Effects of Atoxyl on Animals.—The acute toxicity of atoxyl is perhaps one-fourth of that of inorganic arsenic; and injections have no acute effects on blood pressure. However, they produce chronic effects and anatomic lesions, the distribution of which varies quantitatively in different animals (Igersheimer and Itami, 1909); dogs show mainly characteristic renal hemorrhages with secondary nephritis; cats exhibit mainly nervous symptoms with histologic lesions in the brain and cord. Rats and rabbits are intermediate. The distribution of the arsenic corresponds with the differences in effects. In cats, *f.z.*, the arsenic is found mainly in the nervous system; in dogs, in the parenchymatous organs (Igersheimer and Rothmann, 1911). Mammals also show the optic degeneration, both on local and systemic administration. (The toxicity of atoxyl has also been investigated experimentally by Cianni, 1908.) In *frogs*, Sanno, 1911, found that the toxicity is greatly increased by raising their temperature, presumably by favoring its transformation into more toxic products. (A similar influence is found with colchicine.)

Difference in the Actions of Inorganic Arsenic and Atoxyl.—The atoxyl effects run a slower course, and are devoid of the local actions of inorganic arsenic. This might be due simply to the slow liberation of ionic arsenic. Some of the other differences, such as the optic changes, are more characteristic. They might be attributed to the distinctive localization of the arsenic. It is possible, however, that they are produced by some organic decomposition product. Artificial reduction products are much more toxic than the arsanilate, to mammals as well as to protozoa.

Reduction.—Since arsanilic acid is itself practically non-toxic to trypanosomes, it follows that it must undergo some change in the tissues. The degree of decomposition and therefore the efficiency and toxicity, vary in different animals. The decomposition products have not been isolated, but it is probable that they must contain the arsenic in trivalent form. (Rothermundt and Dale, 1912, however, believe that it is directly trypanocidal.) The artificial reduction products, which vary according to conditions, are much more active than the arsanilate, and paraminophenol-arsenous acid kills the parasites in the test-tube. B. T. Terry, 1912, has found that emulsions of liver and blood reduce arsanilate into directly effective products.

Excretion.—After a single dose of arsanilate, the arsenic is excreted promptly and exclusively by the urine (Croner and Seligmann, 1907). With continued administration, the excretion is somewhat more prolonged; the greater part leaves within three days (Simonet, 1910), but traces continue to be excreted for three weeks (Welander, 1909). The effects are therefore somewhat cumulative. A small part leaves by the feces. Only a small proportion is excreted in inorganic form.

A relatively large part of the arsanilate remains for a long time unchanged in the blood and tissues (Simonet, 1910), but a part is fixed and changed in the cells. The characteristic distribution in different animals is described by Igersheimer and Rothmann, 1909.

PREPARATIONS

Sodii Arsanilas (Atoxyl).—Occurs as white, odorless crystals, of faintly salty taste. Readily sol. in water (1:5 or 6). *Dose*, 0.02 to 0.2 Gm., $\frac{1}{3}$ to 3 gr., hypodermically every other day, gradually increasing if necessary until the single dose reaches 0.65 Gm., 10 gr., and until a total of 6.5 Gm. (100 gr.) has been given. It must not be administered by mouth.

Arsacetin. Sodium acetyl arsenilate, $C_6H_4(NH.CH_3.CO)AsO.OH.ONa + 4H_2O$.—Is less toxic acutely than arsenilate, and is highly parasiticial in mice. In man, however, it is no more effective than the original substance, and is equally liable to cause blindness (J.A.M.A., 1910, 54: 1559); and it is even more apt to produce renal irritation (Borchers, 1910). Its only advantage is the greater stability, so that it can be sterilized without decomposition. The *dosage*, hypodermically, is 0.1 to 0.5 Gm.

Ehrlich, 1907, noticed that some mice treated with arsacetin acquire the curious waltzing habit.

TRYPARSAMIDE

This pentavalent arsenic derivative, sodium phenylglycinamide arsonate, has been found highly effective in certain forms of trypanosomiasis (Tr. gambiense, African sleeping sickness and mal de caderas) and fairly successful in selected cases of cerebral syphilis. It also cures the "black-head disease" of turkeys. Its parasiticial action is more marked for trypanosomes than for spirochetes. It penetrates the tissues, including the central nervous system, more readily than most arsenicals. Its excretion is rapid, so that there is no cumulation. Its acute toxicity is low; doses corresponding to 4 Gm. of arsenic have sometimes been injected without bad effect; but even the smaller therapeutic doses usually produce more or less visual disturbance and sometimes permanent blindness. A few patients develop jaundice. Other untoward effects are unimportant and exceptional.

The compound was developed especially through the Rockefeller Institute; it was synthesized by Jacobs and Heidelberger, 1910; investigated on animals by W. H. Brown and Pearce, 1919; and in human trypanosomiasis by Pearce, 1921. Its application to neurosyphilis is due to Loevenhart and Lorenz of Wisconsin, 1922 and 1923.

Use in Trypanosomiasis.—In trypanosoma Gambiense infections, a single intravenous injection causes the complete disappearance of the parasites from the human blood; but they are likely to recur after 3 days to 6 months. If the injections are repeated in courses, the cure is complete and permanent (L. Pearce, 1921, 1925; Pearce and Brown, 1922). Other trypanosome infections (surra, durine, nagana) are not so amenable.

Therapeutic Results in Neurosyphilis.—Tryparsamide probably does not act clinically as a spirocheticide, for it is practically not effective against the primary and secondary stages of syphilis, nor against the gummata, and has apparently little effect in the early cerebrospinal manifestations. Its value is confined mainly to the disseminated sclerosis, before this has resulted in irreparable degeneration of the nerve cells. Loevenhart is inclined to attribute the effect to the provocation of local inflammatory reactions, that would resolve the sclerotic lesions.

Of patients with early paresis, 40 to 50 per cent. show improvement or complete remission. In tabes, the results are less striking; but there is generally some relief of pain, and sometimes improvement of coordination. Most patients improve in physical condition and gain in weight. The Wassermann reaction decreases, but not parallel to the symptoms; mercurial treatment is therefore not to be neglected. Advanced cases of sclerosis are not benefitted; they may indeed react with temporary exacerbation. The improvement in the early paresis is sufficiently frequent and marked to class tryparsamide as a valuable therapeutic agent, were it not for the risk of blindness. This must be carefully weighed. Generally therefore tryparsamide would be restricted to cases of the type in which it has been most successful, and which have failed to respond to other treatment.

Tryparsamide Amblyopia.—Minor temporary impairment of vision occurs in 10 to 50 per cent. of the patients, both those with trypanosomes

and with spirochetes; in 5 to 10 per cent., the minor impairment remains permanent; and in 1 to 5 per cent., the impairment is serious. The occurrence and outcome are at present largely unpredictable and unavoidable. However, they follow most frequently on the first injection, and do not seem to occur after the fourth injection. Nor do they seem to occur in non-infected individuals. It would therefore appear that they are not due to the arsenical, but rather to an immunologic reaction. It is doubtful whether preexistent syphilitic optic lesion contraindicates or indicates tryparsamide. The optic phenomena are further discussed by A. C. Woods and Moore, 1924.

Other Untoward Results.—The arsenical and direct toxicity of tryparsamide is remarkably low. Even minor disturbances are rare; the more common are dizziness and tinnitus; more exceptional are nausea, vomiting, nitritoid reactions, urticaria, mild dermatitis. A few patients are jaundiced.

Administration.—Tryparsamide should not be administered by mouth. It may be given hypodermically or intramuscularly, but is best injected intravenously; the dose being dissolved in 10 c.c. of sterile water, filtering if necessary. It is freely soluble in cold water and the solution should not be heated, or toxic decomposition products may be formed. The solutions should be prepared daily, and should not be exposed to strong light or to chemical fumes. The drug itself is stable under ordinary conditions. It is a white, odorless, crystalline powder, containing 24.6 per cent. of arsenic.

Dosage in Neurosyphilis.—Tryparsamide is administered in courses of 8 to 15 injections of 2 to 3 Gm. (not to exceed 0.04 to 0.05 Gm. per Kg.), at intervals of not less than a week. Intermissions of two weeks to two months are made between courses. It is probably advisable to continue the treatment for several years. Mercury should be administered in the usual manner.

"Bayer 205."—This substance is usually successful in human infections by *trypanosoma gambiense*, and is also very effective in other trypanosomal diseases. Its composition has been kept secret; it does not contain a metal and it may be surmised that it is related to the trypanosomidal dyes. It is, however, colorless, easily soluble in water, and can be administered intravenously.

The most striking phenomena is the duration of the effect: a single injection not only frees the blood from trypanosomes, but renders the animal resistant to infection for days to months, and during this period, the serum is curative when injected into other animals. The substance itself, however, has little effect on the parasites *in vitro*; in animals also, the action is delayed for several days; and the therapeutic response is greatly influenced by the species of the infected animal. It appears therefore that some complex cooperation of the host is involved in the production of the parasitocidal substance. This is not an ordinary immune substance, for this activity is not destroyed by heating. The serum proteins undergo a marked change through the "205;" they become incoagulable by heat, mercury or tannin (references, Dale, 1924). Large doses in man are hemolytic, and result in hemorrhages and nephritis (M. Martin, 1923).

STOVARSOL

This compound, acetyl-amino-hydroxyphenyl-arsonic acid, has been introduced for the treatment of amebic dysentery; for the encysted as well as for the active stages. Further experience is required. The substance is not used against syphilis or trypanosomes. Unlike the other organic arsenicals, it is administered by mouth: 0.25 Gm., 4 gr. for adults, 2 or 3 times per day, for seven days. It contains about 27 per cent. of arsenic.

THE ARSPHENAMINES

Arsphenamine (Salvarsan, 606, Arsenobenzol) and its derivatives combine a high degree of antisiphilic action with relatively low toxicity, and have therefore a very important place in therapeutics. Voegtlin, 1925, has reviewed the pharmacologic literature.

Composition.—Arsphenamine is the dihydrochloride of diamino-dihydroxy-arseno-benzene. The base itself (see structural formulae, below) has two amino and two phenolic groups, which confer basic and acidic characters respectively, so that the arsphenamines is an ampholyte, like the proteins. The addition of successive molecular quantities of an alkali, for instance, sodium hydroxide, to the dihydrochloride (*i.e.*, the commercial arsphenamine), removes first one and then both HCl groups, forming the monohydrochloride, and then the neutral base; further quantities of the hydroxide then neutralize the H of the phenolic group, yielding the mono and then the di-sodium salt.

Neoarsphenamine and sulpharsphenamine are formed by substitution in the amido groups:

Silver-arsphenamine contains silver, but its constitution is not established. It is possible that the silver is present merely as admixed colloidal metal (reference, Voegtlin).

There are also many other derivative, but their importance is too small at this time to require discussion.

Impurities.—Arsphenamine and its derivatives are so instable that they cannot practically be prepared in pure form. The impurities vary with the method of preparation, and for the most part have not been identified. They are usually more toxic than the arsphenamines, so that it is necessary to determine the toxicity of each lot, by intravenous injection into rats (or mice). This does not assure uniformity of action, but only insures against excessive toxicity. Impurities may also develop on storage. With arsphenamine this probably does not occur with properly prepared ampules; but some lots of the much more labile neoarsphenamine appear to deteriorate in spite of the ordinary precautions. Fortunately this is usually indicated by obvious changes of their appearance.

Colloidal Condition.—The arsphenamines exist in solution largely in a colloid condition. They dialyze slowly; they are precipitated at the isoelectric point; concentrated solutions tend to gelatinize; they can be "salted out" by high concentrations of neutral salts; etc., (Bauer; Raiziss

and Gavron; Raiziss, 1922; H. Freundlich et. al., 1923). The degree of dispersion varies with the nature of the compound, the pH of the solution and other conditions. The colloidal characters are especially marked with the acid arspfenamine salts; and are important as the cause of the immediate "nitritoid" and toxic reactions.

Reaction.—Arsphenamine (*i.e.*, the dihydrochloride) forms strongly acid solutions; its sodium-salt, *i.e.*, the form which is administered therapeutically, is strongly alkaline; neutralization precipitates the insoluble base. Nearsphenamine solutions are practically neutral. Sulpharsphenamine solutions are strongly acid. These and the other derivatives formed by substitution in the amino group show a greater solubility in water through a wider range of pH, and have a higher degree of dispersion. The typical pH of the 2.4 per cent. = $\left(\frac{M}{20}\right)$ arspfenamine salts

is for the dihydrochloride, about 2; monohydrochloride, 2.7; monosodium salt 11.4; disodium salt, 11.8 (Elvove and Clark, 1924). The isoelectric point is at pH 3.39 (Hunter and Patrick, 1925); but there is little ionization between pH 3 and 10; between this range, the base is practically insoluble. It can not therefore exist in the blood in true solution, and even in colloidal solution only if it is stabilized by protective colloids.

Viscosity and Reaction.—The acid solutions of arspfenamine have a relatively high viscosity which increases progressively as the isoelectric reaction is approached. The viscosity of the sodium salts is not much higher than that of water.

Oxidation.—This is the main cause of the decomposition of the arspfenamines. The rate of oxidation varies with the access of oxygen, the temperature (Masucci, 1922) and the pH; and with the character of the compound. Arspfenamine hydrochloride and base are fairly stable; the sodium salts oxidize readily, the rate increasing rapidly with the alkalinity of the solution. The arspfenamine is very unstable in the presence of oxygen, even in neutral solutions. Sulpharsphenamine in its acid solutions is highly resistant to oxidation (Voegtlin and Johnson, 1922).

Bio-assay.—Arsphenamine and its derivative must be tested on animals for a limit of toxic impurities. The tests must be made with strict adherence to the technic prescribed in the United States by the Hygienic Laboratory, (N.N.R.; Lake, 1921; G. B. Roth, 1924). The drugs are injected intravenously into rats, and as the susceptibility of the animals varies, it is required that at least 60 per cent. survive the specified dose for the number of days that is specified for each drug; namely (per Kg. of rat): 100 mg. of arspfenamine; 120 of silver arspfenamine; 200 of nearsphenamine; or 300 of sulpharsphenamine. The tests are made by the manufacturers and checked by the Hygienic Laboratory. In England and Germany, the tests are made on mice.

Individual animals may differ considerably in susceptibility to the same specimen of drug. This holds particularly for nearsphenamine (Heyl, F. W. et al., 1923).

Therapeutic Uses.—The arspfenamines are used with marked success in a variety of protozoan and spirochetal infections: particularly in syphilis, Vincent's angina, frambesia or yaws (Nichols, 1910), relapsing fever (Iversen, 1910), rat-bite fever, and amebic dysentery, (Wadhams and Hill, 1913). They appear less effective against malaria and trypanosomes, in man; and ineffective against yellow fever. Suggestive results have also been reported in anthrax. They have also been tried as *substitutes for ordinary arsenic*, in skin diseases, anemias, as a tonic, etc., but without serious advantage.

Experimental Results.—The introduction of arsphenamine was the direct outcome of the chemo-therapeutic studies of Ehrlich. The substance was prepared by Berthelm, and tested by Ehrlich and Hata, 1910. They found that a single injection of a harmless dose freed animals completely and permanently from spirillosis and certain other protozoan infections, including syphilitic spirochetes.

Spirochetal Cultures.—These are killed by the following concentrations of antiseptics (Akatsu, 1917):

Mercuric chloride.....	1:100,000
Arsphenamine.....	1: 7,500
Neo-arsphenamine.....	1: 2,500
Phenol.....	1: 2,500
Formaldehyde (absolute).....	1: 1,800
Iodine in KI.....	1: 75

The susceptibility of spirochetes is materially greater in the presence of enzymes from the liver, and especially from the blood (Bronfenbrenner and Noguchi, 1913). Bacteria are generally not very susceptible, but according to Roos, 1912, arsphenamine is directly germicidal to anthrax, even in living animals. It is ineffective in rabbits (Mejia, 1913).

Results in Human Syphilis.—Arsphenamine has proved remarkably successful, although it has not fulfilled the original hope of complete cure by a single injection. The conditions are evidently not as simple as in experimental animals.

Early Lesions.—Complete success, similar to that in animals, occurs only in specially favorable conditions, when it is injected during the primary stage. Ordinarily, the spirochetes begin to disappear in a few hours from the chancre and condylomata, and are completely absent in one or two days, so that arsphenamine abolishes promptly the main dangers of contagion. A single dose, however, is not likely to reach all the parasites, so that they generally return unless the injections are repeated for at least one "course." In the latter case, the early use of arsphenamine prevents the development of secondary symptoms and of the positive Wassermann reaction and practically always effects a clinical cure (Fournier and Guenot 1919); the success being in direct ratio to its early use.

Later Active Stages.—A single injection of arsphenamine also produces very marked and rapid improvement after the Wassermann reaction has become positive; so that the results of one administration may equal those of months of mercurial treatment. All the syphilitic symptoms regress at once, except those that have an anatomic basis. Surface lesions and ulcers are repaired with astonishing rapidity. Gummatous and periosteal lesions are usually much improved. Malignant cases, and those that were resistant to mercury, also cede to arsphenamine. The Wassermann reaction generally becomes negative after about five days (sometimes with a temporary exaggeration). The improvement, however, is never permanent after a single injection, and the Wassermann reaction and other phenomena would return in a short time. The arsphenamine is therefore always administered in courses, generally supported by mercury. Under these conditions, the syphilitic phenomena remain completely suppressed and the Wassermann reaction negative. After some 2 or 3 years of such treatment, the disease is permanently arrested in the majority of patients and does not recur even though treatment is stopped. The patients should, however, be kept under observation periodically. The arrest of the disease does not necessarily mean that the disease is completely eradicated. Warthin, 1918, believes that some of the spirochetes perpetuate themselves indefinitely after adapting themselves to the host so as to

produce only slight but continued local reactions, resulting in fibrous degenerations. Such patients cease to be infectious, so that marriage is generally considered permissible after a lapse of five years.

Arsphenamine is much less successful against the fibrous and perivascular syphilitic manifestations, aortitis, tabes, general paresis etc. Presumably these are not as accessible to the arsphenamine or to its active decomposition products.

Comparison of Arsphenamine and Mercury.—The most important advantage of the arsphenamines is the rapid action, which brings the disfiguring or dangerous lesions, especially those of the mucosae, under prompt control, limits contagion, and is highly important in malignant cases. The ultimate results are best if both agents are utilized.

Therapeutic Comparison of the Arsphenamines.—The therapeutic results with the various arsphenamines are so similar that clinicians have been unable to agree as to their relative value. The majority perhaps consider arsphenamine proper as somewhat more reliable. On the other hand it is the most inconvenient to administer, and is most subject to acute reactions. Neoarsphenamine is probably the most widely used, as it lacks these disadvantages; but the delayed toxicities are at least as great and the susceptibility to these is more variable (Pearce and Brown, 1917). A rather serious objection is the occasional toxic deterioration in the ampules. Sulpharsphenamine is less toxic and more stable, and can be administered hypodermically or intramuscularly (Stokes and Belin, 1924) but is perhaps less reliable. It is employed mainly when intravenous injection is undesirable. Silver-arsphenamine possesses the toxicity and disadvantages of ordinary arsphenamine. It was claimed that the silver enhanced the efficiency, (Kolle, 1920) but this is doubtful.

TOXIC AND SIDE-ACTIONS OF THE ARSPHENAMINES

The slow *intravenous injection* of the usual solutions does not give rise to notable local phenomena. There is sometimes intense but fleeting pain in the shoulder, possibly from endocardial irritation. A peculiar disagreeable odor and taste, garlic, ether or suet, is also often perceptible for a short time.

Injection of solutions of arsphenamine or neoarsphenamine into the *subcutaneous tissue* produces quite serious irritation. With acid and alkaline solutions this is due partly to the reaction, partly to the arsphenamine; acid arsphenamine causing very severe and persistent pain; the alkaline solutions of arsphenamine may produce corrosion, ulceration and gangrene. Neutral suspensions of arsphenamine also result in severe but slower irritation, and the absorption is incomplete (H. E. Robertson, 1913; Takahashi, 1914). *Neoarsphenamine* solutions, although neutral, also produce severe inflammation, infiltration and fibrosis, which may proceed to abscess. If an injection should accidentally be made into the subcutaneous tissue, it should be aspirated and promptly diluted by injecting normal saline solution liberally into the site (Dietel, 1925). Thiosulphate solution, which is often used, acts similarly and appears to have no material advantage.

Systemic Toxic Effects.—These are not uncommon, for arsphenamine therapy requires full doses of a toxic agent, administered intravenously, *i.e.*, by the most dangerous route. The clinical toxic phenomena present a considerable variety, but may be conveniently grouped as follows:

A. Immediate: (few minutes).—Anaphylactoid collapse (nitritoid) symptoms.

B. Early: (start in 1 to 4 hours).—Febrile course, kidney and skin reactions.

C. Delayed: (after 24 hours).—

1. Febrile
2. Herxheimer
3. Arsenical

D. Severe late (about 3 days).—

1. Dermatitis exfoliativa.
2. Cerebral Type.
3. Icteric Type.

E. Neurocurrences.

Frequency, Danger, and Precautions.—Some degree of systemic reactions occurs in $\frac{1}{2}$ to 15 per cent. of all injections. They are annoying and alarming, but not often dangerous. The fatality in German clinics was reported by the Cologne Salvarsan Commission (Münch. med. Woch., 1920, p. 477) as 1:19,000. It is greatly influenced by the dosage; for below 0.6 Gm. of arsphenamine, the mortality was only 1:163,000; above this dose, it rose to 1:3,000. The danger may be minimized by using reliable drugs, practically exact technic of preparation and administration of the solutions; preliminary examination of the patient and extra caution in the presence of non-syphilitic visceral, cardiac or vascular disease or acute fevers; careful observation during injection and surveillance of the patient during the whole course, intermitting the injections with the first sign of disturbance, especially of renal, liver or skin involvement.

Physical (Colloidal), Chemical (Arsenical), and Indirect (Immune) Factors.—The *immediate and early reactions* (A and B, into above grouping) are due mainly to *physical reactions* between the colloidal particles of the arsphenamine and of the tissues. They are therefore confined essentially to the intravenous injections, and vary quantitatively with the colloidal instability of the solutions. They are by far most serious with acid arsphenamine, much less with alkaline arsphenamine, and slight and rare with neoarsphenamine. They are probably not essential to the therapeutic effect, and should be avoided as far as possible, by dilution and slow injection, by stabilization of the colloids, or by the selection of the more stable compounds.

The *delayed reactions* are due partly to the formation of more toxic arsenic compounds, *i.e.*, *chemical*; or to the injurious effects of the products of the destruction of the parasites, and of accompanying *immune reactions*. Too little is known about either of these to permit a sharp classification.

Group A: Immediate Toxic "Nitritoid" Reactions.—The early reactions bear a general resemblance to vasodilation ("vasoparesis"); the milder grades to nitrite action; the severer grades to anaphylactic reaction (Swift, 1912).

Symptoms.—These start during, or within a few minutes after intravenous injection. There is a burning ethereal taste; flushing of the face; injection of the conjunctiva; edema of the tongue and eyelids; anxiety, nausea and vomiting; then profuse perspiration. Cough and dyspnea, cyanosis and precordial distress are sometimes present. The pulse is full at first, then weak, with a pallid skin. In severe cases, there is unconsciousness, with scarcely perceptible pulse. Occasionally there are attacks of severe lumbar pain during the injection.

These symptoms may disappear in $\frac{1}{4}$ to $\frac{1}{2}$ hour; or they may be followed by those of Group B (Fordyce, 1916; Schamberg et al., 1917). The immediate symptoms rarely are dangerous. Even actual collapse (which is said to be more frequent after the second dose), usually ends in rapid recovery, very rarely in death (Tomaszewski, 1913).

"Reactions" occur in $\frac{1}{2}$ to perhaps 5 per cent. of the administrations of alkaline arspenamine; the relative frequency depending mainly on the conditions of administration; especially on giving the drug with the stomach empty, and having the patient rest for an hour or more after the administration. The rate of injection, and the proper alkalization, are also important factors. However, a few patients react invariably even with the most careful technic. Patients with tubercular lesions react more frequently (Stokes, 1919).

The occurrence of the immediate reactions does not preclude continuance of arspenamine therapy, but renders it advisable to use neoarsphenamine, with the best technic; if the reaction was alarming, it would be safer to use sulpharsphenamine hypodermically.

Treatment of Nitritoid Reactions.—The resemblance of the symptoms to those of anaphylaxis and nitrite poisoning suggested the use of *epinephrine*, as prophylactic (1 mg. intramuscularly a few minutes before the arspenamine) and for treatment ($\frac{1}{2}$ to 1 mg. by vein). Apparently good results have been reported (Berman, 1918; Beeson, 1919); but patients hypersusceptible to arspenamine are sometimes also hypersusceptible to epinephrine; and the effects of the latter may be as alarming as those of arspenamine (Stokes, 1919; Cole).

Stokes (1919), also claims successful prophylaxis from atropine (1 mg.); or by *fractionated injection*, giving $\frac{1}{10}$ of the arspenamine an hour before the remainder of the dose.

Cause of the Immediate Reactions.—The uncertain occurrence of these clinical reactions suggested that they might be due to chemical impurities (the unidentified "X" substance of Schamberg et al., 1917, and Stokes, 1919) arising in the course of the manufacture or by subsequent decomposition. However, further analysis revealed the essential identity of the phenomena with the circulatory collapse that occurs constantly on the intravenous injection of acid arspenamine and with rapid injection of large doses of alkaline arspenamine solutions, and referred their causation to flocculation and agglutination in the blood; *i.e.*, they are due to physical changes in the colloid state, and not directly to chemical actions.

Effects on Circulation.—The rapid injection of arspenamine solution into the femoral vein of dogs produces a gradual but severe and persistent fall of blood-pressure, *i.e.*, a shock-like state (Auer, 1911). This is preceded by rise of the pressure in the pulmonary artery (Jackson, 1923; Jackson and Raap, 1920) and dilation of the right heart and swelling of the splanchnic organs (Jackson and Smith, 1918). The rise of the pulmonary pressure indicates that the actions are due chiefly to increased resistance in the pulmonary circulation; the heart is also depressed, directly (Auer, 1911; Luithlen, 1913) as well as by the fall of coronary pressure; but the rise of the pulmonary pressure indicates that the cardiac impairment plays a secondary role. All these effects are diminished if the arspenamine is much diluted, or if it is injected very slowly, and they are very slight if it is injected into the portal vein or into the femoral artery. The effects are greatest for acid solutions of arspenamine, and least for strongly alkaline solutions. They are slight for neo-arsphenamine and

sulpharsphenamine, strong for silver-arsphenamine (Jackson and Raap, 1920).

It may be noted that these relations parallel the colloidal properties of these substances. Indeed, Voegtlin, Johnson and Dyer, 1924, observed a direct correlation between the changes of toxicity and viscosity; for instance, warming alkaline arsphenamine solution, under conditions that preclude oxidation, decreases the toxicity (Hunt, 1921), with a corresponding decrease of viscosity. The less dispersed, more viscid and more coagulable colloid compounds tend to produce flocculates, precipitates or agglutinates with the blood, which would obstruct the nearest capillaries; *i.e.*, the pulmonary capillaries if the injection is made a systemic vein (Joseph, 1911). This embolism cuts off a part of the pulmonary circulation and so causes the rise of pressure in the pulmonary artery, and fall of pressure in the systemic arteries, which is the characteristic of the shock in animals, and of the "nitritoid reactions" in man. The arsphenamines do not act on the muscle of the pulmonary vessels, Busorcca, 1924; the systemic vessels of frogs are constricted, Luithlen. If the injection is made into the portal circulation, the pulmonary obstruction does not occur because the emboli are filtered out and broken up before they reach the lung; with injection into the femoral artery, this occurs in the leg. The phenomena are quite analogous to fat-embolism. With dilute solutions, or slow injections, or with the more stable colloids, the precipitates etc. are so scanty and dispersed that they can be washed through the capillaries without notable disturbance (Joseph, 1911).

Interaction of Arsphenamine and Blood.—Precipitation by mixing acid arsphenamine and serum can be demonstrated in the blood vessels as well as in the test-tube (Joseph, 1911). Alkaline arsphenamine is much less precipitant but there is at least a tendency of flocculation (Danysk, 1917), which varies perhaps with different blood, as was claimed by Berman, 1918. The precipitates contain both arsphenamine and protein. Since arsphenamine is practically insoluble at the pH of the blood, it would necessarily be precipitated unless it is kept in colloidal solution by protective proteins. In the case of alkaline solutions these would be formed by the action of the alkali (Oliver and Douglas, 1923), thus explaining the difference in precipitation. The protein precipitation by acid solutions may be due partly to adsorption, partly to the flocculent effect of the phenolic group of the arsphenamine. It may be recalled that the intravenous injection of phenol also produces shock phenomena (Pomaret, 1923).

The characters of the proteins that remain in solution is also altered; fibrinogen, for instance, is rendered non-coagulable by thrombin, so that arsphenamine prevents the *coagulation* of blood, both *in vivo* and *in vitro* (Oliver and Douglas, 1922). Neoarsphenamine and sulpharsphenamine also produce this effect, but only with doses much larger than the therapeutic (Panisset and Verge, 1922; Anwyl-Davies and Mellanby, 1923).

Finally, the arsphenamines alter the properties of the blood corpuscles, so as to produce agglutination, *in vitro* and *in vivo* (Oliver and Douglas, 1922; Oliver and Yamada, 1923). The importance of these in the lung embolism of acute fatalities was shown by Karsner and Hanzlik, 1920.

Protection by Hydrophilic Colloids.—The agglutinating and anti-coagulant effect of the alkaline arsphenamine may be prevented by the previous addition of hydrophilic colloids, which appear to "deflect" the arsphenamine, perhaps by stabilizing its colloidal state. This may be

accomplished by mixing the arsphenamine solution with serum (Kritschewsky, 1921); or more practically with gelatin (Oliver and Yamada, 1922). These reduce the toxicity very greatly, (Oliver, Yamada and Kolos, 1923; Roick, 1915).

Hemolytic Action.—Alkaline arsphenamine solutions are hemolytic, but this is due merely to their alkalinity; acid solutions, or isotonic neutral solutions of neoarsphenamine are not hemolytic (Corridi, 1912).

Leucocytes.—Arsphenamine injections are followed by leucopenia, and after several hours by leucocytosis, especially of neutrophile polynuclear cells (Rzentkowski, 1911; Corridi, 1912; Tunncliffe, 1922).

Excised Organs.—The effects have been studied by Joseph, 1911, (skeletal muscle); Perutz and Rosemann, 1923, (intestines); and Busacca, 1924 (autonomic system).

Sensitization by Repeated Injections.—If arsphenamine injections, are repeated at intervals of several days to two weeks the toxicity appears sometimes to be considerably increased (Flandin and Tzanck, 1921; Busacca, 1923; Launoy, 1923); but the result is uncertain (Berman, 1918) and it is doubtful whether it is analogous to ordinary anaphylaxis (Kolle et al., 1920).

Group B: Early Toxic Reactions.—These are quite common. They start within one to four hours, with chill and febrile symptoms, headache, nausea, and vomiting and diarrhea, of greatly varying severity. The temperature is usually between 100 to 102°F. Occasionally there are severe pains in the legs or back. These reactions also need not cause alarm (Ormsby, 1917) and do not demand interruption of the arsphenamine treatment. The symptoms usually cede in 12 to 24 hours, leaving some lassitude and weakness. More rarely, the temperature, vomiting and diarrhea may continue for several days. In some cases, the urine is scanty and contains albumen and casts (Schamberg et al., 1917).

Relation of the Febrile Reactions to Infections and Water Contamination. Febrile reactions are especially marked in the presence of infections, even if slight (Wechselmann, 1910), or if stale distilled water is used (Wechselmann, 1911; Swift and Ellis, 1911). Various explanations have been proposed for this: Ehrlich's, that the bacterial products sensitize the tissues to arsenic; Yakimoff, 1912, a colloidoclastic reaction between the bacterial proteins and the arsphenamine; Neisser, 1910, destruction of the spirochetes; Luithlen and Mucha, 1913, destructive action of arsphenamine on pathologic tissues.

Kidney Involvement.—A few casts and a traces of albumen are not uncommon on the day following the injection, and the phthalein output may be a little diminished, the blood urea a trifle increased (J. A. Elliott and Todd, 1920). This renal impairment is generally only temporary and has little or no significance. It does not demand interruption of the treatment unless the albumen or casts persist. In that case, the arsphenamine (and mercury or bismuth) should be stopped until the renal irritation has disappeared and then resumed with extreme caution. Serious nephritis develops especially in connection with the skin-lesions, but sometimes also independently.

Dermatitis.—Rather exceptionally, various types of skin eruptions may appear in a few hours to several days, generally accompanied by renal irritation. The more common types are patches of urticarial, scarlatinoid and morbilliform erythemas; or rarely purpura (Labbe and Langlois, 1919). Sometimes there is only itching. The eruptions generally subside in a day or two. Later and more persistent eruptions may occur 6 to 10 days after administration; more commonly after intravenous injection (Schamberg et al., 1917). These skin changes may turn into

serious dermatitis exfoliativa, generally with severe nephritis, with slow recovery, and quite often with fatal outcome (J. E. Moore and Keidel). These severe effects are probably direct arsenic actions. The arsphenamine should therefore be discontinued so long as there is any sign of cutaneous irritation. The early reactions may be due partly to the colloidal phenomena; partly to the liberation of spirochetal endotoxins, *i.e.* Herxheimer reactions; and partly to sensitization of the skin. It has not been possible to separate these. A. Strickler claimed that the administration of arsphenamine (and less actively, of cacodylate) oftens sensitizes the skin of non-luetic persons to luetion (*i.e.* to agar) and to tuberculin skin-tests; but not to the endermic food tests.

Group C: Late Toxic Symptoms.—Several varieties of intoxication may develop after 24 hours:

Delayed Reactions.—These resemble Group B, except that they develop more slowly.

Reaction in Luetic Tissue and Skin.—The luetic lesions, especially of the trunk, often show a bright red erythema ("Jarish-Herxheimer reaction"). These phenomena set in early and last only a few days. Generally they cause little inconvenience; but it is conceivable that analogous reactions in cerebral or hepatic gummas might be immediately dangerous.

In case of gummas in such situations it is safer to precede the arsenic by a course of mercury and iodide.

This type of reaction (which may also occur with mercury alone) has been attributed to the liberation of luetic toxins, while the late "neuro-recurrences" are ascribed to the more vigorous activity of surviving spirochetes. The explanation is hypothetical.

Marasmus.—Occasionally the arsphenamine appears to lower the general health, without definitely ascertainable cause. In such case, it is generally advisable to discontinue the administration until the health has been restored. Anemia has been described by Moore and Keidel, 1921. Ordinarily the blood picture is not changed, even in chronic intoxications (rabbits, Herzog and Roscher, 1923).

Metabolism.—The effects resemble arsenic (Postoiev, 1912). Syphilitic patients, under treatment show some nitrogen loss on the day following the injection; otherwise the changes are inconstant (Cappelli, 1911).

Group D: Severe Late Intoxications.—Occasionally, severe and even fatal reactions occur about 3 days after administration, with phenomena referable either to the kidneys or skin, which have been considered; or to the brain or liver.

Parenchymatous Degeneration.—Fatty and necrotic changes are of inconstant occurrence, clinically and in animals. They resemble ordinary arsenic lesions, involve especially the liver (acute yellow atrophy); then the kidneys, heart, nervous system (encephalitis hemorrhagica) and spleen (Busse and Merian, 1912; Morel, Mourigaud and Policard, 1912; Schlasberg, kidney, 1912; Schirogorow, 1913). Mucha and Ketron, 1912, claim that even small doses damage the renal vessels and glomeruli. The intestines may also show hemorrhagic and inflammatory changes (Saccone, 1912). The lesions occur especially after repeated injection, and are increased by combination with mercury, uranium, epinephrine or Roentgen treatment (Luithlen, 1913; A. Loewy and Wechseltmann, 1913).

Luithlen emphasizes the greater toxicity of arsphenamine to animals which have been subjected to these vascular injuries, and believes them analogous to the Herxheimer reaction; *i.e.*, that this is a specific effect on vessels previously injured by the luetic process.

Cerebral Type (Hemorrhagic Encephalitis).—This occurs especially after large doses, or when ordinary doses are given in close succession.

The symptoms begin in two to four days, with headache, weakness, vomiting, muscular twitching, epileptiform convulsions, suppression of urine, dilation of pupils, absence of reflexes, coma and death in 3 or 4 days. Paralytic symptoms may be observed (Chiari, 1913). The necropsy generally shows edema of the brain or hemorrhagic encephalitis; often also degenerative parenchymatous changes in the kidneys, liver, heart-muscle, spleen, etc. (Busse and Merian, 1912; Tomaszewski, 1913; Corlett, 1913).

The encephalitis appears to be an arsenic action, for similar phenomena may be observed in non-luetic patients (Lube, 1914) and in animals (v. Marschalko and Veszpremi, 1912). It is not inconceivable, however, that some cases may be Herxheimer reactions (Laredde and Jamlin, 1914).

Icterus.—Rather exceptionally, the syndrome of jaundice, generally accompanied by fever, may appear from 3 days to several weeks, or even six months, after treatment. It occurs usually only after several intravenous injections (one or two courses), and is generally believed to be more common with neoarsphenamine, although this is not certain. The symptoms start with sudden intense jaundice. Some recover in a few days to three months (Wosegien, 1923); others run rapidly to a fatal ending, with vomiting, hemorrhagic phenomena in the viscera, tubular nephritis, and the general typical symptoms and autopsy findings of acute yellow atrophy (Severin and Heinrichsdorf, 1912).

Group E: Neuro-recurrences.—Sometimes arsphenamine injections are followed, after an interval of weeks or months, by severe nervous manifestations—epileptiform convulsions, acoustic, more rarely optic, facial, and other neurites. These do not appear to be due to the arsenic, for similar effects may occur in mercurial treatment, and they cede on further arsphenamine or mercury medication. Ehrlich, 1911, suggested that they are caused by the incomplete destruction of the parasites, those which escape being then less exposed to the normal restraining influences, and assuming a greater virulence. Their occurrence calls for vigorous anti-luetic treatment.

Optic Neuritis.—This is a rare sequel of arsphenamine and neoarsphenamine. It is generally classed with the neuro-recurrences; but Arganaraz, 1914, reports a series of cases which he attributes directly to the drug, and not to the spirochetes.

Optic Lesions in Animals.—These require much larger doses than those concerned in clinical amblyopias, so that they are probably quite distinct phenomena. With rabbits, they require the presence of an amino group in the para position. They occur both with tri and penta valent arsenic; but they may be made more intense with the pentavalent, because their lower systemic toxicity permits larger doses (A. G. Young and Loevenhart, 1923).

Toxicity by Mouth.—Neoarsphenamine 0.3 Gm. has been taken by mouth for six successive days, with no other effect than some temporary gastric discomfort and diarrhea. The Wassermann reaction remained positive (M. Friedmann, 1920).

Treatment of Toxic Phenomena.—Patients receiving arsphenamine should be carefully watched, especially if they present any of the contraindications; and the treatment interrupted at once if any toxic phenomena appear. The nephritis and other phenomena would be treated in the ordinary manner. *Sodium thiosulphate* (see Index) appears to be of material benefit in dermatitis, although the clinical opinions are not unanimous (Voegtlin, 1923). Thiosinamine has also been used (Gruenbaum, 1924). The thiosulphate treatment was introduced by Ravaut, 1920, who had found it useful in non-arsenical dermatitis. It appears probable that the action in arsphenamine poisoning is also on the dermatitis rather than

on the arsenic; for it does not decrease the toxicity of arsenoxide (Voegtlin) and scarcely at all that of sodium arsenite; *i.e.* it does not protect against super-fatal doses, and only partly against just fatal doses. This is accompanied by some decrease in the trypanocidal efficiency of arsenicals, *in vivo*. It has been attributed to the formation of colloidal arsenous sulphide (Kuhn and Loevenhart, 1925).

Arsenoxide Theory of Arsphenamine Action.—The non-physical toxic effects of the arsphenamines, as well as the parasitocidal effects occur only after a considerable latent period; and the chemical instability of these substances suggests that they must have undergone chemical changes in the meantime. This is confirmed by the fact that the parasitocidal effect of arsphenamine *in vitro* is so low that it could not explain the therapeutic effects. On the other hand, the principal oxidation product of arsphenamine, amino-oxyphenyl-arsenoxide, briefly called “arsenoxide,” is highly

toxic to protozoa *in vitro*, produces almost immediate disinfection *in vivo*, and has also much higher toxicity to the host (Ehrlich and Bertheim, 1912) *i.e.* 7.5 times as great as that of arsphenamine and 10 times as high as neoarsphenamine (figured on arsenic content). It therefore appears probable that the arsphenamines pass through this form before they produce their actions (Voegtlin, 1925, pp. 71 and 80). The “arsenoxide” in turn would be oxidized and excreted as less active pentavalent compounds. However probable, this course is still hypothetical, for the “arsenoxide” has not been actually isolated from the tissues; but this, again, might be expected from the analytical difficulties. The direct administration of “arsenoxide” is trypanocidal in animals; but its therapeutic index is not as favorable as that of the arsphenamine, because its sudden introduction is too toxic to the host. The tissues are apparently unable to support a fairly high concentration, even for short periods, but are in a better position than the parasites to cope with the long continued liberation of low concentrations of “arsenoxide” (Dale, 1923).

The Sulphydril Hypothesis.—“Arsenoxide” and similar trivalent arsenic oxides react readily with the SH group of organic sulphydril compounds, such as thioglycollic acid, and the “glutathione” which occurs in all tissues that have an active metabolism and which Hopkins believes to play an essential part in the oxidation and reduction processes. This would explain the toxicity both to the parasites and to the host (Voegtlin, 1925, pp. 72 and 81).

RATE AND EXCRETION

Sojourn in the Blood.—Arsphenamine or neoarsphenamine, when injected into a vein, leave the blood stream very rapidly; at least $\frac{3}{4}$ has disappeared within a few minutes (Kolls and Youmans, 1923); in 15 minutes the concentration has fallen to 1:40,000; in 3 hours it is less than 1:100,000 (Schreus and Hollander, 1922). The disappearance is due partly to diffusion, but probably mainly to capillary adsorption of the flocculated colloidal arsphenamine.

Distribution.—Determinations in animals (total arsenic, rabbits, Voegtlin et al., 1923; amino group, dogs, Kolls and Youmans, 1923) show that after a single injection, the arsenic is found most abundantly in the organs whose capillaries would mechanically adsorb the flocculates, *i.e.* in the liver and spleen. These contain about three times as high a concentration as the blood. The bulk of the liver makes this the principal concentrator of the arsenic. It rids itself of this through the bile, which has an arsenic concentration 40 times higher than the blood. The lungs also catch considerable arsenic in their capillaries, and this is excreted more slowly. The bones show most lasting retention (Bulmer, 1923), but traces may be demonstrated in all the organs for months (Ullmann, 1912; Valenti, 1912; Usuelli, 1912). Very little is contained in the central nervous system (McIntosh and Filder, 1916; J. Webster, 1916). The cerebrospinal fluid contains traces of arsenic within an hour after intravenous injection, in a fourth to a half of the patients (Camp, 1912; Mehrtens and McArthur, 1919, average, 0.0036 mg. of arsenic per 100 c.c.; Fordyce et al., 1923). Sulpharsphenamine penetrates into the cerebrospinal fluid (of rabbits) better than the other arspenamines (Voegtlin et al., 1923).

The milk also participates in the excretion (Cafferena, 1912). Traces of arsenic pass through the placenta to the fetus (Burnascheff, 1912; Underhill and Amatruda, 1923). This may be of importance for antenatal syphilis.

Channels of Excretion.—The urine and feces (or more properly, the bile) participate in the excretion in varying degree, determined by the conditions, by the individual, and particularly by the preparation: For arspenamine, which tends to become focculated and adsorbed in the capillaries of the liver, the fecal excretion is 4 to 10 times that by the urine; with the more dispersed neo-arsphenamine, the urinary excretion tends to predominate over the fecal (Voegtlin and Thompson, 1922).

Rate of Excretion.—Arsenic appears in the urine in a few minutes to two hours after the intravenous injection (Abelin, 1911). The excretion rate is highest on the same or the next day (J. Webster, 1916) and is nearly completed in four days (Hoppe, 1910). Traces may be found up to three months (Heuser, 1911). The fecal excretion begins after 3 or 4 days (Underhill and Davis, 1922). After a single injection of 0.9 Gm. the urine contained less than 2 mg., the feces about 18 mg. of arsenic per day (Frenkel-Heiden and Navasartt, 1913). With repeated injections, the excretion rises by both channels, so that nearly 60 per cent. may be recovered within a week after the last injection (Underhill and Davis, 1922). The remaining 40 per cent. is eliminated very slowly (Mathiew, 1922). With intramuscular injections, the excretion begins more slowly and is apt to be less complete, (Irokawa, 1914; Mehrtens, 1921). The excretion by rabbits is essentially similar to that of man (Burnascheff, 1912).

Form of Excretion.—This is not satisfactorily known (Voegtlin, 1925). A small part may be excreted unchanged, although this is doubtful. The arsenoxide-glutathione combination is tenaciously retained, while pentavalent aromatic compounds are rapidly excreted by the kidneys (Voegtlin and Thompson, 1922). From this it may be surmised that the urinary excretion occurs in the latter form. Incidentally, ligation of the ureters increases materially the toxicity of pentavalent arsenicals and ligation of the bile duct raises the trypanocidal action of arspenamine (Voegtlin, Dyer and Miller, 1922).

ADMINISTRATION AND DOSAGE

Arsphenamine is now usually administered intravenously, repeated in "courses," in conjunction with vigorous mercurial treatment. Intraspinal injections are sometimes used in neuro-syphilis, if ordinary treatment has failed.

Intramuscular injection may be quite as efficient as intravenous (Voegtlin, 1925, p. 83), but has become restricted to sulpharsphenamine, because arsphenamine and neoarsphenamine produce considerable irritation. Rectal administration is unreliable, and oral administration is not effective, because of partial destruction and poor absorption.

Courses.—The ordinary "course" consists of 6 to 8 intravenous injections of arsphenamine or neoarsphenamine given 5 to 7 days apart. With very early cases, the first two or three injections may be three days apart. Mercurial treatment is given at the same time (see *Mercury*). The kidneys must be watched.

The patient is then allowed to rest for 4 to 6 weeks, when another course is given. This may be sufficient if the treatment has been started very early, while the Wassermann reaction is still negative. It is advisable, however, to administer six injections of mercury salicylate, after three months and another series half a year later.

With fairly early cases, but with positive Wassermann reaction, a third, and possibly a fourth course are given, with 1 to 2 month intervals between courses. The semi-annual mercury courses are kept up for three years.

Dosage of Arsphenamine.—This should be varied with the strength and condition of the patient. For men, arsphenamine is usually started intravenously (or intramuscularly) with 0.2 Gm., and increased in successive injections by 0.1 Gm. to a total of 0.5 Gm. For women, the starting dose is 0.2 Gm., the full dose 0.4 Gm. For children, the full dose is 0.1 to 0.3 Gm.; for infants, 0.02 to 0.1 Gm.; for nurslings, 0.01 to 0.015 Gm.

Dosage of Neo-arsphenamine.—This is usually taken as $1\frac{1}{2}$ to 2 times that of arsphenamine.

Care of the Patient for Intravenous Administration.—The urine should be examined after each administration. The injections are best given about noon, when the stomach is empty, lunch having been omitted. The patient should remain quiet for the remainder of the day, best in bed, and should not take food until next morning.

Intravenous Administration of Arsphenamine.—The drug is used as the fresh 0.4 per cent. solution, in an excess of alkali, injected by gravity at the rate of not more than 0.1 Gm. per minute. The skin over the vein should be painted with iodine.

N.N.R. advises the following technic:

"The ampule containing the drug is immersed in alcohol, then carefully wiped off, the neck filed across and broken off, and the contents sprinkled on sterile distilled water (10 c.c. for each 0.1 gram of the drug used), contained in a sterile erlenmeyer flask. The drug is allowed to dissolve with little or no agitation. (In case of arsenobenzol brand, hot water is required for rapid solution, with immediate vigorous shaking; then wait for complete solution and cooling.) Normal sodium hydroxide is then added to the solution, using 0.85 c.c. to every 0.1 Gm. of the drug. Thus 0.6 Gm. of the drug would require 5.1 c.c. of normal alkali. A precipitate of the base is first formed, which, after the contents are carefully agitated, is again brought into solution, the fluid being strongly alkaline. Filter the alkalized solution through sterile gauze, 4 ply, and dilute the filtrate with sterile distilled water to make 25 c.c. for each 0.1 Gm. of the

drug. It should stand 30 minutes before using. At least one minute should be allowed for each 25 c.c. of the solution to flow into the vein, using the gravity method. The directions accompanying the drug as to temperature of the water, etc., should be followed."

The solution should be used within half an hour after it is made. It is inadmissible to use the contents of damaged tubes, or remnants of powder from previously opened tubes.

Shaking of arspenamine and neoarsphenamine solutions in contact with air should be avoided, since it may result in rapid oxidation with great increase of toxicity. This is particularly dangerous with neoarsphenamine and alkaline arspenamine, but varies for different specimens (Roth; Schamberg, Kolmer and Raiziss, 1922).

Intravenous Administration of Neoarsphenamine.—This drug dissolves directly in water. It is injected in about 5 per cent. solution by syringe, using a very small needle, and taking at least five minutes for the injections. Only a single dose should be dissolved at a time, in 10 to 15 c.c. of cold sterile, recently distilled water (10 c.c. for 0.5 Gm. or less; 15 c.c. above 0.5 Gm.). The temperature should at no time exceed 22°C. (71°F.).

"The ampule containing the drug is immersed in alcohol; then carefully wiped off; the neck filed across and broken off; and the contents sprinkled on the surface of cool, sterile distilled water and allowed to dissolve *without shaking* the solution. Any product incompletely soluble should be discarded. Solutions of neoarsphenamine must be injected *immediately* after their preparation. Neoarsphenamine must not be warmed and the temperature of the injected fluid should not be more than 20 to 22°C. (68 to 71.6 F.)."

"The drug may undergo deterioration in the ampule, and care should be exercised to use the drugs of normal color and free solubility. N.N.R. (G. B. Roth, 1922)."

Administration of Sulpharsphenamine. "For intramuscular or subcutaneous use the drug is dissolved in sterile, freshly distilled water in the proportion of about 0.1 Gm. to 0.3 c.c.; for intravenous use a greater dilution is desirable, about 0.1 Gm. to 2 to 3 c.c." (N.N.R.).

Intramuscular Injections of Arspenamine and Neoarsphenamine.—These have largely gone out of use. Arspenamine was usually employed as a 10 per cent. neutral suspension; neoarsphenamine in the ratio of 3 c.c. of water per 0.15 Gm. This yields an approximately isotonic solution. Neither drug should be injected into the subcutaneous tissue. Intramuscular injections must not be made too near to the sciatic nerve, or they may cause neuritis (Kissmeyer, 1916).

The absorption of arspenamine from intramuscular injections is slow, some arsenic generally remaining at the site of injection for months (Schuebel, 1914). Neoarsphenamine is absorbed more rapidly (Ullmann, 1912, 75 to 85 per cent. within a week; Swift, 1913).

Oral Administration.—This has been tried in man (0.6 Gm.), and in animals, but the therapeutic effects are very feeble (Schamberg et al, 1916). Vomiting and diarrhea may result, but not serious intoxication (Kolmer and Schamberg, 1912).

Rectal Administration.—This has been recommended (J. M. Joseph, 1918); especially for children (Araujo, 1918). A considerable amount of arsenic may be absorbed (Noeggerath and Reichle, 1921; Mehrtens, 1921), but it is not known in what form and the clinical results are unreliable (Littman and Hutton, 1924).

Spinal Injections of Arspenamine Serum.—Cerebro-spinal lues often resists the intravenous administration of arspenamine, partly because but little of the drug passes into the central nervous system. In such cases, when the ordinary treatment has failed, arspenamine serum may be injected directly into the spinal canal, as an auxiliary; meantime keeping up the systemic treatment. Good results have been obtained in various forms of cerebro-spinal syphilis, especially in early cases, and with the "lightning pains" of tabes. The pains, psychical disturbances and cell count are

usually markedly improved. Spinal injection is said to be dangerous if the lower limbs or sphincters are paralyzed. Dementia paralytica is not improved.

The safest medium for subdural spinal injections is the serum of the patient who has recently received an arsphenamine injection, according to the Swift-Ellis (1913) method. However, watery or serum solutions of arsphenamine (0.5 mg.) have been injected directly into the subdural canal.

Swift-Ellis Method.—The patient receives the ordinary dose of arsphenamine or neoarsphenamine intravenously. Half an hour to an hour later, 40 c.c. of blood are withdrawn from a vein. The blood is permitted to clot and left on ice for 24 hours. Twelve to 15 c.c. of serum are then pipetted off, and centrifuged. It contains about 0.01 mg. of arsphenamine per c.c. It is heated to 56°C. for half an hour, either undiluted, or after the addition of enough normal saline to make 30 c.c. and the total quantity is injected through lumbar puncture, after withdrawing an equal volume of cerebrospinal fluid.

The injections are safe, and may be repeated as often as needed (Draper, 1915), at intervals of two weeks. Exceptionally, severe pain may prevent their employment. The concentration of arsphenamine in the blood and cerebrospinal fluid with the Swift-Ellis method has been studied particularly by Fordyce, Rosen and Meyers, 1923.

Spinal Injection of Arsphenamine Dissolved Directly in Serum.—This was advocated by Marinesco and Minea, 1914; using not over 0.5 mg. of the drug.

It is safer than the watery solutions, but not as safe as the Swift-Ellis method, in which the arsphenamine has been changed into a less diffusible colloid form (Young, 1915). It would be unsafe to give more than two or three consecutive injections (Draper).

Spinal Injection of Watery Arsphenamine Solution.—This causes severe irritation of the cord, and some writers advise that it should not be attempted in man (Ellis and Swift, 1913; Marinesco, 1913; Swift, 1916). Others consider it fairly safe when a careful technic is followed; either using a hypertonic (6 per cent.) solution (Ravaut, 1914; Wile, 1914); or mixing the drug with cerebro-spinal fluid so as to give a concentration of 0.05 to 0.15 per cent., and a dosage of $\frac{1}{2}$ to 12 mg. Neoarsphenamine is almost always preferred. The injections are generally repeated every week to three weeks, and combined with systemic administration (bibliography, Naegli, 1915).

Gennerich, 1913, and Schubert, 1914, use cerebrospinal fluid drawn from the patient, for the solution of the arsphenamines.

Vincent's Angina and Gangrenous Balanitis.—These are promptly arrested by intravenous injection of neoarsphenamine, 0.3 to 0.4 Gm. The pain disappears in a few hours, and the inflammation subsides within a day. A second injection is rarely needed. Dry neoarsphenamine or arsphenamine dusted on the lesion is also effective.

PREPARATIONS

**Arsphenamina* (Arsphen.), U.S.P., Arsphenamine (Diaminodihydroxy-arsenobenzene Hydrochloride).—Contains not less than 30 per cent. of As, and complies with requirements of U.S.P.H.S. A light yellow powder; odorless or slight odor; hygroscopic. Oxidizes on exposure to air, becoming darker and more toxic. Sol. in water, alc. and glycerin. Marketed in sealed glass containers, free from air, containing the ordinary doses. *Dose, Caution!* Intravenous, 0.4 Gm., $6\frac{1}{2}$ grains, U.S.P.

**Neoarsphenamina* (Neoarsphen.) U.S.P. Neoarsphenamine.—A product obtained by the action of sodium methanal sulfoxylate on arsphenamine, consists partially of sodium 3-diamino-4-dihydroxy arsenobenzene methanal sulfoxylate. It contains not less than 19 per cent. of As, and complies with the requirements of the U.S.P.H.S. Neoarsphenamine is distributed in sealed containers of colorless glass, from which the air has been excluded either by the production of a vacuum or by displacement with a nonoxidizing gas.—A yellow powder; odorless or slight odor. On exposure, becomes darker and more toxic. Very sol. in water, glycerin, slightly sol. in alc.—Solutions of neoarsphenamine must be freshly prepared when required for use. *Dose, Caution!* Intravenous, 0.6 Gm., $9\frac{3}{10}$ grains, U.S.P.

Sulpharsphenamine (N.N.R.).—Disodium-diamino-dihydroxy-arseno-benzene-N-dimethylene-sulphonate, mixed with inert salt to an arsenic content of 19 to 24 per cent. It must comply with the requirements of the U.S. P.H.S. Orange-yellow powder, readily soluble in water, yielding a yellow, acid solution.

Silver Arsphenamine (N.N.R.).—A combination of sodium arsphenamine and silver, containing 20 per cent. of arsenic and about 15 per cent. of silver. Readily soluble in water. *Dose*, 0.1 to 0.3 Gm., as $\frac{1}{2}$ per cent. solution, intravenously. May produce argyria, although rarely.

TELLURIUM

General Statement.—Although tellurium and selenium are chemically related to sulphur, their pharmacologic properties are very similar to those of arsenic. They produce the same paralysis of the capillaries, also identical changes in the blood-forming organs. Tellurium is relatively non-toxic, being rapidly reduced to the metallic state. Its most conspicuous effects are suppression of sweat; and a very persistent garlic odor, especially of the breath, due to methyl telluride. These effects are noted in the industries dealing with tellurium. Sodium tellurate has been used to suppress the night-sweats of phthisis.

Compounds.—The more important are tellurous oxide, TeO_2 ; telluric oxide, TeO_3 ; Sodium tellurite Na_2TeO_3 and sodium tellurate, Na_2TeO_4 ; hydrogen telluride H_2Te ; methyl telluride $(\text{CH}_3)_2\text{Te}$; and tellurium tartrate, $\text{Te}(\text{C}_4\text{H}_4\text{O}_6)_4$.

Solubility.—The sodium salts are soluble in water; but the tellurite would be transformed into insoluble tellurous oxide by the acidity of the gastric juice. The alkalinity or the intestine, however, would restore the tellurite. Tellurous oxide itself would therefore be dissolved in the intestines.

Absorption.—This is very incomplete from the alimentary tract, since all the compounds are rapidly reduced to metallic tellurium, which is eliminated by the feces, imparting a blue or gray color to these. A small proportion, however, is easily absorbed; apparently even from the intact skin; for even a trace adhering to the skin imparts the garlic odor to the breath.

Reduction in Body.—All living cells rapidly reduce all tellurium compounds to the metallic state, recognized by the greenish, blue green, blue, or dark grey-blue color, according to the quantity (Kunkel). After intravenous injection, this is found in all the organs, particularly abundant in the liver and kidneys; whilst the lungs, spleen and adrenals are relatively free. Hofmeister, 1894, points out that the distribution of this reduction is quite different from that of dyes. The reduced metal is in an ultra-microscopic state. Beyer claimed that it is in the cell-nuclei.

The deposition of the reduced metal throughout the body occurs also with oral administration. It remains in the cells for a long time, but part is continuously transformed into methyl telluride. This explains the persistence of the odor.

Reduction by Microorganisms.—Gonis, 1905, showed that living bacteria and other micro-organisms reduce tellurite (also selenite). As dead organisms do not effect this reduction, potassium tellurite may be used as an *indicator of living bacteria*, yeasts, molds, etc. When incubated for 24 hours with a concentration about 1:50,000, living cultures of all the more common microorganisms reduce the tellurite, as indicated by the appearance of a black precipitate. This concentration is practically harmless when injected into animals (W. E. King and Davis, 1914).

Excretion.—With oral administration, the major part is reduced to the metallic state, and is excreted as such unabsorbed by the feces. That which is absorbed is excreted partly as methyl telluride by the breath, urine and feces; and partly as a soluble form in the urine and bile (Mead and Gies, 1901).

Methyl Telluride.—A very pronounced odor of garlic, due to methyl telluride $(\text{CH}_3)_2\text{Te}$, appears in the breath within 5 minutes after administration, by any channel and in all animals. It persists for several days up to 8 months after a single dose, according to the quantity taken. In man, it has been noted after as little as 0.0005 mg. (Reisert). The odor was described by Gmelin, 1824, and by Hansen, 1853, who made the first pharmacologic investigations of tellurium.

The odor is also present, though less marked, in the urine, feces, epidermal excretions, blood and viscera.

Hofmeister found that this interesting methyl telluride is produced by all tissues, though to a varying degree; also when tellurite is digested with finely mashed organs *in vitro*; but that it is prevented by any agents that tend to disorganize protoplasm; even by water or normal saline. On the other hand, saponin has little effect, and quinine restrains only in fairly high concentrations. There is no parallelism between the formation of methyl telluride and the reduction to metallic tellurium.

Methyl telluride is also produced by cold blooded animals and invertebrates (earth-worms), not by the higher plants (Knop, Bokorny; quoted from Gies and Mead).

"*Bismuth Breath*."—This has been attributed to contamination of bismuth preparations with tellurium; the two substances often occurring in association.

Toxicity.—This is quite low for oral administration; higher for hypodermic injection. The tellurite is perhaps 10 times more toxic than the tellurate. Commercial tellurate, however, often contains tellurite. Colloidal tellurium is also much less toxic. Martelli, 1914, claims that the toxicity to rabbits is greatly increased by coccidiosis of the liver. Berzelius found hydrogen telluride and selenide more irritant and toxic than hydrogen sulphide.

The toxic and fatal doses may be found in the papers of Mead and Gies; Bruttig; Martelli; Czapek and Weil; and de Angelis.

Metallic Tellurium.—Hofmeister showed that this is gradually converted into the active form in the tissues; for the garlic odor occurred after intravenous injection of the finely powdered metal.

Colloidal Tellurium.—This was investigated by de Angelis. He found it much less toxic than the tellurite. Indeed, the effects were not proportional to the dose. He attributed this to limited power of the organism to transform it into hydrogen telluride, which he assumed to be the really active agent.

Industrial Uses.—These are not extensive. It is employed in the glass industry, to impart a blue, red or brown color to glass. It is being tried in steel-making as a reducing agent in place of coke (Shie, 1920).

Industrial Exposure.—Tellurium occurs as an impurity of lead and copper ores and is encountered industrially in the purification of these metals, especially in the electrolytic refining of lead. Here it occurs in the fumes as hydrogen telluride, and in dust as tellurous oxide and tellurates (Shie, 1920).

Toxic Effect on Frogs.—Czapek and Weil interpret these mainly as paralysis of the central nervous system. Skeletal muscle shows fibrillary twitching, even at a distance from the site of injection. The heart becomes paralyzed late in the poisoning.

General Symptoms in Mammals.—The essential features were described by the earliest investigators, Gmelin, 1824 and Hansen, 1853. Czapek and Weil, 1893, made a comprehensive study and point out the close resemblance to selenium and arsenic; the effects of tellurium, however, being slower and less virulent. They start with somnolence; restlessness, tremors, vomiting and diarrhea; asphyxial convulsions and death. The muscles and nerves remain irritable to the end.

Pathologic Lesions.—These correspond to severe gastroenteritis; intense hyperemia of viscera and lungs; hemorrhage from mucosae; fluid in the serosae; initial parenchymatous nephritis (Martelli, 1914).

Symptoms in Man.—The inhalation of tellurous oxide in fairly large quantity results in nausea, metallic taste, the garlic odor, somnolence, depression and constipation (Mead and Gies). The same symptoms are described for hydrogen telluride. Hansen took a total of 0.34 Gm. of potassium tellurate, distributed over a long period. He recorded unusual sleepiness, nausea, anorexia, and abundant salivation.

Industrial Symptoms.—Shie, 1920, examined 12 lead workers exposed to tellurium. Eight of these showed effects that might be attributable to tellurium, especially the garlic odor, dry mouth and dry skin. These were of about the same frequency and degree with those who had been exposed only 2 weeks, as with those who had worked for a year.

The frequency of the symptoms among these 8 affected workers was as follows: 7 showed garlic odor, metallic taste, dry mouth; 6 showed dry, itching skin and rashes; 5 showed suppression of sweat; 4 showed constipation; 3 showed poor appetite, nausea, vomiting, somnolence; 1 showed loss of hair. None showed albuminuria, or malnutrition.

Effects on Digestive Tract.—Czapek and Weil found that dogs and cats respond to large doses by vomiting and diarrhea, the stools becoming of a rice-water and finally mucous character. The necropsy shows the mucosa of the duodenum and jejunum congested, swollen, with small hemorrhages, covered with a pseudo-membrane; the epithelium is desquamated. The ileum and colon are usually quite normal. Rabbits generally die without gastrointestinal symptoms. Sub-emetic doses do not interfere with digestion. Even fairly high concentrations do not affect gastric and pancreatic digestion *in vitro*. Ptyalin is perhaps somewhat checked (Mead and Gies).

Autolysis.—Fasium found that salts of Te and Se activate ordinary autolysis, whilst they hinder the autolysis of mouse-sarcoma. However, the results were too confusing for application.

Circulation.—Czapek and Weil found the characteristic arsenic effects: Profound fall of blood pressure and dilation of splanchnic vessels with good pressure-response of the heart and vasomotor system. They, therefore, adopt the same explanation, *i.e.*, paralysis of the capillaries.

Secretions.—In man, tellurium diminishes or suppresses perspiration. The statements as to saliva are contradictory. Only very little work has been done on animals; none on the saliva or mucus; very little on other parasympathetic innervation.

Saliva.—The workers of Shie's series complained of dry mouth. Hansen recorded abundant salivation.

Mucus.—Mead and Gies record this as markedly increased in the stomach and intestines. The response to nerve stimulation has not been investigated.

Gastric Juice.—Mead and Gies found the quantity and acidity markedly diminished in dogs, even by small doses. The vomitus was never acid. They suggest that this may be concerned in the indigestion; but evidently the odor itself is nauseating to dogs, for an unpoisoned dog vomited when brought near another tellurium dog.

Bile is frequently regurgitated into the stomach.

No exact experiments on gastric acidity seem to have been made; nor any as to response to pilocarpine, gastrin etc. and none as to pancreas.

Innervation of Smooth Muscle.—No experiments are recorded.

Cardiac Vagus.—Czapek and Weil state that this remains excitable late in the poisoning.

Sweat.—Neusser, 1890, apparently first observed that sodium tellurate, 20 to 60 mg. per day, suppresses the night sweats of phthisis patients. The observations were confirmed by others, and this application endorsed especially by Combemale, 1891. These doses produced no notable bad effect, except slight dyspepsia and the marked garlic odor. The latter was probably mainly responsible for the abandonment of the tellurates, for but little has been written about them since that time.

Dryness of the skin, and skin eruptions attributed thereto were noted by Shie amongst industrial workers. He points out how this may dispose toward heat-exhaustion, although he has not observed any cases.

Mechanism of Sweat-paralysis.—This was apparently demonstrated experimentally by Czapek and Weil (p. 453), but it would be desirable to repeat their experiments. They found in kittens that subtoxic doses suppressed spontaneous sweating of the paws and weakened or abolished response to sciatic stimulation. Pilocarpine provoked a feeble secretion. The gland cells did not show anatomic changes. From this they conclude that tellurium paralyzes the nerve endings, analogous to atropine. They further claimed that arsenic had a similar effect, selenium not.

This line of evidence is not conclusive. The failure of the sweat-formation might have been due to a shock-level of blood pressure, which was not measured.

Blood-picture.—This corresponds with that of arsenic. It was studied especially by Martelli. *Small doses* (tellurite, $\frac{1}{40}$ mg. per Kg. twice per week) produce some leucocytosis, with diminution of hemoglobin.

Moderate Doses ($\frac{1}{20}$ mg. per Kg. on alternate days) produce a leucopenia.

With rapidity fatal doses, the whites increase; the reds decrease, their resistance is lowered, and some hemolysis occurs spontaneously, for instance, in rabbits or guinea pigs with $\frac{1}{2}$ to 2 mg. of sodium tellurite (De Angelis).

Hemolysis.—Luzzato found that sodium tellurite is hemolytic also in vitro. He believes that the action is not due to the tellurite as such, nor to the metallic tellurium to which it is reduced, but to an intermediate product, perhaps H_2Te . In confirmation, Brunti found that colloidal Te is not hemolytic in vitro.

Blood Forming Organs.—The changes in these are strictly analogous to arsenic. Martelli studied especially the bone-marrow in rabbits and guinea pigs. *With small doses*, there is hyperplasia. *Moderate doses* cause leucopenia and hypoplasia. The animals tend to put on fat and increase in weight.

With fatal doses, the bonemarrow appears red, with hyperplasia of the white and red cells. If the animal survives, the picture is as for moderate doses.

Metabolism.—Mead and Gies fed sub-toxic doses of various Te compounds to dogs, for a week, without notable effects. The urine became dark colored from the reduced tellurium.

Glycosuria.—Brutti, 1910, found that 30 to 50 mg. of sodium tellurate per Kg. of rabbit or guinea pig produced in about half of the animals severe glycosuria (3 to 10 per cent. of sugar); with decrease of blood sugar. Mead and Gies did not find any glycosuria after toxic oral doses.

Urobilin.—Intravenous injection of 25 to 50 mg. of colloidal tellurium into rabbits produced marked increase of urobilin in the blood and urine, which de Angelis attributed to the hemolysis.

Kidneys.—Czapek and Weil often observed casts, leucocytes and sometimes red cells in the urine. Mead and Gies also record albumen after hypodermic or toxic oral doses. De Angelis, on the other hand, claims absence of albumen, unless the urine contained hemoglobin.

SELENIUM

General Statement.—The actions of selenium are identical with those of tellurium and arsenic, but it is much more toxic than tellurium. It obtained some notoriety as a possible specific treatment for tumors. This has proven a disappointment.

General Actions.—These were studied by Czapek and Weil, 1893. They attributed its higher toxicity to slower reduction.

Lower Organisms.—Czapek and Weil found sodium selenite practically non-toxic for protozoa or ciliated cells. It checked alcoholic and bacterial fermentations, being reduced to the red metallic tellurium.

A more recent investigation of selenium was made by Woodruff and Gies, 1901. They confirm Czapek and Weil.

Methyl Compound.—This is formed in much smaller quantity than with Tellurium.

Fatal Dose.—Sodium selenite or selenate, oral, hypodermic or rectal, 4 mg. per Kg. of dog, is usually fatal in a few minutes. The powdered metal is much less toxic by mouth. Even 4 Gm. per dog are non-toxic, being mainly excreted by the feces.

Distribution and Excretion.—These are practically identical with tellurium.

Normal Occurrence of Selenium in Tissues.—This was affirmed by Gassmann, 1916, especially for teeth and bones. However, Britsch, 1918, by improved methods found none in animal or vegetable tissues.

VANADIUM

The pharmacology of this metal has been studied by Jackson, 1912. According to Luzzato (1903) poisonous doses of VCl_3 or VBr_3 cause the usual anatomic lesions of metals in the kidneys, liver, intestine, and stomach. No lesions are found in the central nervous system. The blood pressure is raised, and the excitability of the vagus is depressed. Death occurs through respiratory paralysis.

Circulatory Effects.—Jackson found, with intravenous sodium orthovanadate, that the rise of blood pressure is due to systemic vasoconstriction, by direct action on the arterial muscle or vasomotor endings. The heart is not strengthened. The pressure in the pulmonary artery also rises by the systemic and pulmonary vasoconstriction. Perfused lung vessels are strongly constricted (Baehr and Pick, 1913). *Bronchial muscle* also shows moderate but prolonged constriction (confirmed by Baehr and Pick, 1913).

Chronic Vanadium Poisoning.—This occurs especially through its industrial use as a mordant, and by the wearing of dyed fabrics. The symptoms and lesions are those common to other chronic metallic intoxications. The lungs, kidneys and digestive canal are especially affected (Dutton, 1911).

Therapeutic Use.—The pharmacologic actions do not point to any definite therapeutic usefulness. Vanadium has been recommended as an alterative, similar to arsenic, in tuberculosis, diabetes, etc., but the evidence is not convincing.

Sodii Meta-vanadas.—White, almost tasteless powder, sol in water. *Dose*, 1 to 8 mg. ($\frac{1}{60}$ to $\frac{1}{8}$ gr.). According to Jardin (1905) it lessens assimilation and increases protein destruction.

TUNGSTEN

A brief discussion of its toxicity is given by Fantus, 1917. Very little is known about the subject.

ANTIMONY

The actions of antimony resemble those of arsenic. The chief difference lies in greater local irritation and a more difficult absorption. Consequently, when given by the mouth, doses can be chosen whose only action is that of producing nausea, or if somewhat larger, vomiting. The intravenous injection of antimony compounds is very effective against a variety of tropical protozoan infections. Excessive doses, intravenously or by mouth, produce toxic symptoms resembling acute and subacute arsenic poisoning. Application of antimony preparations to the skin produce local inflammation.

Antimony has an interesting history. Paracelsus in the sixteenth century praised it as a panacea, and it was used against the plague, etc., perhaps a forecast of its most recent use in chemotherapy. However, numerous deaths caused its formal proscription.

Differences in Antimony Compounds.—As with arsenic, the 3-valent is more toxic (to ten times) than the 5-valent. The organic derivatives show similar relations, the side-chains being relatively unimportant (Brunner, 1912). Cloetta found the pyrostibiate much less toxic than tartar emetic.

Nauseant and Emetic Action.—These are due mainly to the local action. "Tartar Emetic," the tartrate of antimony and potassium, is the compound usually employed internally. As an *emetic* it has fallen out of favor, its action being too slow and too depressing. The emetic dose is 0.03 Gm., $\frac{1}{2}$ grain. As a *nauseant* it has advantages over all other metals, since the dose required for this is only about one-tenth of that which produces vomiting. Its continued use, however, may become dangerous. It is employed mainly as a depressant expectorant in the first stages of acute bronchitis; often in the form of Wine of Antimony, 1 c.c. = 4 mg., $\frac{1}{15}$ gr.; or smaller doses (1 mg.) may be repeated every hour with precaution against excessive depression. It also enters into a number of compound expectorants, such as Mistura Glycyrrhizæ Co. (8 c.c. = 2 mg. of tartar emetic and 1 c.c. of paregoric); and Compound Syrup of Squill (2 c.c. = 4 mg. of tartar emetic).

Mechanism of Emetic Effect.—This is chiefly reflex; for while emesis occurs both by gastric and venous administration, the latter requires much larger doses and the vomiting occurs much more slowly (Keimann and Simonowitsch, 1872). Among animals, antimony is emetic for dogs and pigs, but not for horses, beef or sheep. The nauseant action, and the increase of the salivary and bronchial secretion, are also reflex (V. E. Henderson and Taylor, 1910). Like other irritants, antimony is said to increase *uric acid excretion* (Abl 1913).

Antimony Chemotherapy.—The intravenous injection of tartar emetic is highly effective against a number of tropical diseases due to animal parasites; especially against kala-azar, bilharziosis, filariasis and Delhi boil; good results have been obtained in leishmaniasis, sleeping sickness and frambesia. The efficiency against spirochetal and malarial infections is low, presumably because the antimony is too rapidly excreted.

The other antimonial preparations have no material advantage over antimony and potassium tartrate. This is too irritant to be administered intramuscularly. Intravenously, it is injected as 1 per cent. solution in normal saline. The initial dose is 0.04 to 0.06 Gm., $\frac{2}{3}$ to 1 grain. In bilharziasis, this is followed every second day with 0.12 Gm., stopping the course when a total of 2 Gm. has been injected (*i.e.*, about the 15th injection). Delhi boil requires from $\frac{1}{3}$ to $\frac{1}{2}$ Gm.; kala-azar 3 Gm. As much as 0.24 Gm. have been given at one dose, and a total of 5.85 Gm. in 86 days (Christopherson); but the therapeutic dose is not far from the toxic, and is usually followed in a few hours by irritating cough, metallic taste, salivation and nausea, colic, sometimes diar-

rhea, and occasionally by skin rashes. There is less danger of cumulative poisoning than with arsenic, since the antimony is more rapidly excreted. After intravenous injection of 0.12 Gm. of tartar emetic, 30 per cent. of the antimony is excreted by urine in 48 hours; and of 1.7 Gm. injected in a six week course, 1 Gm. was recovered from the urine. No data are available for the feces. Antimonious oxide may be injected intramuscularly, $\frac{1}{5}$ per cent. suspended in a mixture of equal volumes of glycerin and water (A. J. Clark "Applied Pharmacology").

Trypanocidal Action.—Antimony and bismuth, as well as arsenic, are highly toxic to trypanosomes, although not to all protozoa.

As with arsenic, the trivalent form of antimony, in inorganic or organic combination, is much more toxic to protozoa, bacteria and yeast, than is the pentavalent form (Friedberger and Joachimglu, 1917).

At the suggestion of Cushny, various investigators (Plimmer and Thomson, 1907; Mesnil and Brimont, 1908; Thomson and Cushny, 1910; Camac, 1911, and others) have successfully used injections of antimony-sodium tartrate in experimental and human trypanosome infections. The intravenous dose for man is 10 mg., in saline. Rowntree and Abel, 1910, advocate certain organic compounds, such as sodium-antimony thioglycollate. They have an advantage over the organic arsenicals in that the parasites do not become immune as readily. They are also cheaper. The trypanocidal activity of tartar emetic is greater in the presence of serum; this does not hold for arsenicals (Shilling and Goretta, 1914).

Jemma, 1916, states that tartar emetic is specific in the Leishmaniasis of children. *Malaria.*—Tartar emetic has proven inefficient even in large intravenous doses (Law and Newham, 1917; J. W. W. Stephens et al., 1917).

Local Action.—Applied to the skin, antimony chloride is a strong caustic. The double tartrate of antimony and potash (tartar emetic) when applied over long periods, produces a pustular eruption. This is due to the decomposition of the double salt, which is but slightly irritant, by the acid secretion of the follicles into more the irritant antimonious oxide, Sb_2O_3 , and other compounds. Such salves were formerly used for counter-irritation, but have been abandoned as too destructive and toxic.

Toxicology.—Overdoses produce precisely the same effects as arsenic, but vomiting is always a prominent phenomenon, the poison being rapidly excreted into the alimentary canal. Small doses long continued lead to a train of symptoms of *subacute poisoning*, entirely analogous to those produced by arsenic in the same manner (Gaehtgens, 1876; Soloweitschyk, 1880), also including the metabolic changes. Antimony has not been recorded as giving rise to industrial poisoning, except through contamination with arsenic. However, the pentasulphides that are used in the rubber industries are fairly soluble in human gastric juice (Carlson, 1915). Antimony is sometimes used in the glaze of cheap granite ware. This should be prohibited by law (as it is in some European countries), since some samples yield from 3 to 14 mg. of dissolved antimony in a single cooking test (E. W. Miller, 1916).

In distinction to arsenic, selenium and tellurium, antimony is not converted into volatile compounds by molds (Knaff-Lenz, 1913).

Treatment of Antimony Poisoning.—The chemic antidotes are eggs, milk and tannin (tea, etc.), or in its absence magnesia.

Potassium hexatantalate precipitates antimony compounds, even in the tissues; but it could be utilized only orally, since its hypodermic injection is too toxic (Rosenthal and Severin, 1912).

Habituation.—One difference from arsenic is that the continued administration of antimony to mammals does not lead to tolerance; nor does arsenic habituation confer tolerance to antimony. This difference is explained by the observation that the absorption of antimony is not diminished (Cloetta, 1911); on the contrary, it is rather increased (Brunner, 1912; he claims some tolerance for 3-valent but, not for 5-valent). Protozoa also do not become immune as readily as with arsenic (Rowntree and Abel, 1912). Antimony immunity can be induced in infusoria and does not extend to arsenic (Neuhaus, 1910). Bacteria immunized to arsenic are also resistant to antimony (Marks, 1910).

PREPARATIONS

* *Antimonii et Potassii Tartras* (Antim. et Pot. Tart.), U.S.P.; *Antimonium Tartaratum* (Antim. Tart.), B.P.; Tartarated Antimony (Tartar Emetic), $2K(SbO)C_4H_4O_6 + H_2O$.—Colorless, transparent crystals or white granular powder. Sweet, then metallic taste. Efflorescent. Slightly acid to litmus. *Incompatible* with alkalies and tannins. Sol. in water (1:12) or glyc. (1:15). Insol. in alc. *Dose*, expectorant, 3 mg., $\frac{1}{20}$ gr., U.S.P.; 2.5 to 8 mg., $\frac{1}{25}$ to $\frac{1}{8}$ gr., B.P.; emetic, 30 to 60 mg., $\frac{1}{2}$ to 1 gr., B.P.

Vinum Antimoniale (Vin. Antim.), B.P.—Contains 0.4 per cent. of Tartarated Antimony. *Dose*, expectorant, 0.6 to 1.8 c.c., 10 to 30 minims; emetic, 8 to 16 c.c., 2 to 4 drachms, B.P.

Antim. Oxid., B.P., Antimonious Oxide, Sb_2O_3 .—Grayish powder, insol. in water. *Dose*, 0.06 to 0.12 Gm., 1 to 2 gr., B.P.

Pulv. Antim., B.P.—Antimonious oxide, 1 part; calcium phosphate, 2 parts. *Dose*, 0.2 to 0.4 Gm., 3 to 6 gr., B.P.

Antim. Sulphur., B.P.; Sulphurated Antimony.—A mixture of antimony sulphides and oxides and sulphur. Orange-red powder. *Dose*, 0.06 to 0.12 Gm., 1 to 2 gr., B.P.

URANIUM

The salts are very corrosive, consequently readily absorbed, and highly toxic. Their systemic actions are similar to those of other metals, with a special paralytic effect on respiration; this resembles cyanide poisoning superficially. They produce a characteristic nephritis; glycosuria; and a unique edema.

Systemic Actions.—These have been studied especially by Woroschilsky, 1890, and D. E. Jackson, 1910. In **acute poisoning**, the respiration is peculiarly affected, first increased, then paralyzed. This results in the usual asphyxial phenomena, stimulation of the vasomotor center and rise of blood pressure. The respiratory paralysis is the cause of death. The blood is rendered non-coagulable by an unknown mechanism.

Sublethal doses are followed in a few days by albuminuria and glycosuria; parenchymatous degenerations; gastro-intestinal disturbances; paralytic symptoms; and changes in the blood vessels.

Excretion of Uranium.—This occurs mainly by the kidneys, which may be a factor in the nephritis (Karsner, Reimann and Brooks, 1918).

Anatomic Changes in Uranium Nephritis.—These affect both the tubular epithelium and the glomeruli, one or the other predominating according to conditions (Fleckseder, 1907; Heineke and Myerstein, 1907; Dickson, 1909). The vascular mechanism is involved first, but the tubular changes progress longer and finally predominate (MacNider, 1912). The anatomic and functional changes are more severe in old animals, and are increased by anesthetics, especially chloroform (MacNider, 1913, 1914). Dogs are more resistant than rabbits (O'Hare, 1913). The epithelium shows fatty changes; the glomeruli are congested; or the glomeruli shrink, with enlargement of the glomerular space (Tribe et al., 1916).

Christian, 1911, describes characteristic hyaline droplets in the vessel-walls of the glomerular tufts. These do not occur in other vessels of the kidneys or in other organs.

(The histology of uranium nephritis is also described by J. Oliver, 1916; and by Tribe et al., 1916.)

Repeated injections of small doses produce a **chronic interstitial nephritis** with fibrous changes. (These are not as severe as with chromates; arsenic did not produce interstitial changes; R. M. Smith, 1911.) The histologic lesions are similar to human chronic diffuse nephritis, but not quite identical. They are not associated with arterial lesions (Dickson, 1912).

Some samples of uranium produce extensive **arterial calcification** in rabbits; in the kidneys this also involves the microscopic vessels and the glomerular capsules (P. Dominguez, 1926).

Urine Changes.—In the early (vascular) stages, the quantity and specific gravity of the urine are increased. Albumen, glucose, and acetone substances appear, especially in older dogs (MacNider, 1914). A further increase of urine flow may be secured by caffeine or salines, although the response is slower than normal (Théohari and Giurea, 1910; Boycott and Ryffel, 1913; Mosenthal and Schlayer, 1913). With the appearance of the epithelial changes, the urine decreases, the tubules being obstructed by the swelling and desquamation of the cells. This is not relieved by diuretics, although the vascular response to the diuretics may be preserved (MacNider, 1912, 1914, 1915). The excretion of chlorides and urates is diminished in acute, somewhat increased in the subacute nephritis; i.e., it varies in the same direction as the urine flow.

Pohl described a subacute nephritis in rabbits, with polyuria until death, and with increased excretion of nitrogen and diminished chloride output. Dünner, 1915, finds this inconstant. The intravenous injection of calcium or of hypotonic NaCl converted this subacute nephritis into an acute form. Isotonic saline had no effect.

In this stage, the renal vessels are engorged and the blood flow through the kidneys is increased, but the oxygen consumption is diminished (Tribe et al., 1916).

The excretion of endogenous creatinine is diminished in both stages; but injected creatinine is completely excreted in the subacute, retained in the acute (Kraus, 1913). The *phenol-s-phthalein* excretion also varies in the same direction as the urine flow (Eisenbrey, 1913). It bears no definite relation to the histologic lesions (Smith, 1911).

The most marked effect of uranium nephritis is a depression of the factor: urine-urea divided by plasma-urea. This is fairly parallel to the anatomic injury (Watanabe et al., 1917).

The non-protein *nitrogen retention* in the blood goes parallel to the phthalein retention; both increase and recover together, except that the phthalein responds more promptly (Frothingham, Fitz, Folin and Denis, 1913; Karsner and Denis, 1914). However, Mosenthal, 1914, points out that the increase of non-protein nitrogen in the blood is not necessarily proof of retention, but could be explained by increased protein destruction or by inspissation of the blood through polyuria.

Acidosis.—MacNider, 1916, finds the toxicity of uranium associated with *acidosis*, sodium carbonate having a distinct saving effect. It also protects the uranium kidneys against anesthetics, so that these produce much less epithelial degeneration.

These findings are confirmed by Goto, 1917.

Karsner, Reimann and Brooks, 1918, also constate that uranium poisoning is almost always accompanied by acidosis; and that this is more severe in older animals. The albuminuria always precedes the acidosis; so that the acidosis is not the cause of the nephritis.

Hepatic Degeneration.—This has been studied on dogs by MacNider, 1919. It is similar to that seen after mercury, and is parallel to the acidosis, rather than to the dose.

Uranium Glycosuria.—This develops on the first or second day. The action consists partly in increased permeability of the kidneys for sugar, for it may occur without hyperglycemia (Franck, 1913), and may even relieve hyperglycemia when this is due to decreased permeability of the kidney cells (Pollak, 1911). The sugar does not bear any definite relation to the other urinary constituents, except albumin, which goes fairly parallel (Wallace and Myers, 1914). However, uranium may itself cause hyperglycemia, even when the kidneys are excised, so that part of its action must be extra-renal (Fleckseder, 1906).

Nephritic Glycosuria.—Glycosuria without hyperglycemia occurs with many nephritic poisons. With cantharides, it is attributed to increased permeability of the vessels; with uranium, chromium, tellurium, mercury and aloin, to lesions of the tubular epithelium (Luzzato, 1914).

Uranium Hydrops.—The hypodermic administration of uranium salts produces general anasarca and ascites (Leconte, 1854; Richter, 1904), a highly albuminous fluid transuding mainly into the serous cavities, but also into the other tissues, and extending even to the fetus *in utero* (Bibergeil, 1905).

It seemed natural to explain this by nephritis and anuria, but this explanation does not correspond to the facts. Nephrectomy alone does not produce hydrops, so that the anuria does not furnish the explanation. On the other hand, the uranium-hydrops occurs in nephrectomized animals, so that the kidneys are not concerned in its production (Fleckseder); nor do the histologic kidney lesions bear any relation to the edema (R. M. Smith, 1911). The fundamental change consists presumably in an altered permeability of the capillary walls (Richter, 1904). The injection of the blood of uranium animals into chromate animals also produces edema (Heinecke, 1905; Blanck, 1906). Edema, however, occurs only in animals which are freely supplied with water—otherwise the uranium causes anuria without hydrops (Fleckseder). Retention of salts is not connected with its production (Richter, 1905). In acute uranium poisoning, the *lymph flow* is not increased (Jackson, 1910).

Uranium poisoning interferes with the restoration of the blood-volume after saline infusion (Bogert, Underhill and Mendel, 1916).

Oral Intoxication by Insoluble Uranium Compounds.—Although uranium oxide and uranyl nitrate are nearly insoluble in water, they are highly toxic when given by mouth (to guinea pigs), since they are fairly soluble in dilute hydrochloric acid (Karsner et al., 1918).

Influence of Light.—The resistance of guinea-pigs to uranium poisoning is decreased if they are kept in the dark, but this is reversed by the injection of eosin (Karsner, Shen and Wahl, 1922).

Therapeutic Uses.—The soluble uranium nitrate, has been used in diabetes mellitus and in phthisis in doses of 75 mg. (1 gr.); largely diluted. The results are too indefinite to justify the further employment of so dangerous an agent.

Uranii Nitratis, $\text{UO}_2(\text{NO}_3)_2 + 6\text{H}_2\text{O}$.—Light yellow prisms; bitter, astringent taste. Freely sol. in water (1:1.2) or in alc. *Dose*, 0.01 Gm., $\frac{1}{6}$ gr., diluted. Use with caution.

BISMUTH

The insoluble basic bismuth salts are used on inflamed surfaces. They act largely mechanically, as protective and drying dusting powders. The use of soluble bismuth preparations is therefore irrational. The insoluble bismuth compounds are also employed in X-ray diagnosis. Even large doses are ordinarily harmless, but they may become poisonous under special conditions. Intramuscular injections of bismuth compounds are parasiticidal and are employed in the treatment of syphilis. The medicinal use of bismuth is said to date from Dr. Odier of Geneva, 1785.

Local Actions of Insoluble Basic (oxy) Bismuth Salts.—These form fine adhesive powders. The subcarbonate, subsalicylate and magma are insoluble in water. The subnitrate and subgallate are somewhat hydrolyzed and therefore very slightly soluble (Bonček, 1910; Stingel, 1911). Their solubility in the body-fluids is only very slight.

They have a marked healing effect when dusted on wounds and on inflamed mucous surfaces. Applied to wounds, they dry the secretions and form a protective covering, so that the wound heals as under an aseptic scab. This action is partly mechanical, due to the stoppage of the lymph and blood capillaries by the fine particles of the powder (H. H. Meyer, 1885). Other indifferent substances in an equally fine state of subdivision have a similar action. However, a small amount of bismuth undoubtedly goes into solution, and aids by exerting an astringent and mild antiseptic action; indeed, the basic bismuth salts are among the most effective of the non-irritant intestinal antiseptics (Sollmann, 1908). In the alimentary canal, the basic bismuth salts act not only in the manner indicated, but also by precipitating hydrogen sulphide (Stingel, 1911). Bismuth stools are therefore black. The subcarbonate (not the subnitrate) is a slowly acting antacid (J.A.M.A., 60:1175).

Therapeutic Use in Digestive Disorders.—The combination of these actions render the subnitrate or subcarbonate (0.5 to 2 Gm., 8 to 30 gr., every two or four hours) very useful for allaying *diarrhea* (X-ray observations, Hesse, 1913) and *gastritis*, and sometimes against vomiting. They may be combined with other intestinal antiseptics, such as salol. The bismuth powders are similarly useful in *gastric ulcer* (1 to 2 Gm. suspended in fluid, before each meal). They lessen gastric secretion and acidity (Bastedo). In normal individuals, bismuth is not constipating, even with the large doses used in X-ray work (Cannon, 1911). This indicates that the effects are on the inflammation, and not on the peristalsis.

Hulse, 1910, claimed that "bismuth-milk" (a suspension of the hydroxide) does not check diarrhea, the stools remaining light-colored. However, Stingel found that these preparations also bind sulphides.

Like other intestinal sedatives, bismuth subnitrate is said to diminish *uric acid excretion* (Abl. 1913).

Use in X-ray Diagnosis.—The opacity of the bismuth salts to X-rays makes them suitable for outlining the shape and movements of the alimentary canal, but they have been largely displaced by barium sulphate. About 50 Gm. (2 ounces) of bismuth subcarbonate (not the subnitrate) are administered, suspended in buttermilk, thick soup, etc. Best and Cohnheim, 1911, believe that the bismuth meal delays the emptying of the stomach by an hour.

Other Uses.—Bismuth is used as dusting powder or ointment (30 per cent.) on *ulcers* and other open surfaces and mucous membranes. Suspensions containing 10 per cent. of bismuth subnitrate may be injected

in *urethritis*. Bismuth poisoning may arise if it is applied too extensively, or if it is confined, as in the injection of bismuth paste into sinuses.

Bismuth Paste.—E. Beck introduced a paste of 1 part of bismuth subnitrate and 2 parts of petrolatum, in chronic suppurative abscesses and sinuses, often with curative results. The injections are made at first every three or four days, then not oftener than once a week. Acute abscesses do not respond. Stomatitis has followed its use after three weeks; on its occurrence the remaining paste should be washed away with warm oil. Jensen, 1913, also reports nitrite poisoning from fistulæ infected with b. coli.

The technic and precautions for the use of bismuth paste are described by E. G. Beck, 1916.

Differences between Insoluble Bismuth Salts.—The subnitrate and subcarbonate, the oldest of the insoluble bismuth compounds, answer every purpose.

Various *organic salts* have been introduced as substitutes, such as the subgallate (Dermatol), especially for dusting powders; but it is difficult to see how they can be superior to the much more economical older products. In other substitutes, antiseptic aromatic radicals have been introduced, but the same or better results can be secured by mixing the ordinary bismuth salts with other insoluble antiseptics, such as salol or betanaphthol; in fact, however, the bismuth alone is sufficiently antiseptic for all purposes for which it is used.

There is little difference between the actions of the *subcarbonate and subnitrate*; but on the whole, the subcarbonate deserves the preference, since it can not give rise to nitrites. The subnitrate has also been said to be irritant, since it consists of sharp-pointed microscopic crystals, whereas the subcarbonate is amorphous. This supposed irritant action is wholly imaginary, as can be shown by dusting the subnitrate on the conjunctiva.

The use of *soluble bismuth salts* is irrational, since they lack the soothing qualities which constitute the main value of the insoluble products. The double citrates are indeed partly precipitated in the acidity of the stomach; but the quantity of the precipitate is too small to be effective (Sollmann). Their introduction was due mainly to the extravagant desire for "elegant pharmacy" which was responsible for the oil-free cod-liver oil preparations.

Absorption and Excretion.—A small amount of the basic bismuth salts is dissolved by the acid gastric juice, is absorbed, and excreted by the urine (Dorner and Weingaertner, 1909), mouth and large intestines. The quantity is not sufficient to produce any systemic effects. The corrosive soluble salts are absorbed more extensively, and even the insoluble salts may be absorbed sufficiently from extensive burns to produce poisoning (T. Kocher, 1882). In human poisoning the bismuth was found mainly in the stomach and kidneys, and a little in the liver (Barthe, 1913).

Poisonous Effects of Bismuth Compounds.—Even very large doses of insoluble bismuth salts do not ordinarily produce any harmful effects when taken by mouth. Under other conditions, toxic symptoms may arise. They occur especially if bismuth is injected into sinuses or cavities, or applied to extensive burns; and to a varying extent from the therapeutic intramuscular injections.

The phenomena may take several forms: nitrite effects from the reduction of bismuth subnitrate; capillary thrombosis from precipitation of bismuth sulphide in the intestinal vessels; chronic bismuth poisoning; and the acute effects of soluble corrosive bismuth salts.

Cabot, 1912, had collected thirty-three human cases of which thirty-one were from injections into sinuses or wound dressings in extensive burns. He also reviews the experimental work. The *literature* of bismuth poisoning is also reviewed by W. H. Higgins, 1916; and J. Phillips, 1917.

Nitrate Poisoning.—The use of the relatively enormous doses of bismuth subnitrate for radiodiagnostic purposes has caused several intoxications, with methemoglobinemia, intense cyanosis, diarrhea, dyspnea and death by arrest of respiration. These effects

are not due to the bismuth, but to the production of nitrite by the reducing action of putrefactive fecal bacteria, especially in the large intestines and rectum (Benneke and Hoffman, 1906; Boehme, 1907; E. G. Beck, 1909; Zollinger, 1912; Zadek, 1914).

Precipitation of Bismuth Sulphide.—Bismuth forms a black and very insoluble sulphide. Since H_2S is always present in the large intestine, the feces are always colored black. When the bismuth is in the blood, the precipitation may occur in the vessels of the large intestine, and lead to capillary embolism, and this to ulceration, with the clinical symptoms of vomiting, diarrhea, cramps, colic, and colitis—the latter very rarely as severe as with mercury. The *autopsy* in bismuth poisoning shows the staining of the cecum, adjoining colon and appendix; less in the descending colon; and none in the small intestines (Cabot, 1912).

Bismuth sulphide is also precipitated in the *mouth*, and forms a "lead-line" at the junction of the gums and teeth; then patchy discoloration of the adjacent mucosa and tongue, and general stomatitis. These are prominent symptoms in chronic bismuth poisoning (Warfield, 1912).

Direct Systemic Actions.—These can be elicited by intravenous injection of the non-precipitant salts. They may also occur from relatively small doses of the soluble bismuth salts when taken by mouth, since these are strongly corrosive.

If a soluble bismuth salt is injected directly into the blood, it produces the arsenic phenomena on blood vessels. There is perhaps also a direct involvement of the central nervous system and depression of the vasomotor center. The heart muscle is also depressed. The blood pressure sinks therefore very rapidly (Meyer and Steinfeld, 1885).

Clinical Bismuth Poisoning.—This is characterized by fever, headache, stomatitis, lead-line, gastro-intestinal irritation, colic, and albuminuria. It differs from lead poisoning by the absence of paralytic, circulatory, blood and respiratory changes. Fatal cases may show convulsions and lock-jaw (Zollinger, 1912). If bismuth symptoms develop with Beck's paste, this should be removed with warm olive oil, curetting if necessary (Zollinger, 1912).

Effects of Bismuth Injections on Syphilis.—The intramuscular injection of bismuth compounds suppresses spirochetal infections in rabbits (Sazerac and Levaditi, 1921) and in man (Fournier and Guenot, 1921). The parasites disappear from the primary lesion after the first to third injection; the chancre undergoes rapid cicatrization; the contagious syphilides heal about as rapidly as under arsphenamine; the cutaneous and visceral lesions, papules, gummata and bone changes cede after 3 or 4 injections; the effects on neurosyphilitic phenomena are about the same as for arsphenamine; the Wassermann reaction responds more slowly than for arsphenamine, but may be improved even in cases that have resisted arsphenamine and mercury (Fourcade et al., 1922). Altogether, bismuth appears rather less effective and slower than arsphenamine (C. N. Myers and Corbitt, 1923), and more prompt than mercury. It would not be sufficiently effective if used alone; and as yet, its intermediate position makes it appear less suitable for routine combination treatments than the more widely separated arsphenamine and mercury. It is used especially with patients that are intolerant or resistant to either arsenic or mercury. The three metals have also been used in alternation. Against trypanosome infections bismuth is only temporarily successful (Sazerac and Levaditi).

Administration and Dosage.—The intravenous injection of the soluble bismuth salts is so toxic that it is inadmissible; nor would it probably give any greater therapeutic response than the intramuscular injections, which are used exclusively. Bismuth therapy involves the same principle as the intramuscular mercury therapy; *i.e.*, to establish intramuscular depots of slowly soluble metal compounds, which may then be gradually and continuously absorbed. It presents the same inherent difficulty,

namely that the absorbability of the deposit becomes progressively impaired and finally arrested by local fibrosis (Mueller, 1922), so that the patient may become studded with old bismuth nodules, which generally do no good, but which may do grave harm if a number of them should suddenly become broken or otherwise activated. This objection is least for the potassium bismuth tartrate, which according to X-ray examination usually disappears from the site of the injection within two weeks, and only exceptionally requires two to 6 weeks; the salicylate, which also gives good clinical results, shows as a rule considerably unabsorbed after 45 days. The oleate and the metallic bismuth injections are the least absorbed, (Cole et al., 1926) and are also generally least active therapeutically.

The slow absorption of these compounds indicates that it is probably preferable to administer them in small doses with weekly intervals, rather than twice weekly, as was the original practice. It is now advised to inject 0.1 Gm. of the potassium bismuth tartrate or of the bismuth salicylate, as 10 per cent. suspension generally in olive or almond oil, once a week, for a course of 10 to 15 injections; then to rest a month to permit absorption, and follow with a second course. If the injections are made into the gluteal muscle, there is very little pain, and this may be diminished by the addition of a local anesthetic, or preferably of camphor and creosote, 5 per cent. of each. Subcutaneous injections are much more painful and should be avoided.

Toxic Actions and Precautions.—The therapeutic doses may produce foul breath, black "leadline" at the alveolar margin and sometimes black spots on the buccal mucosa and throat; and annoying but not serious stomatitis. These phenomena usually occur when the total dosage reaches 2 to 2.5 Gm., but occasionally even with 0.5 Gm. Salivation is relatively less than with mercurial stomatitis. The administration should be stopped as soon as these effects appear. The black discoloration then generally fades in 2 to 3 months. If the warning is not heeded and the bismuth continued, serious ulcerative stomatitis is likely to result, and other toxic effects develop: diarrhea, albuminuria, skin-reactions, sometimes to serious exfoliative dermatitis, and jaundice. The skin and the urine should be watched, and the bismuth stopped with the first sign of disturbance. These precautions render bismuth treatment practically safe. Oral hygiene should be prescribed, to prevent undue stomatitis.

The toxicity for rabbits was investigated by Sazerac and Levaditi, 1921. Intravenous injection proved fatal in a few days with the dosage of 5 mg. of the potassium bismuth tartrate per Kg., but with intramuscular injection 60 mg. per Kg. was well tolerated, and 100 mg. was toxic and 200 mg. was fatal in 4 days. The histologic lesions involve mainly epithelial degeneration of the convoluted tubules of the kidneys and cloudy swelling of the liver cells (Lucke and Klauder, 1923). The toxicity and urinary elimination of various bismute preparations has been studied by C. L. Leonard, 1926.

PREPARATIONS

Bismuthi Betanaphtholas (Bism. Betanaph.), (Orphol).—A compound of bismuth and betanaphthol of somewhat varying composition, yielding not less than 73 per cent. of Bi_2O_3 . Decomposed into its constituents in the intestine. A buff-colored to grayish-brown, amorphous powder; odorless, tasteless, nearly insol. in water and alc. *Dose*, 0.5 Gm., 8 gr.

Bism. et Ammon. Cit.—Of somewhat varying chemical composition; yields not less than 46 per cent. of Bi_2O_3 . Very sol. in water and sparingly sol. in alc. Used for making bismuth solutions and elixirs. *Dose*, 0.125 Gm., 2 gr.

Liq. Bism. et Ammon. Cit., B.P. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Magma Bismuthi (Magma Bism.), (Milk of Bismuth).—A thick, white, opaque liquid, containing bismuth hydroxide and bismuth subcarbonate in suspension in water. Prepared by precipitating a solution of Bismuth nitrate with Ammonia; corresponding to about 6 per cent. of Bi_2O_3 . *Dose*, 4 c.c. (1 drachm).

**Bismuthi Subcarbonas* (Bism. Subcarb.), U.S.P.; *Bism. Carb.*, B.P. (Bismuth Oxycarbonate).—Of varying chemical composition; yields not less than 90 per cent. of Bi_2O_3 . White powder; odorless and tasteless. Insol. in water or alc. *Incompatible* with acids, sulphur, sulphides, and iodides. *Dose*, 1 Gm., 15 gr., U.S.P.; 0.3 to 1.2 Gm., 5 to 20 gr., B.P., in powders or suspension.

Troch. Bism. Co., B.P.—Each contains 0.15 Gm. of Bism. Subcarb., 0.15 of Magn. Carb., and 0.5 of Calc. Carb.

Bism. Subgallas (Bism. Subgall.), U.S.P. (Dermatol).—Of varying chemical composition; yields not less than 52 per cent. of Bi_2O_3 . An amorphous, bright yellow powder, odorless and tasteless. Insol. in water or alc. *Dose*, 1 Gm., 15 gr., U.S.P.

**Bismuthi Subnitras* (Bism. Subnit.), U.S.P., B.P. (Bismuth Oxynitrate).—Of varying chemical composition; yields not less than 79 per cent. of Bi_2O_3 . A white powder; odorless, almost tasteless, and slightly hygroscopic; almost insol. in water, insol. in alc. *Incompatibilities*, see Bism. Subcarb.; effervesces with soluble carbonates. *Dose*, 1 Gm., 15 gr., U.S.P., 0.3 to 1.2 Gm., 5 to 20 gr., B.P.

Bism. Subsalsyl., U.S.P.; *Bism. Sal.*, B.P.—Of varying chemical composition; yields not less than 62 per cent. of Bi_2O_3 . A white or nearly white, amorphous or crystalline powder; odorless, tasteless; almost insol. in cold water. *Incompatible* with acids, alkalies, alcohol, tannin, or iron. *Dose*, 1 Gm., 15 gr., U.S.P.; 0.3 to 1.2 Gm., 5 to 20 gr., B.P.

Potassium Bismuth Tartrate, N.N.R.—A basic tartrate, containing about 66 per cent. of bismuth. White powder, soluble in water, insoluble in alcohol. Decomposed by most local anesthetics. *Dose*, intramuscular, 0.1 to 0.2 Gm. as 10 per cent. suspension in oil, once per week till 1 to 3 Gm. have been injected.

IRON

Iron occurs widely distributed in the body, in several more or less firm and non-ionizable combinations. It is found in all chromatin and therefore in all cells; in the hemoglobin of the blood; and in granular form as "reserve iron" in the blood-forming and destroying organs. It is also a necessary constituent of the oxidases.

Iron is therefore of great importance in metabolism. When administered to normal animals, it has no systemic action, but increases the "reserve iron." In most anemias, the administration of iron tends to restore the hemoglobin to the normal and therefore improves nutrition. The soluble ionizable salts exert local astringent effects.

Direct systemic actions may be secured by the intravenous or hypodermic injection of non-precipitating salts, or by the absorption of corrosive preparations. The effects resemble those of arsenic (H. Meyer and Williams, 1881; Jacoby, 1887). Toxic effects occur with 60 mg. per kilogram, hypodermic or by vein; but not with therapeutic hypodermic doses (Lépine, 1897). E. J. Stieglitz, 1921 found that injected iron is deposited partly in the kidneys, and that this is mildly nephritic.

Astringent Action and Uses.—The soluble salts, especially the ferric, precipitate proteins readily and are therefore styptic, astringent, irritant and even corrosive. Their internal administration is apt to produce some gastric irritation and constipation. The tincture of ferric chloride is employed as an astringent, especially in gargles (1:10); this, and other iron salts, particularly the Liq. Ferri Subsulph., are also used as local styptics.

In *hemorrhage*, the efficiency of coagulant astringents is low; even under favorable experimental conditions (Hanzlik, 1918).

The administration of iron does not cause renal irritation.

Ringworm.—Garrett, 1913, recommends painting the scalp with undiluted Liq. Ferri Chlor. Fortis.

Income and Output of Iron.—The body of an adult man contains about 3.0 to 3.5 Gm. of iron, of which about 2.4 to 2.7 Gm. are in the form of hemoglobin. On a normal diet, he excretes daily about 20 mg. of iron; even in starvation the excretion averages about 8 mg. (F. Mueller). This is normally replaced by the absorption of iron from the food. A daily minimum income of 6 to 12 mg. is required to maintain the equilibrium. The iron content of the ordinary daily diet may vary between 7 and 35 mg., generally between 11 and 19 mg., 16 mg. being the mean value (Sherman, 1907; extensive bibliography). The iron income is therefore ordinarily more than sufficient for the needs; this even in otherwise poorly nourished individuals, since a vegetable diet is relatively rich in iron.

Iron Content of Foods.—This varies considerably, a fact which may be utilized in the treatment of anemias. It suffices to remember that blood, meat, yolk of eggs, and the green portions of vegetables, carrots, fruits, etc., are especially rich in iron (17 to 40 mg. per 100 Gm. of dry substance); while egg-white, milk, and the cereals (especially white flour) are poor in iron. Whole wheat, potatoes and the legumes are intermediate.

Dock (*Rumex crispus*), according to Sachet, has the highest iron content of any plant, and has therefore been recommended for anemia (Vasseur, 1905). It is claimed (Gilbert and Lereboullet, 1906) that this content of organic iron can be considerably raised by cultivating the plant on a soil artificially enriched with ferrous carbonate.

The iron of plants, when once fixed in the leaves, is not transported into new tissue; differing in this respect from N, K or P (Gile and Carrero, 1916).

Metabolism of Iron.—The increase of the iron content of the body in growing animals, and the equilibrium in adults, are sufficient evidence that food-iron is normally absorbed, metabolized and excreted. The controversy, whether inorganic iron compounds can also be metabolized, may now be considered settled in the affirmative; their fate is identical.

All compounds of iron undergo some preliminary and probably unimportant changes during digestion. They are then *absorbed*, mainly from the duodenum, but also in decreasing order from the succeeding portions of the intestine. A part generally escapes absorption and is eliminated by the feces. The part which is absorbed passes into the intestinal epithelium in a dissolved condition, the organic compounds being at the same time changed into looser combinations. The absorbed iron may then pass directly into the capillaries; or through the stroma into the lymph, reaching the blood via the thoracic duct. The relative rôle of the blood and lymph absorption is not yet clear, but it seems that normally the main absorption is directly into the blood.

From the blood, the iron is deposited as granules in an easily decomposed organic form (ferratin) in the cells of the hematopoietic organs, in the liver and red marrow, and particularly in the spleen, to a less extent in the kidneys. In this form it remains until it is used or excreted. The *spleen* seems to be important in maintaining the iron reserve and in preventing excessive excretion.

The *excretion* occurs mainly by the large intestines with traces in the urine, bile and gastric juice. The excreted iron is in firm organic combination.

The *utilization* of the iron, its transformation into hemoglobin, occurs only as needed; so that the total quantity of hemoglobin does not rise above normal. The same is probably true of its utilization by other cells. An *excessive absorption* of iron results merely in an increase of the reserve stock.

The administration of iron is therefore useful only in those conditions in which the normal income or the assimilation of iron is deficient.

Organic and Inorganic Iron.—To understand the following discussions, it is necessary to have a clear conception of the terms "inorganic" and "organic" iron. *Inorganic iron preparations* contain the metal in ion-form; *i.e.*, the iron can be separated from them by electrolysis; and they give the ordinary iron reactions (with ammonium sulphide, ferrocyanide, or hematoxylin) without preliminary treatment of any kind. It is immaterial whether the iron is combined with an organic or inorganic anion. Even the albuminate of iron is considered as "inorganic" in this sense.

Organic iron ("masked" or "non-ionic") *preparations*, on the other hands, contain the metal as a constituent part of the molecule, in a non-dissociable condition, so that they do not give the iron tests until the metal has been liberated by the decomposition of this molecule. There are all degrees in the firmness of the organic combination; some are decomposed by dilute acids (ferratin, the granules in which the iron reserve is stored in the spleen, liver, etc.); in others (hemoglobin, and the iron of food) nothing short of combustion or heating with concentrated acids will liberate the iron. In certain inorganic compounds, *e.g.*, the various double salts containing citric and tartaric acid, the iron is also largely non-ionic, but can be easily liberated. In molecular compounds, such as ferrocyanides, the iron is very firmly combined.

Hematoxylin (fresh $\frac{1}{2}$ per cent. solution in water) is one of the best reagents, since it retains its yellow color with masked iron, but is blackened by inorganic (Macallum, 1897). However, acids interfere with the reaction, so that "dialysed iron," although inorganic, does not react until it is made alkaline. Ammonium sulphide is also a good reagent; but its prolonged contact liberates iron from the less firmly masked compound.

Nature of Food-iron.—Iron occurs in food exclusively in organic form, more or less firmly masked, generally in combination with nucleo-proteins. The first natural iron nucleo-protein was prepared by Bunge, 1885, from egg-yolk and named *Hematogen*, Zaleski also found an iron nucleo-protein in the liver. This was later isolated by Marfori and Schmiedeberg, 1894, and named *Ferratin*. These products are probably not uniform substances, since they contain varying proportions of iron (Salkowski, 1909). Schmiedeberg and Marfori also prepared what they considered an *Artificial Ferratin*, by the interaction of iron and alkaline egg-albumin. It has been shown, however, that this has absolutely no relation to the natural substance, being simply a rather firm ferri-albuminate (De Groot, 1895; Battistini, 1895). While true ferratin is not attacked by digestion, the artificial is converted into ferric chloride. It has therefore no advantage over the ordinary mild iron salts.

Hemoglobin holds the iron much more firmly than most other compounds. It is converted into hematin in the stomach (Rep. Counc. Pharm. Chem., 1911; 64). Its further fate is not known, but at least a part of its iron is evidently absorbed, since its administration can satisfy the iron requirements of the body. It has no serious therapeutic advantage.

Outline of the Iron Controversy.—Even the ancients employed iron in the treatment of anemia; drinking water in which swords had been allowed to rust. Perhaps they were led to do so by an obscure idea that the strength of the steel would in some way pass into the patient. However, Celsus advises to treat enlargement of the spleen by drinking the water in which the glowing iron is drenched in the smithies (and which presumably contain colloidal iron oxides), because, he avers, domestic animals raised about smithies, and who drink this water, have abnormally small spleens ("quod animadversum est in his animalibus, quae apud hos fabros educata exiguos lienes habent;" liber IV, Cap. IX).

With the discovery of the presence of iron in the blood (Meninghinis, 1746), the therapeutic results seemed to be easily explained on the assumption that the iron is absorbed and converted into blood, much as the nitrogen of food is converted into muscle. The earlier experiments, however, failed to show any absorption of the medicinal iron preparations. This led some writers to consider the clinical results obtained with iron as largely imaginary; while others (especially Bunge, 1885) were inclined to attribute them to the local actions of iron in the alimentary canal.

There could never be any question as to the absorption of food-iron, for the hemoglobin increases with the growth of the animal. The same holds true for certain organic irons, and Macallum (1894) and Hall (1896) studied this absorption by microchemic methods. The absorption of inorganic iron was also proven, but the latter result was criticized, the objection being made that the iron had produced corrosion. This was finally withdrawn, but it was now claimed that inorganic iron, while it is absorbed, can not be converted into hemoglobin (Abderhalden, 1899; Hoffmann, 1900); but that it is nevertheless beneficial in anemia, by stimulating the blood-producing organs to a better use of the organic irons. This objection was also found untenable and abandoned (Abderhalden, 1906). It appears therefore that inorganic iron is absorbed, assimilated and converted into hemoglobin, precisely like food-iron.

The long resistance to the acceptance of this explanation was due largely to the fact that the conversion of iron into hemoglobin was an instance, unique at that time, of the synthesis, in the animal organism, of a protein from an inorganic compound. It is now probable that the phosphorus of nucleo-protein, and probably other proteins, may also be derived from inorganic sources. However, even without prejudice, the problems of iron metabolism presented some peculiar difficulties, which could be only gradually overcome (critical bibliography, Erich Meyer, 1906).

Evidence from Excreta.—If one wishes to show the absorption of nitrogen or of chlorides, it suffices to estimate the quantity of these substances in the food, and in the feces and urine. The same method was applied to iron. The results seemed to show that absolutely no absorption occurs, for the iron of the feces approximates that of the food (Kletzinsky, 1854) and the iron in the urine is not at all increased. It was soon shown, however, that the intestines are the principal channel for the excretion of the iron; for the feces contained this metal even in starvation; and when iron was injected subcutaneously very much more was excreted by the feces than by the urine. It was therefore evidently impossible to decide whether the fecal iron was unabsorbed or excreted. Absorption could be proven, by this method, only if it predominated greatly over the excretion. The estimation of the iron in the bile and in the intestinal juice gave similarly inconclusive results.

Iron Excretion by Urine.—This always contains traces of iron (in man, normally 1 to 2 mg. daily), partly in rather loose, partly in very firm combinations (Wolter, 1910). There is practically no increase if iron is administered by mouth (E. W. Hamburger, 1878; Kobert, 1891), even when organic iron is continued for weeks (Gottlieb, 1890). Nor is there any increase on intravenous injection of ferratin (Cloetta, 1900). Some increase occurs in fever, nephritis, hepatic disease, leucemia, and especially in diabetes. This indicates that the iron of the urine comes from tissue destruction, and not from the iron of the food or drugs (Tartakowsky, 1904).

Intestinal Excretion.—The iron leaves the body mainly by the feces. This is true for starvation (Bidder and Schmidt, 1852; F. Mueller), and for the normal iron income; or when iron is administered orally, hypodermically or intravenously. However, the total excretion of the injected iron requires several weeks (Gottlieb, 1891). It was at first assumed that the excretion occurred mainly by the *Bile*, but actual observation showed that the quantity of iron in the bile is small (mean, about 40 mg. per liter); and that it is not materially increased by the administration of iron (E. W. Hamburger, 1880; Anselm, 1892, 1916). The iron must therefore be excreted through the *Intestinal Epithelium*. This is confirmed directly by fistula experiments, in which the access of food to isolated parts of the intestine is prevented (Kobert; Gottlieb, 1891; Honigmann, 1896). These show that the excretion occurs mainly in the large intestine; the excreted iron being very firmly combined, so that it gives the iron reactions only after incineration (Tartakowsky). In rabbits, after hypodermic or peritoneal injection of iron salts or hemoglobin, the main excretion is through the epithelium of the upper duodenum (Chevallier, 1914). As with metals in general, the excretion is a slow process; requiring several weeks for the complete elimination of a hypodermic injection (Gottlieb).

Chemic Evidence of Absorption in Small Intestine.—A fistula in the lower ileum would separate fairly sharply the place of the principal absorption, the small intestine, from the principal excretion, the large intestine. Honigmann, 1896, found in this way that about 80 per cent. of citrated iron was absorbed in the small intestine. Rabe, 1912, by using fistula dogs, found that the greatest absorption of saccharated iron occurs in the duodenum, the lower portions playing a progressively smaller rôle.

Iron Content of Organs.—Changes in the iron content of individual organs, or of the entire body, also give evidence of the absorption of iron. We have seen that *injected iron* is excreted slowly; and must therefore be temporarily stored in the body. Jacoby, 1887 and 1890, found that iron preparations, injected into a vein, had disappeared from the blood in two to three hours. At this time, only 10 per cent. had passed into the excreta; about 50 per cent. was deposited in the liver, and the remainder in other organs (spleen, kidney, intestines). The *Liver* is also normally very rich in iron (this is true likewise of animals which do not form hemoglobin—molluscs, crayfish, lobster, etc.). The liver iron decreases with iron-poor food, or when there are extra demands for iron, as in pregnancy or after hemorrhage. The iron content of the liver may thus be taken as an index of the iron stock of the body, and therefore of absorption. With small animals, the iron content of the *entire body* can be estimated.

Since the animals must be killed to estimate the iron, control experiments are necessary. These would be impossible if the animals were chosen at random, for the individual differences of iron content are often greater than the quantities which could be absorbed. Bunge found, however, that the proportion of iron in new-born animals is very high (increasing very rapidly in the last three months of fetal life; Hugouenecq, 1899); and that it decreases steadily during the period of lactation (because milk is very poor in iron) until it has reached a practically constant quantity—about the seventeenth day in guinea pigs or rabbits, and the twenty-third or twenty-fourth day in dogs. The animals of the same litter can therefore be used for controls, some being fed, at the end of the lactation period, with iron-poor food, others with the same food to which the iron preparation is added. Rice and milk, which contain a very small proportion of iron, are commonly employed. The animals which do not receive the iron thrive very poorly, remaining small and emaciated. Those which receive iron, in any form, show an unmistakable increase in the total iron content of the body, especially of the liver, spleen and bone-marrow (Hall, 1894; Kunkel, 1895; Oerum, 1906).

Abderhalden, 1900, and Haeussermann, 1897, objected to the experiments of Hall, that he used corrosive doses of the inorganic preparations, as was necessary with small animals to obtain differences beyond the experimental error. Kunkel, however, who worked also with dogs, had used therapeutic doses. These experiments therefore prove that *inorganic, as well as organic iron can be absorbed and deposited in the liver and other organs*.

Microchemic Evidence.—Important information was obtained by applying the color reactions for iron directly to the tissues. The macroscopic examination of the depth of stain gives a general idea of the quantitative distribution of the iron, the details being revealed by microscopical study. Since, however, the iron compounds are apt to dissolve in the fixing solutions, many of the earlier experiments gave fallacious results. The best method consists in hardening the tissues in alcoholic ammonium sulphide and converting the ferrous sulphide into the more stable Berlin blue, by treatment with potassic ferrocyanide and dilute hydrochloric acid. Only the inorganic and the loosely combined organic iron is revealed. The experiments are made on animals with different diets, or fed on iron, for varying periods. The method is of value especially for showing the place and manner of absorption, and the course of iron through the system.

Course of Absorption.—Macallum, 1894; Quincke, and Hochhaus, 1896; and Abderhalden, 1906, found the reaction after the administration of iron preparations, especially strong in the epithelial cells of the *duodenum*. The results below the duodenum were inconstant, depending upon the quantity administered. The *gastric epithelium* gives no reaction.

The *large intestines* show a diffused iron reaction of the epithelium, and granules in the submucous leucocytes. It was generally assumed that this iron was in the course of excretion. However, Tartakowsky found that the large intestine shows no sulphide reaction in starvation or with iron-poor food, although the chemic examination of the intestinal contents proves the continued excretion of fixed iron. It would therefore seem that the excreted iron is too firmly combined to give the sulphide reaction; and that the sulphide reaction of the large intestine is also due to iron in the course of absorption. However, the amount absorbed here must be small.

The absorption of iron must therefore take place mainly *through the cells of the duodenum*. This differs from other metals, which are absorbed *between* the cells (Hoeber, 1907). The iron reaction is essentially identical, whether organic or inorganic iron is fed. Since food-iron does not give the sulphide reaction, even in the intestinal contents, it must be broken down into ionic iron within the epithelium. This does not exclude the possibility that a part of the organic iron may be absorbed unchanged; for this would not be revealed by the microchemic reaction.

Further Course of the Absorbed Iron.—The iron reaction is also seen in the stroma of the duodenal villi; in the central lacteal, and sometimes in the mesenteric lymph

glands, partly dissolved in the lymph plasma, often as granules in the lymph corpuscles (ferrocetes) (Quincke; Gaule; Abderhalden). Gaule, 1896, also found that iron administration does not increase the iron content of the spleen, if the lymph is prevented from reaching the circulation, by a fistula of the thoracic duct. These observations would indicate that the iron reaches the blood through the lymph. Frantz Mueller obtained just the opposite results: The lymph of the thoracic duct contained no iron; and the fistula did not prevent the accumulation of iron in the organs. The difference is perhaps explained by the dosage: Gaule worked with large doses and his histologic results at least could be referred to corrosion; while Mueller used smaller doses. It is therefore probable that the iron normally passes directly into the intestinal capillaries. It is then rapidly deposited in the organs.

Reserve Stock of Iron.—Animals on an ordinary diet lay up a considerable reserve stock of iron, as loose protein compounds, especially in the liver and spleen. This reserve disappears ("siderosis" of Quincke) gradually when a diet poor in iron is given, or when there is an extraordinary use of iron, as after hemorrhages, or during pregnancy (when considerable iron is transferred to the fetus). In acute hemolytic anemia of rabbits, the reserve iron largely disappears, especially from the liver cells, when the blood is regenerated. Small amounts are still present in the endothelium of the hepatic capillaries, in the spleen and in the renal cortex (Muir and Dunn, 1915). The deposits increase, on the other hand, when the iron of the food is increased.

The liver of crayfish and lobsters is also rich in iron, although these animals do not form hemoglobin. It is therefore probable that the storage of iron in the liver was originally for the purpose of excretion, rather than as a reserve depot for the reformation of hemoglobine.

Relation of Spleen to Iron Metabolism.—The constant occurrence of loosely bound iron granules in the spleen, varying in quantity with the iron income and blood destruction, shows that it is one of the important depots for reserve iron (Chevallier, 1914). Even animals fed on iron-free food from birth, and whose liver is free from reserve iron, contain some in the spleen (Schmidt, 1912). However, this function is shared by many other organs, so that splenectomy does not entail any constant or important changes in normal iron metabolism (Austin and Pearce, 1914). When the iron income is inadequate, the loss of the spleen may perhaps lead to a less effective retention of iron, as is believed by Asher and his pupils, 1909 and 1911. On the other hand, excision of the spleen has real, if not very conspicuous effects on the red blood corpuscles.

Effects of Splenectomy.—These have been investigated especially by Pearce and pupils, 1912 to 1915. They find that excision of the spleen from normal dogs is followed by moderate anemia, with very slow recovery. The decrease is greater for the hemoglobin than for the blood count. The mechanism of this anemia is not clear. Subsequently, as the anemia recovers, the red cells become abnormally resistant to hemolytic agents and the fatty bone-marrow becomes cellular. The cells of the lymph nodes and perhaps of the liver show a compensatory increase of phagocytic function toward the red cells.

Splenectomy does not modify the bile-pigment excretion, with or without hemoglobin injection (Hooper and Whipple, 1917).

Injection of Spleen Extracts.—Intraperitoneal injection produces for one or two days a distinct increase of hemoglobin and corpuscles in normal, not in splenectomized animals, apparently by stimulating the bone-marrow. Feeding of spleen is ineffective (Krumbhaar and Musser, 1914). Splenic extract has no hemolytic action *in vitro*; nor does the blood of the splenic vein contain more free hemoglobin than the splenic artery (*ibid*).

Spleen and Bone-marrow Extract.—Leake, 1923, found that the intravenous injection of saline extracts of spleen and of red bone-marrow produces in rabbits a slight increase of red corpuscles and hemoglobin; but if the two extracts are injected together, the increase is considerably more marked. It is apparently due to stimulation of the bone marrow. Similar changes are reported for oral administration to man, and it is claimed that this is of considerable benefit in secondary anemias; not in pernicious anemia (Leake and Evans, 1924). Further confirmation of the clinical claims appears desirable, in view of the difficulty of predicting the spontaneous course of secondary anemia.

Red Bone Marrow.—This contains lecithin, hemoglobin and other organic iron compounds. Glycerin extracts have been tried in anemias, to stimulate the production of corpuscles. The results are not convincing. The extracts also contain pressor and depressor principles (O. H. Brown and Guthrie, 1905; Brown and Joseph, 1906).

The injection of hemolyzed blood also stimulates the bone marrow to increased formation of corpuscles, and so does oxygen deficiency, as in high altitudes (for bibliography, see S. Isaac, 1920).

Assimilation of Iron.—It would be quite conceivable that the absorbed iron, particularly the inorganic preparations, were of as little use to the organism as the particles of solid carbon which are absorbed by the lungs. It had to be shown therefore that the iron can be actually assimilated and converted into hemoglobin. This could not be studied on normal animals, because the normal income of iron is amply sufficient for all the needs of the organism; an excess has no effect whatever on the hemoglobin. The animals must be reduced to a condition in which the needs exceed the ordinary income. In young and actively growing animals, this may be secured by a diet poor in iron (milk and rice). This produces a progressive fall of the percentage of hemoglobin, and the animals become emaciated and do not develop. As soon as iron, in any form, is added to the diet, the animals recover very rapidly (Hösslin, 1890; Cloetta; Tartakowsky; Abderhalden). It must therefore be concluded that *all forms of iron can be assimilated*.

The same result is obtained with adult animals. These can not be rendered markedly anemic by an iron-poor diet; for by drawing on their reserve stock, and possibly utilizing the iron several times, they can keep up an almost normal percentage of hemoglobin for a considerable period. Nor can they be rendered permanently anemic by a single hemorrhage, even though it is severe, or is repeated next day (Whipple et al., 1918, 1920; C. S. Williamson, 1924). Under these conditions, there generally remains enough reserve-iron to permit complete regeneration, and the latter is therefore not materially accelerated by the administration of iron, organic or inorganic. Meat diet hastens the recovery, but this is probably not through its iron content.

If, on the other hand, a number of hemorrhages are made at suitable intervals, so as to simulate chronic hemorrhage and secondary anemia, then the iron reserve becomes exhausted and recovery occurs only when iron (in any form) is added to this diet (Kunkel, 1895; Tartakowsky, 1903 and 1904).

Abderhalden at first contended that even these experiments did not prove the assimilation of inorganic iron: He concluded from his data that the undernourished animals did not improve as rapidly by the simple addition of inorganic iron, as did the animals which were placed on a normal (iron-containing) diet plus inorganic iron; but that the improvement was more rapid on a full diet plus inorganic iron than on a full diet alone. He interpreted these observations to the effect that inorganic iron was not assimilated as such, but that it increased the assimilation of organic iron, perhaps by stimulating the bone matter. Jacquet, however, pointed out that the slower improvement, when the iron was added to the restricted diet, would be explained by the lower protein content of this diet; and Tartakowsky showed that inorganic iron added to a diet rich in iron does not hasten the improvement, as it should if it stimulated the bone-marrow. Abderhalden seems to have dropped his objection.

Changes in Bone-marrow.—When iron is administered in anemia, the marrow doubtless shows greater activity, more nuclear erythrocytes and mitotic cells; but this is the natural accompaniment of the increase of hemoglobin. The observation of Schmincke, 1913, with iron administration in human anemia, that the increase of erythrocytes considerably precedes the increase of hemoglobin, is also not convincing proof of direct bone-marrow stimulation, until we know more about the normal and pathologic sequence of blood regeneration.

A. B. Macallum, 1890, found in frogs that the hemoglobin arises from the transformation of the iron-containing nuclear chromatin of the hematoblasts.

Disassimilation of Iron.—A part of the reserve iron is doubtless derived from the destruction of the red corpuscles and their hemoglobin; for the injection of hemoglobin or hematin increases markedly the iron content

of the liver, spleen and marrow. The transformation of hemoglobin into the less firmly masked iron may be seen in extravasations of blood, and takes place there in gradual stages. The impossibility of producing severe anemia in adult animals by limiting the iron of the food, *indicates that the iron-stock may be used several times*. But a portion is undoubtedly lost by the feces and urine.

Fate of Hemoglobin.—If free hemoglobin occurs in the plasma, as a result of injection or hemolysis, in concentrations above about 0.12 per cent., the excess is mainly filtered through the kidney and produces hemoglobinuria. A part, however, and with lower concentrations all of the dissolved hemoglobin is taken up and destroyed by the liver, spleen, kidney, etc. In the liver, the hemoglobin is converted into bile-pigments. If the amount of this exceeds the excretory capacity of the bile, it results in icterus (Pearce, Austin and Eisenbrey, 1912).

With hemolysis so severe as to destroy nearly half of the blood in three days, Muir and Dunn, 1915, found nearly all of the iron of the destroyed hemoglobin deposited in the liver, spleen and kidneys. A third of the total iron of the blood may be thus deposited in twenty-four hours.

The conversion of hemoglobin into bile-pigment is not quantitative on intravenous injection, and the feeding of blood does not modify the bile flow, or the secretion of bile-pigment (Whipple and Hooper, 1917).

Although it is practically certain that bilirubin is produced from hemoglobin, the steps of the process are unknown. From their formulas, it may be a rather simple oxidation (Kuester, 1916).

Local Actions on Alimentary Canal.—These were advanced in explanation of the therapeutic effects when the assimilation of inorganic iron preparations was still in doubt. The inorganic salts of iron produce an astringent effect, which may conceivably support their other actions, by improving digestion, (Kobert, 1882). There is always danger, however, that the useful action passes into irritation, and, in fact, iron causes digestive disturbance (especially constipation) more often than improvement.

It was also suggested that the inorganic iron protected organic iron against precipitation by *sulphides* in the intestines. This would, of course, be superfluous, since food-iron is not precipitated by sulphides. Accordingly, Stockman, 1893, found that iron produced its therapeutic effect even when it was administered as the sulphide. On the other hand, other metals which bind H_2S with avidity (*f.i.*, bismuth), are entirely ineffective in chlorosis.

Effects on General Nutrition.—While these are doubtless mainly the indirect result of the increase of hemoglobin, it must not be overlooked that iron forms a constituent of all cells, and some of its effects may be direct; but its importance in this connection is difficult to estimate. The majority of organisms require some iron, even those which do not form hemoglobin. (The blood of some *invertebrate animals* contains copper or manganese in place of iron.)

Therapeutic Use in Anemias.—The administration of iron would be useful in all conditions in which the need for iron exceeds its income; conditions which are characterized by a low percentage of hemoglobin, and by the general clinical picture of anemia.

The plainest indication for iron is furnished by the anemia produced by severe or repeated *hemorrhage*. *Infantile anemias* are often traceable to a deficient iron content of the food, and would be greatly benefited by iron. Some cases of simple anemias in adults may also be due to this cause.

Iron Content of Milk.—Anemia is apt to occur if the infant is kept too long on an exclusive milk diet. It may also be favored by an inferior quality of milk: while normal human milk contains 3.5 to 7.2 mg. of iron per liter (mean 5 mg.), that of unhealthy mothers is poorer in iron; and artificial infant foods generally contain only 1.4 to 2.6 mg. Cow's milk is even poorer in iron than is generally believed. It contains 0.4 to 0.7 mg., mean 0.5 mg. per liter; the higher figures of older determinations were due to contamination from metallic containers (Edelstein and Csonka, 1911).

Most instances of anemia, and especially chlorosis, can not be attributed directly to deficient iron income; but nevertheless, the administra-

tion of iron often secures brilliant results. It must therefore be supposed that conditions exist in these diseases, which demand an extraordinary income of iron to keep the hemoglobin normal.

Iron in Chlorosis.—A complete explanation of the action of iron in chlorosis can be furnished only when the *pathology* is understood. This is not the case at present; little is known beyond the fact that the hemoglobin is decreased (Födisch, 1832) much more than the number of corpuscles (several authors, 1842), and that the excretion of iron by the urine is nearly normal. Even the question, whether the reserve stock of iron is altered, does not seem to be decided. Digestive disturbances are often present, but they may be secondary or accidental; indeed, they disappear spontaneously with the iron treatment.

Our knowledge of the *etiology* is equally unsatisfactory. It has indeed been shown by Stockmann that the diet of chlorotic girls is often very poor in iron (containing 2.8 to 3.2 mg. per day, instead of the normal, 6 to 14 mg.). But this, as well as other unhygienic conditions, can be considered only as contributory factors, since many persons are subject to these conditions, while chlorosis is confined to females about the age of puberty. There is no evidence of defective absorption of iron.

The *treatment* is much more successful than might be expected. The administration of iron holds the first place. This should be supplemented by proper hygiene—good air, rest, suitable diet, stomachics, attention to the bowels (aloes), etc. Arsenic, phosphorus or manganese are often used in addition to the iron: it is difficult to judge of their value.

Pernicious Anemia.—Iron is useless in those cases of anemia in which there is no deficiency in the income or store of iron; but in which the fault concerns the formation or destruction of the corpuscles. In pernicious anemia, a most severe destruction of the corpuscles (probably through an unknown hemolytic agent) is accompanied by a very considerable increase of the reserve iron of the liver and spleen (Rumpf, 1901) and of the dissolved iron of the spleen (Erben, 1900). The urinary excretion of iron remains normal (Queckenstedt, 1913). Clinical experience has confirmed that the administration of iron is useless in this condition.

Starvation.—In pigeons, starvation (direct or by rice-disease) produces quite promptly a very marked anemia, which is not prevented or benefited by the administration of iron, in the form of Vallet's mass (Barlow, 1926). This may be analogous to the anemia of marasmus, and to the pernicious anemia. The three have the common feature of hypochlorhydria.

Administration.—Although both organic and inorganic iron are absorbed and produce therapeutic effects, the ionized iron appears to be more active therapeutically, for reasons not fully understood. On the other hand, inorganic-iron preparations are more apt to set up digestive distress, which may interfere with the prolonged administration that is ordinarily needed. In such cases, it is necessary to begin with the milder organic or insoluble preparations; and to induce a tolerance to the local effects by progressing slowly to the stronger compounds. The ferrous carbonate can be given to most patients without difficulty, and is sufficiently effective. The most suitable form and dosage are governed by individual experience. The *daily dose* should correspond to about 0.1 Gm. of iron. This would be contained in about 5 or 6 Bland pills, but would require 30 to 250 Gm. of the organic preparations (Morawitz, 1914).

The *order of irritation and efficiency* is about as follows (in ascending order): food-iron; other organic irons; reduced iron (in powder or pills); ferrous carbonate (saccharated; Blaud's pill); the double "scale" salts; ferrous sulphate; ferric chloride.

Reduced iron should be given just before meals, to permit the solvent action of the gastric juice. All other inorganic iron preparations should be taken just after meals, taking care to protect the teeth. The incompatibilities of iron must be remembered. The tendency to constipation may be met by aloes or other laxatives.

Hypodermic Administration of Iron.—Iron ammonium citrate has been used clinically, 1 c.c. of 10 per cent. solution daily. It is efficient, but has no advantage over oral administration; it is rather painful, and sometimes produces severe local and systemic reaction, gastritis etc. These accidents have not been observed in animals even with much larger doses (L. W. Rowe; 1917).

IRON PREPARATIONS

Only the most important preparations need to be studied. It may be remembered that ferric salts have a reddish, the ferrous a greenish color. The most important *incompatibilities* are: alkalies, salicylates, phenol.

Organic iron preparations had a brief popularity when it was believed that inorganic preparations were not absorbed. The modern conceptions have caused them to be practically abandoned, except in so far as iron foods are emphasized in the diet in anemia.

PREPARATIONS—INSOLUBLE IRONS

Ferrum, U.S.P., B.P.; Iron.—Metallic iron in the form of fine, bright, and non-elastic wire. Used only for preparing the salts.

**Ferrum Reductum* (Ferr. Reduct.), U.S.P.; *Ferrum Redactum* (Ferr. Redact.), B.P.; Reduced Iron (Iron by Hydrogen; Quevenne's Iron).—Iron reduced to the metallic state by the action of hydrogen upon ferric oxide. Very fine, grayish-black, lusterless powder, without odor or taste. *Dose*, 0.06 Gm., 1 gr., U.S.P.; 0.06 to 0.3 Gm., 1 to 5 gr., B.P., as powder.

Troch. Ferr. Redact., B.P.—0.06 Gm., 1 gr.

Ferri Carbonas Saccharatus (Ferr. Carb. Sacch.), U.S.P.—Contains not less than 15 per cent. of FeCO_3 . Made by precipitating ferrous sulphate with sodium bicarbonate, and diluting with milk-sugar. A greenish-brown powder, gradually becoming oxidized by contact with air; odorless, and having at first a sweetish afterward slightly ferruginous, taste. Only partially sol. in water. *Dose*, 0.25 Gm., 4 gr., U.S.P., suspended in water.

Ferrous Carbonate tends to give off CO_2 and absorb oxygen, changing rapidly into a basic carbonate and finally into ferric hydroxide. The change may be retarded by the addition of sugar, as in the pharmaceutic forms; but these should always be prepared as freshly as possible.

Ferr. Carb. Sacch., B.P.—Not less than 50 per cent. of Ferrous Carbonate, preserved by Glucose. *Dose*, 0.6 to 2 Gm., 10 to 30 gr., B.P.

Mist. Ferr. Co., B.P. (Griffith's Mixture).—About 0.7 per cent. of Ferrous Carbonate in suspension in flavored water. Must be freshly prepared. *Dose*, 15 to 30 c.c., $\frac{1}{2}$ to 1 ounce, B.P.

**Massa Ferri Carbonatis* (Mass. Ferr. Carb.), U.S.P. (Vallet's Mass.).—A pill-mass, with not less than 35 per cent. of FeCO_3 . *Dose*, 0.25 Gm., 4 gr., U.S.P.

Pil. Ferr., B.P.—Pill-mass with 22.5 per cent. of FeCO_3 . *Dose*, 0.3 to 1 Gm., 5 to 15 gr., B.P.

**Pil. Ferr. Carb.*, U.S.P. (Blaud's, Chalybeate, or Ferruginous Pills).—0.065 Gm., 1 gr., of FeCO_3 , made from ferrous sulphate and pot. carb. *Dose*, 2 pills, U.S.P.

Contrary to the prevailing impression, the U.S.P. Blaud's pills are quite stable, and preferable to the proprietary substitutes (Warren, 1915).

Ferri Hydroxidum Cum Magnesii Oxido (Ferr. Hydrox. cum Mg. Oxid.), U.S.P. (Arsenic Antidote; Ferric Hydrate with Magnesia).—40 c.c. of Solution of Ferric Sul-

phate are diluted with 125 c.c. of water. This is added, when needed, to 10 Gm. of Magnesium Oxide or 300 c.c. of Magma Magnesia diluted with water to about 750 c.c.

Always keep the dilute solution of ferric sulphate and magnesia mixture on hand in separate bottles, ready for immediate use, so that this antidote to arsenical poisoning may be quickly prepared.

Dose, 120 c.c., 4 ounces, U.S.P.

PREPARATIONS—COLLOIDAL IRONS AND "SCALE SALTS"

Liq. Ferri Oxychloridi.—A colloidal solution of ferric hydroxide in ferric chloride; approximately $\text{FeCl}_3 + 8\text{Fe}(\text{OH})_3$, containing the equivalent of about 3.5 per cent. of metallic iron. It is only mildly astringent. *Dose*, 0.5 to 2 c.c., 8 to 30 minims.

Liq. Ferri Dialysatus. (Dialysed Iron).—This is a similar solution from which the excess of acid and chloride has been removed by dialysis. It has the same iron content and is less astringent. *Dose*, $\frac{1}{2}$ to 2 c.c., 8 to 30 minims.

Liquor Ferri et Ammonii Acetatis (Liq. Ferr. et Ammon. Acet.), U.S.P. (Basham's Mixture).—The average dose, 15 c.c., 4 drachms, U.S.P., contains 0.4 c.c. of Tr. Fer. Chlor., 5 c.c. of Liq. Ammon. Acet.; Acetic Acid, Elixir, etc. Must be recently prepared.

**Ferri et Ammonii Citras* (Ferr. et Ammon. Cit.), U.S.P. (Soluble Ferric Citrate, Ammonio-ferric Citrate).—A mixture of iron citrate and ammonium citrate containing about 17 per cent. of Fe. Thin, transparent, garnet-red scales, without odor and having a saline, mildly ferruginous taste; deliquescent in moist air. Readily and completely sol. in water; insol. in alc. *Dose*, 0.25 Gm., 4 gr., U.S.P.; 0.3 to 0.6 Gm., 5 to 10 gr., B.P., in solution.

Vin. Ferr. Cit., B.P.—1.8 per cent. of Ferr. et Ammon. Cit. *Dose*, 4 to 16 c.c. 1 to 4 drachms, B.P.

Vin. Ferr., B.P.—Prepared by macerating iron in Sherry Wine; Contains the equivalent of 0.125 to 0.3 per cent. of Fe. *Dose*, 4 to 16 c.c., 1 to 4 drachms, B.P.

Ferr. et Poi. Tart., B.P. (Ferrum Tartaratum).—Garnet scales. *Dose*, 0.3 to 0.6 Gm., 5 to 10 gr., B.P.

Ferr. et Quin. Cit., B.P.—Contains about 12.5 per cent. of quinine and 13.5 per cent. of Fe. *Dose*, 0.3 to 0.6 Gm., 5 to 10 gr., B.P.

Ferr. Phos. Sol. U.S.P.—Ferric phosphate, made soluble by the presence of Sod. Cit.; corresponding to not less than 12 per cent. of Fe. Bright green scales. Freely sol. in water, insol. in alc. *Dose*, 0.25 Gm., 4 gr., U.S.P.

(El. Ferr. Quini et Strych. Phosph.—See Index.)

(Syr. Ferr. Phos. c. Quin. et Strych.—See Index.)

PREPARATIONS—SOLUBLE FERROUS SALTS

**Syrupus Ferri Iodidi* (Syr. Ferr. Iod.), U.S.P.—5 per cent. of ferrous iodide, FeI_2 . Pale green acid liquid of strong iron taste. Very susceptible to oxidation, turning brownish. It combines the therapeutic properties of iron and iodides, and is often prescribed in goiter (2 drops, twice daily, gradually increased to 15 drops three times daily; Marine and Lenhart, 1911) and as a general tonic in "scrofulous" conditions. Average dose, 1 c.c., 15 minim. U.S.P., contains about 52 mg., 0.85 gr., of iodine.

Syr. Ferr. Iod., B.P.—7 per cent. of FeI_2 . *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Ferr. Phosph. Sacch., B.P.—60 per cent. of ferrous phosphate, $\text{Fe}_3(\text{PO}_4)_2 + 8\text{H}_2\text{O}$, preserved with glucose. Partially sol. in water; sol. in HCl. *Dose*, 0.3 to 0.6 Gm., 5 to 10 gr., B.P.

Syr. Ferr. Phosph., B.P.—1.7 per cent. of ferrous phosphate. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.

Ferri Sulphas (Ferr. Sulph.), U.S.P., B.P.; Ferrous Sulphate (Green Vitriol); Iron Proto-sulphate, $\text{FeSO}_4 + 7\text{H}_2\text{O}$.—Large, pale green crystals; odorless, saline styptic taste; effloresces in dry air. Freely sol. in water (1:1.4), practically insol. in alc. *Dose*, 0.1 Gm., $1\frac{1}{2}$ gr., U.S.P.; 0.06 to 0.3 Gm., 1 to 5 gr., B.P.—The crude salt is employed as a deodorizer for fecal matter, but is not germicidal.

Ferri Sulphas Granulatus (Ferr. Sulph. Gran.), U.S.P.—The preceding, in granulated form. *Dose*, 0.1 Gm., $1\frac{1}{2}$ gr., U.S.P.

**Ferri Sulphas Exsiccatus* (Ferr. Sulph. Exsic.), U.S.P., B.P.—80 per cent. of anhydrous FeSO_4 , 1 part being equivalent to about 1.5 parts of the crystalline salts. Grayish-white powder; astringent taste. *Dose*, 0.06 Gm., 1 gr., U.S.P.; 0.03 to 0.2 Gm., $\frac{1}{2}$ to 3 gr., B.P.; in pills, often with aloes.

Pil. Aloes et Ferr., B.P.—10 per cent. of Ferr Sulph. Exs.; 20 per cent. of Aloes. *Dose*, 0.25 to 0.5 Gm., 4 to 8 gr., B.P.

PREPARATIONS—SOLUBLE FERRIC SALTS

Ferr. Chlor., U.S.P.; Ferric Chloride (Iron Perchloride).—Contains FeCl_3 equivalent to 20 per cent. of Fe. Very sol. in water (1:0.2) or alc.; sol. in glyc. *Dose*, 0.06 Gm., 1 gr., U.S.P.

Liq. Ferr. Chlor., U.S.P.—30 per cent. of FeCl_3 or 10 per cent. of Fe. *Dose*, 0.1 c.c. 1½ minims, U.S.P.

Liquor Ferri Perchloridi Fortis (Liq. Ferr. Perchlor. Fort.), B.P.—20 per cent. of Fe.

Liq. Ferr. Perchl., B.P.—5 per cent. of Fe. *Dose*, 0.3 to 1 c.c., 5 to 15 minims, B.P.

* *Tinctura Ferri Chloridi* (Tr. Ferr. Chlor.), U.S.P.; *Tr. Ferr. Perchlor.*, B.P.; Tincture of Ferric Chloride (Tincture of Iron).—About 13 per cent. of FeCl_3 or 4.5 per cent. of Fe. Prepared by mixing the Liquor with Alcohol; the U.S.P. directs it to stand three months before using, to permit the formation of esters. A bright amber acid liquid, of slightly ethereal odor and very astringent taste. Miscible with water or alcohol. *Dose*, 0.6 c.c., 10 minims, U.S.P.; 0.3 to 1 c.c., 5 to 15 minims, B.P., diluted. Often used as local astringent in tonsillitis (equal parts of the tincture, glycerin and water).

Liq. Ferr. Subsulph., (Monsel's Solution; Solution of Basic Ferric Sulphate).—13.5 per cent. of basic ferric sulphate. *Dose*, 0.2 c.c., 3 minims. Used mainly locally, as styptic.

Liq. Ferr. Tersulph., U.S.P. (Solution of Ferric Sulphate).—10 per cent. of Fe as Ferric Sulphate, $\text{Fe}_2(\text{SO}_4)_3$.

Liq. Ferr. Persulph., B.P.; Solution of Ferric Sulphate.

Ferri Oxidum Saccharatum.—(Ferr. Oxid. Sacch.), N.F. (Soluble Ferric Oxide, "Eisenzucker").—It contains ferric oxide equivalent to at least 2.8 per cent. of Fe; made soluble by the addition of sugar and a small amount of alkali. *Dose*, 0.6 Gm., 10 grains.

Iron (Chalybeate) Mineral Waters.—These contain the iron most often as ferric bicarbonate; sometimes as sulphate, oxide, and very rarely as chloride.

GERMANIUM

The injection into rats of the dioxide of this rare element was reported by Hammett et al., 1922, and J. H. Muller and Iszard, 1922, to cause considerable increase of the blood cells, attributed to stimulation of the bone marrow. This does not occur in rabbits (Minot and Sampson, 1922), and no significant effects have been observed in any type of clinical anemia (Garvin, 1922; Alexander, 1923).

MANGANESE

Occurrence.—Traces of manganese occur naturally in all organs, in man and various animals, its presence being fairly constant in the same species (Bertrand and Medigreceanu, 1912). The amount in wheat, for instance, is about equal to the iron, and is independent of the manganese percentage of the soil (Headdon, 1915). The manganese of animals is derived partly from vegetable, but mainly from animal food; but does not disappear from the body even on manganese-free food.

Actions.—When administered by mouth, the salts of this metal (but this does not apply to the permanganates) produce no noticeable effect. Manganese is absorbed to a slight degree from the alimentary canal, being deposited mainly in the liver and kidneys, and passing also to the fetus *in utero*. Its excretion begins within three hours, mainly by the intestine (as sulphide in the feces), and the bile; but the urine participates (Bargero, 1906, dog; Piccinini, 1910). It appears to take about the same course as iron (Harnack and Schreiber, 1901). Benedetti, 1906, and Piccinini, 1910, 1912, claim that it increases the reserve iron. Benedetti has investigated its fate by subcutaneous injection (citrate, dog). It is toxic by vein (Bargero), and also causes fatty degeneration of the liver.

Manganous chloride accelerates autolysis when added to excised liver; perhaps by converting indigestible proteins into forms that can be attacked by the liver enzymes (Bradley and Morse, 1915).

Manganese on Plant Growth.—Small amounts of manganese and other elements especially zinc and boron increase materially the growth of plants. This is easily measured on cultures of the mould *Aspergillus niger*. It has been suggested that they act by killing competing or infective bacteria; but they appear to act directly, for they

actually enter the plant cells, and manganese is indispensable for the activity of laccase, a vegetable oxytase. The subject is discussed by Bertrand, 1912.

Manganese Toxicosis.—Chronic poisoning results from exposure to the dust of any of its compounds in the industries, in zinc mines, grinding, etc. (Embden, Casamajor, 1913; Jaksch, 1913.) The symptoms are nervous, with mental and ataxic disturbances. The prognosis is good as to life, bad as to recovery. The condition has not been produced in animals (literature, v. Oettingen and Sollmann, 1926).

Manganii Dioxidum Præcipitatum (Mangan. Diox. Præc.).—Consists chiefly of manganese dioxide (MnO_2). Prepared by precipitating manganese sulphate by ammonia in the presence of hydrogen dioxide. Heavy, fine, black powder, without taste or odor; insol. in water or alc. *Dose*, 0.25 Gm., 4 gr.

CHROMATES

Uses.—Chromium trioxide (chromic acid) is used externally as a caustic. It and the chromates have some toxicologic importance, the dichromate being used in dyeing and in "battery fluids." They are also interesting by producing a characteristic nephritis and glycosuria.

Kolipinski, 1902 and 1908, reported favorable results from chromium sulphate (8 gr., three to four times daily) in neurathenia, tabes and other nervous conditions. They have not been adequately confirmed.

Acute chromate poisoning exhibits corrosive effects and nephritis with death in one to forty-eight hours. The fatal dose of potassium dichromate is below 8 Gm.; of chromic acid, 6 Gm. The *treatment* is by evacuation and demulcents. *Chronic poisoning* produces local irritation (severe dermatitis, ulcers, etc.) and nephritis.

Ulcers are produced by chromate dust, especially where the skin is already injured. They develop slowly, but are very penetrating and heal with difficulty. It also causes ulceration and perforation of the nose.

Fate.—When bichromates are given by the mouth, they are reduced to chromous oxide and partly deposited as such in numerous organs, the rest being excreted by the urine (Kappeler, 1896).

Chromate Nephritis.—This is produced experimentally by hypodermic injection of the chromates. It is mainly tubular, but the glomeruli are involved first. All the phenomena are similar to uranium (including retention, glycosuria, chronic nephritis, etc.); except that edema is not common (Gergens, 1876; Hellin and Spiro, 1897; Schlayer and Hedinger, 1907; Ophuls, 1908; Austin and Eisenbrey, 1911; R. M. Smith, 1911; Folin, Karsner and Denis, 1912; MacNider, 1912; Eisenbrey, 1913; E. Franck, 1913; glycosuria, Mosenthal and Schlayer, 1913; diuretics, etc.).

PREPARATIONS

Chromii Trioxidum (Chrom. Triox.), U.S.P.; **Acidum Chromicum** (Acid. Chrom.), B.P.; Chromium Trioxide, Chromic Acid (Chromic Anhydride), CrO_3 .—Dark red, needle-shaped crystals, very deliquescent and very sol. in water (1:0.6). *Explosive* with all organic matters. Used as a caustic, solid or in solution (1:1); as astringent (2 to 3 per cent.); for urethral injections (1:2,000 to 4,000); and against sweating feet (5 per cent.).

Liq. Ac. Chromici, B.P., 25 per cent.

Potassii Bichromas, B.P., $\text{K}_2\text{Cr}_2\text{O}_7$.—Large orange-red crystals. Sol. in water (1:10). *Incompatible* with alcohol and all reducing agents. *Dose*, 6 to 12 mg., $\frac{1}{10}$ to $\frac{1}{6}$ gr., B.P., diluted (against gastric ulcer); locally, 1:10 solution against rodent ulcer and cancer.

ALUMINUM

The soluble salts are strongly precipitant to proteins, and therefore astringent and antiseptic. They are used externally, and sometimes against diarrhea. They are not readily absorbed from the alimentary

canal, so that even very large doses cause only local exudative inflammation (vomiting and diarrhea). The precipitates redissolve in an excess of protein.

The quantities which may be dissolved from aluminum cooking vessels, even by dilute acids, are too small to be of any importance. Alum baking powders are perhaps more objectionable.

Absorption and Distribution.—It was formerly stated that aluminum salts are not absorbed (Plagge and Lebbin, 1893). Gies 1911, Steel, 1911, and Kahn, 1912, however, showed that considerable absorption occurs even from biscuits baked with alum baking powder, and this tends to accumulate in the body. The bile is especially rich; the parenchymatous organs retain considerable; the brain and heart but little.

On the other hand, the Referee Board, 1914, found no aluminum in the blood after administering to men 1 Gm. per day for four days.

Aluminum occurs naturally in the ash of bird feathers (Gonnermann, 1918).

Excretion.—Schmidt and Hoagland, 1919, administered soluble and insoluble aluminum compounds, over long periods. They recovered the entire ingested aluminum (within limits of error) from the feces; none from the urine. Steel, 1911, also found it mainly in the feces even after intravenous injection. Kahn, 1912, claims that it is excreted partly by the urine, after oral administration.

Effects on Metabolism.—Schmidt and Hoagland, 1919, administered to men over extended periods about 0.5 Gm. per day of aluminum, as potassium or sodium alum, and as alumina. They found that the metal is excreted in the feces partly as phosphate; thus deflecting the phosphates from the urine, or preventing their absorption and utilization. This is practically unimportant, unless the income of phosphorus is deficient.

They also give the bibliography since the Referee Board report.

Delayed Symptoms.—The aluminum compounds spread very slowly even when injected subcutaneously, and appear to penetrate cells with great difficulty; for the symptoms appear only several days or weeks after the injection (Siem, 1886), at a time when the metal has entirely disappeared from the blood, and has become fixed in the cells. The symptoms then resemble those of subacute arsenic poisoning. They never occur when aluminum salts are given by mouth, no matter in what doses, nor how long continued. Roth and Voegtlin, 1916, found that prolonged feeding of aluminum salts to animals produced mainly gastro-intestinal irritation.

Astringent Action.—This has been studied by Barinetti, 1914.

Precipitant Action.—A 1 per cent. solution of alum precipitates most suspensions, but does not affect emulsions.

PREPARATIONS

**Alumen* (Alum.), U.S.P.; *Alumen Purificatum* (Alum. Pur.), B.P.; Potassium Alum (Aluminum Potassium Sulphate), $\text{AlK}(\text{SO}_4)_2 + 12\text{H}_2\text{O}$; or Ammonium Alum, $\text{AlNH}_4(\text{SO}_4)_2 + 12\text{H}_2\text{O}$.—Large colorless crystals; strongly astringent taste; without odor. Freely sol. in water (1:7.2), practically insol. in alc.; freely sol. in glyc. *Incompatible* with alkalis, carbonates and lead salts. *Dose*, 0.5 Gm., 8 gr., U.S.P.; 0.3 to 0.6 Gm.; 5 to 10 gr., B.P. Used as gargle (1 to 5 per cent.; somewhat injurious to teeth); as urethral injection (0.5 to 1 per cent.); and as skin lotion (1 per cent.).

Alumen Exsiccatum (Alum. Exsic.), U.S.P., B.P. (Burnt Alum).—Alum with 45 per cent. of water (of crystallization) expelled. It is used as a mild caustic.

Glycerinum Aluminis (Glycer. Alum.), B.P.—20 per cent. of Alum.

Liquor Aluminii Acetatis (Liq. Alum. Acet.), N.F., (Burov's Solution).—A clear colorless solution containing about 5 per cent. of neutral aluminum acetate, $\text{Al}(\text{C}_2\text{H}_3\text{O}_2)_3$. Used as a mild astringent and antiseptic. A 1 per cent. dilution is said to be antiseptic and 5 per cent. germicidal (Kuehl, 1913). For application to the skin it should be diluted five to fifteen times.

Liq. Alum. Subacet., N.F.—Contains nearly 8 per cent. of basic aluminum acetate, $\text{Al}(\text{OH})(\text{C}_2\text{H}_3\text{O}_2)_2$. It is practically equivalent to the preceding and is used in the same dilutions.

Aluminii Chloridum (Alum. chlor.), N.F.— $\text{AlCl}_3 + 6\text{H}_2\text{O}$. Freely soluble in water (1:1); and in alc. (1:3). It has no special advantage over alum as a general astringent and antiseptic. Stillians, 1916, recommended it in hyperhidrosis (painting of the skin with 25 per cent., at first every 2 to 3 days; later once a week).

Aluminii Hydroxidum (Alum. Hydrox.).—Chiefly $\text{Al}(\text{OH})_3$. Prepared by precipitating a boiling solution of alum with sodium carbonate. White, bulky, amorphous

powder, odorless and tasteless. Insol. in water and alc. Used as mild astringent and desiccant.

BAKING POWDERS

These are chemicals which serve as substitutes for yeast-fermentation, aerating bread and pastry dough by evolving carbonic acid. They are of course altered in this process. The decomposition products are partly expelled by the heat of baking. The fixed residue is the part which could conceivably produce pharmacologic action.

The baking powders belong to four chemic types (Crampton, 1889):

1. **Cream of Tartar Powders.**—Mixture of acid potassium tartrate and sodium bicarbonate. Reaction: $\text{KHC}_4\text{H}_4\text{O}_6 + \text{NaHCO}_3 = \text{KNaC}_4\text{H}_4\text{O}_6 + \text{CO}_2 + \text{H}_2\text{O}$. Residuum: 11 Gm. of Rochelle Salts per loaf of bread. Innocuous.

2. **Phosphate Powders.**—Calcium super-phosphate and sodium bicarbonate. Reaction: $\text{CaH}_4(\text{PO}_4)_2 + 2\text{NaHCO}_3 = \text{CaHPO}_4 + \text{Na}_2\text{HPO}_4 + 2\text{CO}_2 + \text{H}_2\text{O}$. Soluble residuum: 3.5 Gm. sodium phosphate per loaf of bread. Innocuous.

3. **Alum Powders.**—Alum (usually ammoniac) and sodium bicarbonate. Reaction: $(\text{NH}_4)_2\text{Al}_2(\text{SO}_4)_4 + 6\text{NaHCO}_3 = \text{Al}_2(\text{OH})_6 + 3\text{Na}_2\text{SO}_4 + (\text{NH}_4)_2\text{SO}_4 + 6\text{CO}_2$. Residuum, per loaf of bread: 1.3 Gm. aluminum hydrate; 3.65 Gm. sodium sulphate; 1.1 Gm. ammonium sulphate. The aluminum hydrate is insoluble in water; in the stomach, some is dissolved by the hydrochloric acid, and perhaps by the proteins. Gies, 1911, considers this seriously objectionable. The sulphates are practically without action. (The addition of alum whitens pastry baked from inferior flour. This fraudulent use is prohibited in several countries.)

4. **Ammonium Carbonate.**—Decomposed and volatilized as $\text{NH}_3 + \text{CO}_2$. Expelled so completely that it is inactive.

Some baking powders are mixtures of several of the above. They are often diluted with indifferent substances (starch, etc.).

CERIUM

Cerium resembles aluminum. The insoluble Cerium Oxalate is employed against vomiting, especially in pregnancy (Simpson, 1854; Mills, 1876), but it is probably useless. It is non-toxic even in large doses.

Since cerium oxalate is not absorbed (Bachem, 1907), its action must be entirely local and analogous to that of bismuth. This has been demonstrated experimentally by Baehr and Wessler, 1909: They found that it had no effect on central vomiting (apomorphine), but that large doses delayed vomiting from local gastric irritation (ipe-cac). They also showed that central vomiting was not affected even by the soluble and absorbable cerium nitrate. The systemic effects corresponded to those of Thorium, but the metal is excreted exclusively by the feces.

Cerium has been claimed to be beneficial in tuberculosis, but the evidence appears quite inconclusive (see Editorial, J.A.M.A., 1920, 75: 247).

Injection of neutral solution of cerium tartrate injures the heart, lowers the blood pressure, and arrests respiration. Death occurs by pulmonary edema. Repeated sub-lethal doses do not seem to produce nephritis (Ozaki, 1919).

Cerii Oxalas (Cerii Oxal.).—A mixture of the oxalates of cerium (about 40 per cent.; Coblenz, 1910), didymium, lanthanum, and other associated elements. Fine white or slightly pink powder, without odor or taste. Insol. in water, alc. or eth. *Dose*, 0.05 to 0.5 Gm., 1 to 8 gr., as powder.

Cerium Nitrate (soluble) has been substituted, in doses of 0.05 Gm. or less, but is irrational.

YTTRIUM AND ZIRCONIUM

Neodymium, Praesodymium, Lanthanum, Yttrium and Zirconium (as the chlorides) also precipitate proteins, and the observed effects can be attributed to this reaction (antisepsis, paralysis of muscle, etc.) (Dreyfuss and Wolf, 1905; Bachem; Hobert, 1907; Hoebner and Spaeth, 1914). Their oxalates are all practically non-toxic by mouth, even in enormous doses (50 Gm. per dog).

BERYLLIUM SULPHATE

Seaman, 1912, found that this salt, when administered to dogs with food, resulted especially in nutritional disturbances: emaciation, with loss of N, S, and P. Large doses produced vomiting without acute toxic symptoms. Hypodermically, it caused local edema and necrosis. Intravenous injections were markedly toxic, with disturbances of circulation, respiration and temperature; diuresis, bloody diarrhea and vomiting. It inhibits the action of digestive ferments.

THORIUM

The chemic effects resemble those of aluminum. The nitrate of thorium is markedly astringent, precipitating proteins and coagulating blood. Injected hypodermically, it causes ulceration. The toxicity is slight. It is fairly well tolerated by the stomach, very large doses being required to produce vomiting. It is not absorbed from the alimentary canal. The addition of sodium citrate prevents the coagulant action. When this solution is injected intravenously, it has absolutely no effect on the circulation, or any other function, even when 0.25 Gm. are injected per kilogram of dog. However, the animals remain emaciated, and show ulcers of the gums. When killed, after some weeks, an extensive calcification of connective tissue is noticed. The thorium is excreted by the kidneys. The solutions have no effect on the excised muscle or heart of frogs (Chace and Gies, Brown and Sollmann, 1905). The nitrate was tried for stimulating ulcers, but did not prove superior to alum. The oxalate and oxide are practically insoluble.

The thorium-sodium citrate solution is impervious to X-rays, and has been suggested for radiographic work (Burns, 1915). It has been displaced by other agents (sodium iodide or bromide, colloidal silver, iodized oil).

RADIO-ACTIVE METALS

Thorium, radium, and uranium undergo atomic decay into a series of new elements (emanation, etc.). This decay is accompanied by the generation of rays which produce irritant or destructive effects. These are employed to irritate or destroy pathologic tissues. This requires specialized experience. Smaller doses of the emanation are used internally especially against chronic joint and rheumatic diseases. Their therapeutic status is still uncertain.

Nature of Radio-activity.—Radio-activity is defined as “the property of spontaneously emitting radiations capable of passing through plates of metal and other substances opaque to ordinary light and having the power of discharging electrified bodies.”

Varieties of Rays.—The rays emitted by the disintegration of the metals are of three kinds, differing in their nature, their velocity, penetration and ionizing power:

Alpha-rays are positively charged helium atoms; the beta rays are negatively charged electrons, identical with the cathode rays; the gamma rays are electromagnetic vibrations in the ether, a variety of the roentgen-rays, but of shorter wave length and deeper penetration.

The *penetrating power* of the alpha, beta and gamma rays is as 1:100:10,000, the roentgen rays ranging between 1,000 and 10,000. The alpha rays are stopped by a sheet of paper; of the beta rays, 90 per cent. are stopped by 2 mm. of aluminum or by 5 mm. of muscle tissue; with the gamma rays, 62 mm. of aluminum are required to reduce the rays to one-half. The maximum range through soft tissue is 0.09 mm. for alpha, 2 cm. for beta, and over 100 cm. for gamma rays.

The *ionizing power* varies in the inverse direction, *i.e.*, 10,000 for alpha, 100 for beta, and 1 for gamma rays.

Although the nature of these radiations is different, they have many qualities in common. They cause a large variety of chemical actions and produce similar destructive effects on living tissue.

Sources of Radiation.—The *cathode-rays* are produced when an electric discharge is passed through a high vacuum tube. They consist of beta-rays; *i.e.* negatively charged electrons, propelled from the electrode with half to two-thirds the velocity of light. The *roentgen* or *x-rays* (Roentgen, 1898) belong to the gamma group, *i.e.* they are ether-waves somewhat analogous to light, but of very much shorter length. The principal *radio-active metals* are: thorium, radium, uranium, and some others (ionium, polonium, etc.), and their disintegration products. Potassium is also feebly radio-active. The different metals emit the three varieties of rays in different proportions which are constant for each metal, regardless of its combinations or other conditions.

The *discovery* of radio-activity started with the observation of Becquerel, 1896, that uranium salts act on photographic plates through black paper. Similar rays were discovered in thorium in 1898 by Schmidt and Mme. Curie; and in the same year the Curies discovered polonium and radium.

Properties of Radium.—Radium is a bivalent element, closely related to barium. Because of its chemic reactivity, it can not be kept in the metallic state and is therefore marketed in the form of its salts, especially the soluble bromide or chloride, and the insoluble sulphate and carbonate. It is generally mixed with more or less of the corresponding barium salts and is sold on the basis of its radium content, as determined by the radioactivity.

Disintegration of Radium.—This proceeds at such a rate that half of the element will be transformed (*i.e.* a "half-period") in about 1,700 years. It goes through a number of successive products. The first is formed by giving off alpha rays and consist in a gas niton, or radium "emanation" or "radon," with a half-period of not quite four days; this emits weak alpha rays, changing to radium A (induced radioactivity) and this, with successive losses of alpha, beta and gamma rays, in proportions characteristic for each compound, goes through radium B, C (three varieties), D, E, and F. A table of the rays and of the transformation rates is given in N.N.R. The most penetrating rays are given off by the C group, which is therefore by far the most active group, whether one starts with radium, or with "radon."

Disintegration of Other Radioactive Metals.—Radium itself is formed by the disintegration of uranium, through the stages of: Uranium = Uranium X = Ionium = Radium. Thorium takes the course:

Thorium — α = Mesothorium; — β = Radiothorium; — α = Thorium X; — α = Emanation; — α = Thor. A; — β = Thor. B.; — α = Thor. C; — α = ?

Properties of Radium Emanation—Radium emanation or "radon" consists of the element "niton," a heavy, inert gas of the argon group. It is liberated continuously from slightly acidulated solutions of radium salts, and may be collected, purified, liquefied and dispensed in capillary tubes that are applied to, or implanted in the tissues, in place of radium. It produces the same effects, but because of its rapid decomposition its action diminishes quickly and stops automatically in a few days; whilst the

action of radium endures indefinitely and practically undiminished. The emanation may also be dissolved in water, for internal use. *Thorium emanation* loses its activity within a few minutes.

Radium Deposit.—Substances exposed to radium become coated with active deposits, consisting of all the degradation products. The “half period” of this “induced radioactivity” in an hour. Such deposits on lead foil may be used for superficial application; or exposed sodium chloride may be used for making solutions for intravenous injection.

Standardization of Radioactivity.—This is measured by the ionization of gases, as reflected in the discharge of a gold-leaf electroscope. With large quantities of radium, the gamma rays alone are used, by screening with 1 cm. of lead. With small quantities, the rate of emanation is measured. The common unit of radioactivity is the “curie,” *i.e.*, “the quantity of emanation present when 1 Gm. of radium element is in equilibrium with its disintegration products.” Further details are given by Stratton, 1915. The emanation of a milligram corresponds to a millicurie; and that of 0.001 mg. to a microcurie. The “Mache” unit is a rather uncertain unit, which should be discarded. It is generally understood as about $\frac{1}{2,700}$ of a microcurie.

Radio-active Thorium Compounds.—Ordinary thorium gives off alpha-rays and changes into mesothorium (discovered by O. Hahn, 1907). Its chemic properties resemble those of radium and barium, differing in the intensity and power of radiation. It gives off beta-rays and changes into Radiothorium, and this, by giving off alpha-rays, passes successively into Thorium X and Emanation. The *thorium X* is therefore the principal radio-active product. The distribution, excretion and effects are described by Plesch, Karzag and Keetman, 1912. The actions and therapeutic uses are in all respects similar to radium. It is less efficient, but much cheaper (Schwarz and Zehner, 1912; Falta and Zehner, 1912; Gudzent, 1912). Ledoux and Lebard, 1913, consider mesothorium even better than radium against malignant tumors, and believe that thorium X, because of its richness in alpha-rays, is especially suitable for internal medication.

Fate of Radium.—Soluble radium salts, injected or taken by mouth, are excreted rather slowly, mainly by the large and small intestines, somewhat by the urine, none by the liver or skin (E. Smith and Bellingham, 1912; Brill and Zehner, 1912). The storage is mainly in the liver and spleen. The insoluble radium sulphate is very little absorbed, but its emanations are carried through the tissues.

The *emanation* has a high lipid coefficient, and is distributed in the organs in proportion to its solubility (Knaff-Lenz, 1912). With inhalation, the amount in the blood increased with the time of exposure. The excretion is rapid, especially by the expired air, and partly by the urine. It is completed in about four hours.

Actions and Therapeutic Applications.—The three varieties of rays produce very similar effects qualitatively, differing mainly in degree and in the power of penetration. These two properties vary inversely, *i.e.*, the actions of the alpha rays are superficial and most intense; those of the hard gamma rays are the deepest and most moderate. The effects on living tissues progress, according to the duration of the exposure, from stimulation to inflammatory reaction and to destruction. The susceptibility of the tissues varies, being in general proportional to the growth-rate, and being additive to already exciting irritation, inflammation or necrotic degeneration. Tumors are therefore more susceptible than normal tissue; rapidly growing tumors more than benign; sarcoma especially lymphosarcomas more than carcinoma. Lymphoid tissue, the sexual glands and capillary endothelium are also very susceptible.

Topical Application.—One of the most important fields of radiotherapy is in the treatment of tumors. Specialized training and experience are required to decide the advisability of the treatment, and to select and apply the rays so as to secure the desired degree of action on the tumor tissue, with the minimum of harm to the normal tissues. In cases of deep-seated tumors, the injury to the intervening tissues is minimized by suitable screens to absorb the less penetrating rays; by cross-firing from several sites on the surface; or by implantation of radium or emanation directly into the tumor. Ovaries and testicles are especially susceptible to permanent injury.

An important field of radio-therapy is in the treatment of myelogenous and lymphatic leukemias. In these, irradiation of the spleen and superficial lymphatic enlargements generally results in marked, though often only temporary improvement. Patients with severe anemia may occasionally react with acute exacerbation of the anemia. Fibroid disease of the uterus, with the concomitant hemorrhage, is often benefitted; the possibility of injury to the ovaries must be kept in mind. Sarcomas in general are frequently reduced in size; with deep-seated carcinomas the results are generally palliative; radium may be used as a prophylactic after operation. In tubercular adenitis, radium tends to favor shrinking and fibrosis. Radium-therapy has a wide field in various pathologic conditions of the skin.

Systemic Application.—Radium emanation may be administered for systemic effects, by inhalation, or more conveniently and accurately by drinking emanation-charged water. The most definite effects are claimed as relief from pain in fibrous arthritis deformans (250 c.c. per day of the solution containing 1.5 millicuries per liter). The phenomena and results are perhaps analogous to those produced by oxyiodobenzoic acid, colchicum, etc.; *i.e.*, probably a beneficial inflammatory reaction of the affected structures. Good results have also been claimed in angioneurotic edema. The claims for arteriosclerosis and glycosuria lack reliable control.

Intact Animals.—Continued exposure of mice (London) to radium produces in three or four days, nervous depression terminating in coma. In rabbits, the symptoms begin in two weeks and last many months. They consist in loss of hair, ulceration of the skin, nervous changes similar to those in mice, and sexual impotence. In man, overexposure has produced persistent diarrhea, vomiting, general weakness, and coma.

Inhalation of large amounts of emanation also leads to dyspnea and depression (but no true narcosis), terminating in death. The autopsy shows widespread hyperemia, with histologic changes in the brain cells, and to a less degree in other central nerve cells. (Knaffl-Lenz, 1912; Poulsson, 1908.)

The susceptibility of the individual organs, according to Horowitz, is greatest in the central nervous system, lymphatic tissues, sexual glands and liver. It is less in the kidneys, suprarenals, cartilage, muscle, and vessels; least in salivary glands, pancreas and mucous membranes.

Central Nervous System.—Obersteiner found the following symptoms in mice which died after three to five weeks' exposure to radium: convulsions; forced movements; motor restlessness; paralysis of individual extremities; ataxia; paralysis of sphincters; trophic disturbances. The autopsy showed inflammatory changes of the entire nervous axis, with the degenerative lesions in the nerve cells. These may have been secondary to the hemorrhages from injured capillaries.

Sexual Organs.—The spermatozoa of guinea pigs, when exposed to radium *in vitro*, soon lose their motility (London and Goldberg). The testes of exposed guinea pigs show atrophy, degeneration of the epithelium, and absence of spermatozoa (Albers-Schoenberg; London; Frieden). The interstitial tissue is much less affected. The ovaries exhibit analogous changes (Halberstadter; London). Clinically, these result in artificial menopause.

Ova and Embryonal Development.—In general, cell-division is accelerated by small and retarded by large doses.

Blood-formation.—The bone-marrow, spleen and lymph glands are markedly affected by radiation so that the blood-picture changes.

Lymphatic Tissue.—This reacts especially strongly. Inflammatory changes are found in the spleen, intestinal follicles, mesenteric glands, etc. (Heineke; London). Smaller doses destroy the follicles and increase the connective tissue. The leucocytes are diminished by emanation and by X-rays. It is not known whether there is increased destruction or lessened production.

Blood.—The hypodermic injection of soluble radium salts produced rapid increase of the red cells, persisting for several weeks. The hemoglobin did not rise as much. The leucocytes were also increased by small doses but diminished by large (Brill and Zehner, 1912). *In vitro*, sheep corpuscles are hemolyzed, and methemoglobin is formed (thorium X, Schwartz and Zehner, 1912).

Sailer, 1916, reports good results from the radium treatment of *polycythemia*.

Leukemia.—Treatment with X-rays, radium and thorium X causes a temporary decrease of the leucocytes and the size of the spleen, and delays the progress of the disease. The clinical improvement is often even better than the blood-picture. However, the results are not permanent. Repeated treatment may again be effective, keeping the cells about 20,000 to 30,000; but eventually the patients succumb (Stengel, 1917; Griffin, 1917; Peabody, 1917).

Radium is sometimes effective when X-rays or benzol fail (Ordway, 1916). It is applied over the spleen; or first over the bones.

The serum of X-rayed patients caused immediate and marked reaction on injection into lymphocytic patients (Capps, 1917). However, thorium X also decreases the red corpuscles and produces parenchymatous changes. It should not be used where such lesions exist (Hahn, 1914).

Blood Coagulability.—This is promptly and markedly increased.

Hemolysis.—Radium (emanation) is said to hemolyze the corpuscles of guinea pigs, but not of rabbits.

Capillaries and Vascular Endothelium.—These are readily injured by radiation. The irradiated skin shows dilation of the vessels, emigration of leucocytes; later swelling of endothelium and extravasations (Thies).

The effects of mesothorium on the vessels of the rabbit's ear were studied by Ricker, 1914.

Skin.—The effects are identical with X-rays. After a quiescent period of several days to two weeks, the changes begin, and resemble sunburn; with increase of pigment, rubefaction and burning sensation. This may subside in a few days with a little scaling or it may pass into intense congestion, vesication and loss of hair. The blisters rupture, leaving a raw surface covered with necrotic, diphtheritic membrane. This may progress to highly indolent and painful ulceration. The ulcers heal slowly and incompletely. The repair starts in about 30 days. Where the corium is destroyed (generally by necrosis of the vessels), the epithelium tends to invade the underlying tissue and may result in cancer of the skin. Selective destructive changes occur in cutaneous tuberculosis, carcinoma and sarcoma (Pusey, 1912).

The duration of the latent period depends on the dosage and on individual susceptibility. The non-penetrating "soft" alpha rays are the most effective on the skin, so that unscreened radium is more harmful than x-rays.

Blood-pressure.—The clinical use of radium (emanation) is said to lower the blood pressure by 20 to 25 mm. (Loewy and Plesch).

Excised Heart.—Zwaardemaker, 1916, claims that the potassium of Ringer's fluid may be replaced by equiradioactive quantities of any of the radioactive metals; and that therefore the action of potassium in aiding automatic contractions is due to its radioactivity. Further work is needed to confirm this theory.

Glucose Permeability of Kidneys.—H. J. Hamburger and Brinkman, 1917, claim that this is also affected by potassium, uranium and radium in equiradioactive doses.

Urate Metabolism.—Investigations with modern methods have failed to show any effect on the uric acid of the blood, by radium, intravenously or by inhalation (Fine and Chace, 1914).

Therapeutic Use in Gout.—Favorable effects are claimed. In most cases the treatment brings on an acute attack, generally mild, in the first six to fourteen days of treatment. Improvement sets in after three to four weeks, parallel to diminution of urates from the blood. Cases with anatomic lesions are not so favorable.

Therapeutic Use in Arthritides.—Emanation treatment is said to be markedly successful in chronic joint and "rheumatic" lesions, sciatica, tabes, pain, etc. The main effect is on the pain but the inflammatory phenomena are also decreased. The improvement

is often, but not always, preceded by the "reaction", a flare-up of the inflammatory symptoms (Lowenthal; Fuerstenberg). The late fibrous and anatomic changes are not removed. The results are therefore better in early cases and in young subjects. Acute arthritis, arthritis deformans, and luteic or tubercular lesions are not affected. Progressive polyarthritis and chronic myalgia react well.

This was the first, and is probably the most successful use of the emanation (Loewenthal; Laqueur). The mechanism of the action is not explained. It may be mainly analgesic; but Gudzent assumes a direct effect on the inflammation, activation of autolytic ferments, and general increase of metabolic processes.

Plants.—These may be stimulated to accelerated growth, or killed, according to the dosage.

Bacteria.—The rays are rather feebly bactericidal, the alpha-rays being most effective. Toxins are probably not injured (Goldberg).

Ferments.—Autolysis is increased (Neuberg). Other ferments differ in susceptibility. Diastase is first hindered, then accelerated; pepsin and trypsin are augmented.

Vitamins.—These are not affected by radium rays or emanation (Funk, 1916).

Decomposition of Lecithin.—Schwartz, 1904, observed discoloration and odor in the yolk of hen's eggs, suggesting decomposition of lecithin. This occurred also *in vitro*. Wohlgemuth referred this to stimulation of autolytic ferments; but Meserenzky observed the decomposition even in boiled yolk. Werner and Ascher, 1912, confirmed the decomposition, and showed that the injection of decomposed lecithin or choline into animals produced degenerative changes analogous to the rays, in the blood, testes, skin, etc. Promising results were also obtained with tumors. The same effects are produced by thorium X. This also decomposes *proteins* and reacts with many other organic substances (Falta and Zehner, 1912). Fernan and Pauli, 1915, find that the changes by proteins by radium rays resemble those of heat coagulation.

Effects of Other Electromagnetic Vibrations.—The effects of the different varieties of these waves are in general in inverse ratio to the length of the waves; but modified by the special susceptibility of the individual tissues. Arranging them in order of decreasing wave-length, the Hertzian waves are apparently inactive. Radiant heat causes local vasodilation. Visible light stimulates the retina, is mildly germicidal, and in more intense, irritates the skin. Ultra-violet light acts much more intensely, with strong germicidal action, marked irritation of the skin, the production of antirachitic vitamine from cholesterol, and beneficial effects in rickets and tuberculosis.

SILVER

The inorganic silver salts, especially the nitrate, are used to produce astringent, caustic and antiseptic effects. They form resistant precipitates with proteins, so that their local action is easily controlled. The toxicity for higher animals is low, and the antiseptic efficiency is high. In the presence of the tissues, silver surpasses mercury, since the protein compounds of silver as well as the colloidal oxides and metallic silver liberate a small quantity of silver ions. These may be used directly when antiseptic action without irritation is desired.

Silver is not absorbed in sufficient quantity from the alimentary canal to produce systemic actions. Because of its precipitation by proteins and chloride even large doses of silver nitrate rarely produce serious poisoning. Long-continued use results in blackish discoloration of the skin (argyria) by the deposition of silver particles, probably organic. Traces must therefore be absorbed.

Argyria.—This develops gradually after prolonged internal or external use of silver when the total dose has reached 15 to 30 Gm. (*f.i.*, $\frac{3}{4}$ grain of silver nitrate, 3 times daily, for 2 months; Bastedo, 1920). Since silver is now rarely used in this way the condition

is infrequent. It has been produced by the application of silver-containing hair dyes. It may also occur locally from the use of organic silver preparations on lacerated tissue (Olson, 1917).

Argyrisms consists in a bluish-black discoloration of the skin, especially where exposed to light; and of internal organs and mucous membranes (Frommann, 1857; Riemer, 1876). The black granules do not consist of metallic silver, for they are easily soluble in KCN, and difficultly in concentrated nitric acid. In the skin, they are situated in the connective tissue of the corium in the collagen, and especially in the elastic fibers. They remain indefinitely. No silver can be demonstrated in the urine. The argyrisms does not give rise to other symptoms. In animals, silver deposition has also been produced in internal organs, but not in the skin.

Argyrisms persists indefinitely or disappears very slowly. Crispin, 1914, and Olson, 1916, believe that recovery is hastened by methenamine. (Mercuric chloride decolorizes the granules *in vitro*, but not *in situ*.)

Silver Stains—The stains following shortly after the application of silver salts are quite distinct from argyrisms and disappear spontaneously. Recent and superficial stains are easily removed by 10 per cent. potassium iodide or cyanide; or by 10 per cent. mercuric chloride in 10 per cent. ammonium chloride (Mankiewicz, 1916).

Systemic Actions.—These are never seen in man but may be produced in animals by the injection of non-precipitant silver solutions (AgCl in sodium thiosulphate, Gaetgens, 1890; colloid AgCl or AgI, Gros 1912). The actions are mainly on the central nervous system, consisting of paralyses and spasms, beginning in the lower extremities; disturbances of respiration; and fall of blood pressure (paralysis of vasomotor center?); sometimes diarrhea. The secretion of bronchial mucus is greatly increased, probably by injury to the epithelium, and may lead to asphyxia. Death occurs usually promptly, by paralysis of respiration; the diaphragm being paralyzed before the other respiratory muscles. The heart is but little affected and may beat after death. In frogs, the paralysis is preceded by convulsions (Ball, 1865; Jacoby, 1877; Gaetgens).

Chronic systemic poisoning shows changes in the blood corpuscles; disturbances of metabolism; cloudy swelling of the heart and skeletal muscle; and fatty degeneration of the liver and kidney (Bogoslowky).

Therapeutic Use of Silver in Nervous Diseases (Insanity, Epilepsy, Etc.).—This was a survival of the fantastic teaching of the middle ages, when it was based on its dedication to the moon, and the supposed connection of the latter with lunacy. Although it is absolutely proved that silver can not be absorbed in amounts sufficient to have any action whatsoever, it has been tried again and again against all forms of nervous disease, with uniformly negative results.

Local Astringent and Caustic Action.—Silver nitrate acts as astringent, irritant or caustic, according to the strength and duration of its application. The surface turns white, then gradually gray and black by the reduction to metallic silver and oxide. The nitrate, fused into pencils ("Lunar caustic") is used in substance for the removal of warts, etc., and the stimulation of ulcers and granulations. The pencils should be moistened before use. Solutions are employed for their astringent and antiseptic action in acute and chronic catarrhal inflammations of mucous membranes.

The mucous membranes should always be cleansed before the silver is applied. The solutions must be made with distilled water. The caustic and astringent action may be stopped with sodium chloride. The antiseptic action of silver nitrate extends quite deeply, since it forms easily soluble double salts of silver albuminates and sodium chloride in the tissues (Lublinski, 1914).

Silver Pills.—Pills of silver nitrate, 10 to 20 mg., $\frac{1}{6}$ to $\frac{1}{3}$ gr. (made with kaoline and petrolatum), are sometimes used in gastric ulcer, etc. There is probably a slight local

action before the silver is precipitated, and after it is dissolved by protein. The *oxide*, 0.03 to 0.1 Gm., $\frac{1}{2}$ to 1 $\frac{1}{2}$ gr., may be similarly employed.

Toxic Actions.—Silver nitrate to 0.01 or 0.1 Gm. by mouth produces no symptoms. Swallowing pieces of the pencils up to 2 $\frac{1}{2}$ Gm., is also often harmless. Larger quantities cause acute gastritis. The fatal dose would be above 10 Gm. (Lewin); even 30 Gm. have been survived. The *treatment* would be by sodium chloride and demulcents.

Colloidal Silver Preparations.—The antiseptic action of silver nitrate is complicated by irritation, pain, astringency and corrosion. These may be desirable for the destruction of tissue or the stimulation of indolent wounds, but when they are not necessary for such purposes, they are distinctly undesirable. They may be avoided by the use of colloidal silver preparations. In these, the mass of silver does not exist as free ions; and therefore does not precipitate chloride or proteins, and is therefore non-corrosive, and relatively or quite non-astringent and non-irritant. The antiseptic action of these is also due to silver-ions, which may be present in free form, or adsorbed by the colloids (Pilcher and Sollmann, 1924; Ritman, 1912; Dreser, 1917; Schlee; Kusunoki, 1922; Paul; Neegard, 1923). The concentration of these is small, and their precipitant and corrosive effects are generally mitigated by the presence of proteins, which serve as protective colloids and as demulcents (Kolthoff and Tomicek, 1925). The major part of the silver which is in colloidal form appears to be inactive, and does not increase the antiseptic action, even on prolonged contact (Pilcher and Sollmann, 1924). The activity of these preparations is therefore quite independent of their silver content, but is determined by the ion concentration, which varies for the different compounds. The "oligodynamic" action of metallic silver is also due to the liberation of silver ions (D. Abel, 1920).

Analogy with Silver Ion Effects.—The mechanism of these effects is analogous to the late action of silver nitrate. This probably acts in two stages: (1) the immediate irritant and germicidal effects produced by the direct application of the free silver ions; and (2) the later, milder antiseptic effects produced by the re-solution and ionization of the silver-protein compounds that were formed in the first stage. If this second stage alone is desired, (*i.e.*, antiseptis without irritation), the direct application of the colloid compounds may have advantages over their indirect production from silver nitrate, aside from the avoidance of irritation. The absence of coagulation membrane would facilitate their access to the cells; they form more concentrated solutions than are likely to be formed from the re-solution of the silver precipitates in situ; the colloidal aggregates are likely to be smaller and therefore more reactive; and because of the absence of irritation, they are likely to be more frequently applied and would therefore secure a more continuous action.

Manufacturers of colloidal silver preparations have been somewhat loth to concede that the ionized silver is alone responsible for the antiseptic action, and cite results with various bacteria that do not correspond with the ionization. However, these results differ so much among themselves (*f.i.* Dakin and Dunham against Culver, 1918 and Young et al., 1919) that they are evidently not reliable; whilst a striking correspondence exists between the ionization (as judged by the inhibition of the growth of yeast) and the concentrations that have been selected, for instance, for conjunctivitis, by the empirical experience of the clinics.

Composition and Classification.—Metallic silver and insoluble compounds of silver, such as the oxide, the halogen salts (iodide, chloride, etc.) and silver protein precipitates may be brought into "colloidal solution;" *i.e.*, if they are sufficiently finely divided, they become miscible with water, so that they apparently go into solution (although physical chemists classify such "colloidal solutions" as permanent suspensions of the insoluble substance in a state of ultra-microscopic particles).

The commercial preparations are for the most part produced by dissolving reduced silver or silver oxide, or some protein-silver precipitate in an excess of a denatured protein, and drying in vacuo. This results in substances that dissolve very freely although somewhat slowly in water, yielding brown-colored "colloid solutions," which contain only small quantities of free silver ions, *i.e.* these are so enveloped with protective colloids (protein) that they do not precipitate chloride or proteins. They consist of probably indefinite mixtures of metallic silver, silver oxide, and various silver-protein compounds, all in colloidal form. The proportions of these and the properties of the mixture vary according to the conditions under which they are produced. Although there are gradations, the products on the market fall into a small number of fairly definite groups: The members of each group are practically equivalent therapeutically, although they possess minor peculiarities, due mainly to the nature of the proteins that are used as protective colloids.

It should be noted that the adjectives "strong" and "mild" refer to the therapeutic action, *i.e.* to the silver ions, and not to the total silver content, which happens generally to be in the inverse order.

Strong Argento-protein (Protargin Strong or Protargol Type).—This class contains the lowest percentage of silver (7 to 8.5 per cent.), but in solutions this becomes largely ionized; so that they have the strongest germicidal action, but are also distinctly irritant. The irritant action of protargol is estimated as about $\frac{1}{10}$ that of silver nitrate (Neisser), confirming that practically all the silver is ionized. The strong argento-proteins are therefore therapeutically between silver nitrate and mild argento-protein.

Protargol is said to be prepared by precipitating a "peptone" (albumose) solution with silver nitrate, or with moist silver oxide; dissolving the silver peptonate in an excess of protalbumose; and drying in vacuo (Fraenkel). Another preparation (Protargentum) is said to be prepared by quite a different process; *i.e.*, by the action of silver nitrate on gelatin, in the presence of an alkali, precipitation by alcohol, and drying.

Mild Argento-protein, Protargin Mild or Argyrol Type.—This class contains 19 to 30 per cent. of silver, of which only a small fraction is ionized; together with alkali proteins which confer well-marked demulcent properties. They are therefore not irritant, but rather soothing. To this type belong argyrol, cargentos, silvol, solargentum etc. They are prepared by the interaction of alkali-protein with moist silver oxide, and drying in vacuo.

Collargol appears to be a variety of the mild argento-protein type, containing a larger proportion of colloidal silver (78 per cent.), said to be prepared by reducing silver nitrate with ferric citrate (Bechhold, p. 366), and also stabilized by alkali albumen. It was intended mainly for intravenous injection, to provoke the "colloidal reaction" which is sometimes useful in infections. It has been suggested that the proteins plays the major part in this reaction (Bottner, 1921; W. Lutz, 1921).

Electrically Dispersed Silver.—Metallic silver may be brought into colloidal solution by forming an arc between silver electrodes under water. These solutions, however, are very dilute and unstable, and gradually form silver oxide and ionic silver.

Colloidal Silver Haloid Salts.—Silver iodide and chloride may also be obtained as colloidal suspensions. These do not differ in principle from the other colloidal preparations; some are more, some less ionized.

Interference of Chlorides and Proteins.—Silver chloride is soluble and therefore ionizable only to a limited extent, so that in the presence of chlorides the silver-ion concentration does not reach the irritant and astringent level, but the concentration may still suffice for a limited degree of antiseptic action. This may be favored by the presence of proteins; for by acting as protective colloids, these increase the dispersion and therefore the solubility of the silver chloride (Stas; Glovczynski, 1914). The following table (adapted from Pilcher and Sollmann, Jour. Lab. and Clin. Med. 9:260. 1924) illustrates the concentrations required to arrest gas-formation by yeast, in various media; and gives also, for comparison, the concentrations used clinically for surface applications (conjunctiva, nose and throat, etc). The latter is of the same order as the activity in watery solutions. Bacterial cultures are killed in five minutes by silver nitrate 1:1,000.

Preparation	Silver-content (per cent.)	Concentrations equivalent to 0.1 per cent. AgNO ₃ in water, inhibitory effect on yeast			Concentrations generally used on mucous membranes (per cent.)
		Water (per cent.)	0.8 per cent. NaCl (per cent.)	Blood (per cent.)	
Silver nitrate.....	63	$\frac{1}{10}$	8	4	$\frac{1}{5}$
Strong argento-protein...	7 to 8.5	1	10	36	2 to 10
Mild argento-protein....	20 to 25	12	10	80	25

Changes on Standing.—Watery solutions of the colloidal silver compounds tend to alter on standing, the direction of the changes being the reverse in the strong and mild argento-protein: With the *protargol type*, the silver-ions decrease slowly, by about $\frac{1}{5}$ in a month, by $\frac{1}{2}$ in a year. Their therapeutic activity would be correspondingly decreased, but this would have little therapeutic importance. With the *argyrol type*, the silver ions increase, by slow ionization of the colloidal silver, and the solutions therefore become more efficient but also more irritant. This process is sufficient to be clinically important; the silver ions increasing by $\frac{1}{3}$ to $\frac{1}{2}$ in a week, and by $\frac{1}{2}$ to 3 times, in a month and onward (Sollmann and Pilcher, 1924).

Therapeutic Uses.—The colloidal silver compounds are used mainly on mucous membranes, as antiseptics and germicides. The strong argento-protein group is the most effective, but is distinctly irritant and stimulant. The compounds of the mild argento-protein group act also largely as mucilaginous demulcents and protectives, and as detergents, by dislodging pus. They are also used in pyelography. Collargol has been used especially for intravenous injection.

Dosage and Administration.—The concentrations for mucous membranes range from 0.1 to 10 per cent. for strong argento-protein; from 5 to 50 per cent. for mild argento-protein, and from 0.02 to 1 per cent. for collargol. These are applied every two to four hours, if possible.

The details are shown in the following table.

	Argento-protein Strong Per Cent.	Argento-protein Mild Per Cent.	Silver Nitrate Per Cent.
Eye:			
Conjunctivitis, simple, purulent or gonorrheal....	2 to 10	Solution, 25 Ointment, 10	0.2 to 2 (see text)
Prophylaxis against ophthalmia neonatorum....	2 to 10	25	1 to 2 (see text)
Prophylaxis before ophthalmic operations (several days).....		25	
Corneal ulcers.....		50	
Nose and throat.....	0.5 to 10	Spray, 10 to 20 Swab, 25 to 50	2 to 10
Wounds and ulcers.....		1 to 10, solution or ointment 10, dusting powder	0.1 to 10
Gonorrhea:			
Injections—Prophylactic....	2	10	
Acute.....	1/4 to 1	3 to 10	
Chronic.....	2 to 10	10 to 20	
Urethral irrigation.....	1:2,000 to 1:1,000	1:1,000	{ 1:10,000 to 1:2,000
Urethral suppositories.....	5 to 10	20 (0.13 Gm. or 2 grains)	
Cystitis.....		20 to 50 (5 c.c.) or 10 to 25 (30 c.c. left in the bladder)	1:5,000
Gynecologic practice:			
Solutions.....	2 to 10	25 (tampons of solution in glycerin)	
Tampons.....	5		
Ointments.....	2		
Suppositories.....	5	Suppositories, 20 (0.3 Gm. or 5 grains)	
Rectal:			
Irrigation.....	0.1	0.1 to 1	
Injection.....	2	10	
Suppositories.....	5 to 10	20 (0.13 Gm. or 2 grains)	
Gastric douche.....			1/20 to 1/10, followed by saline
Oral administration.....	0.002 to 0.015 Gm. (1/32 to 1/4 grain)	0.3 Gm. (5 grains)	
Pyelography.....		2 (solargentum) 50 (cargentos)	

Solutions should be recently prepared, and should be protected against light. Ointments and suppositories are used with the same concentrations as the aqueous solutions. Stains on linen are removed by 1:1,000 solution of mercuric chloride. The usual concentrations for special purposes are shown in the above tabulation.

(Early Preventive) Treatment of Venereal Diseases.—The ordinary routine consists in washing the parts thoroughly with soap and water, after which the urethra is injected with a 2 per cent. argento-protein strong solution, which is held in the urethra for five minutes. The glans is then inuncted with 30 per cent. calomel ointment for five minutes.

The efficacy is marked if the treatment is applied thoroughly within an hour after exposure, and is fair up to three hours. In the A. E. F., the

ratio of disease to exposure was about 1:30 without prophylactic treatment, and 1:90 with treatment. Prophylaxis, therefore, reduced the incidence to about one third (Ashburn, 1919). It is practically useless after five hours.

Ophthalmia Neonatorum.—Silver nitrate is effective, but must be used with caution, or cauterization of the cornea and blindness may result, especially if the applications are repeated (J.A.M.A. 77:802, 1921). For prophylaxis a single drop of 1 per cent. silver nitrate should be placed in the conjunctival sac, at birth, after cleansing the eye lids. This should be followed in a few minutes by normal saline, to arrest the irritant action. In treatment, where the applications are repeated, the strength should never be above 1 per cent., and generally not over $\frac{1}{2}$ per cent.

PREPARATIONS

* *Argenti Nitras* (Arg. Nit.), U.S.P.; *Argent. Nit.*, B.P.; Silver Nitrate (Lunar Caustic); AgNO_3 .—Colorless crystalline tables, becoming gray to black on exposure to light in the presence of organic matter. Odorless; metallic taste. Very sol. in water (1:0.4), sol. in alc. (1:30). *Incompatible* with chlorides, bromides, iodides; carbonates and hydroxides; organic drugs and reducing agents. *Dose*, 10 mg., $\frac{1}{16}$ gr., U.S.P.; 16 to 30 mg. $\frac{1}{4}$ to $\frac{1}{2}$ gr., B.P. Maximum dose, 30 mg., $\frac{1}{2}$ gr.

Argenti Nitras Fusus (Arg. Nit. Fus.), U.S.P.; *Fused Silver Nitrate* (Stick Caustic). AgNO_3 , fused and moulded into pencils. A small quantity of AgCl is added to toughen the mass.

Argenti Nitras Induratus (Argent. Nit. Indur.), B.P.; *Toughened Caustic*.—Contains 5 per cent. of KNO_3 .

Argenti Nitras Mitigatus (Argent. Nit. Mitig.), B.P.; *Mitigated Caustic*.—Contains 1 part AgNO_3 and 2 parts KNO_3 .

* *Argento-proteinum Forte* (Arg.-Prot. Fort.), U.S.P. Strong Protargin (Protargol).—A silver and protein compound. Contains not less than 7.5 per cent. and not more than 8.5 per cent. of silver. A brown, odorless powder, usually somewhat hygroscopic; freely sol. in water, almost insol. in alc. Slightly but distinctly irritant; not precipitated by chlorides, which however interfere with the action. Applied as a 0.1 to 10 per cent. solutions. Solutions are best made by sprinkling the powder on cold water, without stirring. Solutions of strong argento-protein should be freshly prepared and dispensed in amber-colored bottles.

Products of this type are: Proganol-Heyden; Protargentum-Squibb; and Protargol-Winthrop.

* *Argento-proteinum Mite* (Arg.-prot. Mit.), U.S.P. Mild Protargin (Argyrol).—A silver and protein compound. Contains not less than 19 per cent. and not more than 25 per cent. of silver. Dark brown or almost black scales or granules; frequently hygroscopic; freely sol. in water, almost insol. in alc., chloroform and ether. Not precipitated by nor incompatible with chlorides. Applied as 10 to 40 per cent. solution in water. Solutions of mild Silver-protein should be freshly prepared and dispensed in amber-colored bottles.

Products of this type are: Argyn-Abbott; Argyrol-Barnes; Cargentos-Mulford; Silvol-Parke Davis; Solargentum-Squibb; Vargol-Heyden.

Silver Iodide.—Freshly precipitated silver iodide was recommended by Siter and Uhle, 1905; but has not come into general use. Thum, 1915, gives a formula for concentrated solution of silver iodide. Colloid silver iodide has been used intravenously, similarly to collargol; producing leucocytosis etc. (von Voigt and Corinth, 1919). A colloidal silver iodide preparation is marketed as "*Neo-Silvol*," a colloidal silver chloride as "*Lunisol*."

GOLD AND PLATINUM

Gold and Platinum are so easily reduced to the metallic state that they are devoid of general action when taken by the mouth. When injected into the circulation they produce an arsenic action. (Gold, Schultz, 1892; Platinum, Kebler, 1878; Cohnstein, 1892).

Gold cyanide was advised against tuberculosis and scrofula by Chrestien 1853. It fell into disuse, but has again been resuscitated, with doubtful justification. Bruck and Glueck, 1913, claim successful results from intravenous injection of gold-potassic cyanide (especially when combined with tuberculin!) in lupus; also in syphilis, though inferior to arsphenamine. Hauck, 1913, however, reports a fatal result. DeWitt, 1918, found gold salts unsuccessful in experimental tuberculosis of guinea pigs. Indeed, they tended to shorten life, through hemorrhage and hyperemia. Further references in Merck's Report, Vol. XXVII.

More recently, interest in the treatment of tuberculosis by gold salts (under the name of "*Sanocrysin*") has been revived by Mollgaard; but this also does not seem to realize the expectations of its introducers (Editorial J.A.M.A., 1926, 86:487).

Auri et Sodii Chloridum (Aur. et Sod. Chlor.), Gold and Sodium Chloride.—A mixture of equal parts of anhydrous gold chloride (AuCl_3) and anhydrous sodium chloride. Orange-yellow powder, odorless, saline and metallic taste; deliquescent. Very sol. in water. *Dose*, 5 mg, $\frac{1}{12}$ gr.

TIN

Actions.—This metal is absorbed in part even from non-corrosive preparations. However, poisoning is rare, the metal not passing very easily into soluble form, and having no pronounced tendency to cumulative action. The symptoms on injection devolve to some extent on the central nervous systems, as stimulation and subsequent paralysis. The arsenic action and paresis of the heart are also prominent. With more chronic poisoning the gastroenteritis is most marked, but there is also an ataxia and motor paralysis, resembling chronic lead-poisoning (White, 1880).

Salzer, 1918, reports chronic poisoning resulting from a dental plate of "Watt's metal." There were nervous symptoms and anemia.

Absorption and Fate.—When soluble salts of tin are fed, a small quantity is absorbed and accumulates in the tissues, traces appearing also in the urine. When soluble salts are injected hypodermically elimination occurs slowly, mainly by the alimentary tract, but somewhat by the urine, producing marked injury of the kidneys. Considerable quantities are retained: 20 to 25 per cent. in the skin, 5 per cent. in the liver (Salant and co-workers, 1914).

COPPER

Cupric sulphate irritates the nerve endings in the stomach which give rise to the vomiting reflex, and thus has a rather specific emetic action. It is also used on mucous membranes as an astringent and caustic. It has a relatively high toxicity for fungi, protozoa and algæ, and has been employed for the purification of water, etc. It is not a reliable bactericide. Its absorption is limited and its toxicity to animals is therefore low. Its use for brightening the green color of vegetables is innocuous under proper conditions, but under others it may be somewhat harmful. Mallory found that the administration of copper compounds was followed by hemochromatosis, and is inclined to attribute hepatic cirrhosis to the ingestion of copper, especially with alcoholic liquors. This requires confirmation.

Emetic Action.—Copper sulphate is effective and prompt, with short nausea. However, it is irritating; and should it not be effective, there is some danger of poisoning, and it must be removed by lavage. It is therefore not recommended, except in phosphorus poisoning, in which it oxidizes the phosphorus and coats the globules with a layer of metallic copper. The emetic dose is 0.5 Gm., 8 gr. in a single dose; or three doses (if necessary) of 0.25 Gm., 4 gr. each, fifteen minutes apart. It should be dissolved in a glass of water.

Astringent and Caustic Action.—Solid copper sulphate is used as a mild escharotic against granulations and trachoma. The everted lid should be lightly touched with the copper crystal or pencil, and then rinsed with water. The pencils are made by fusing 1 part of potassium alum with 2 parts of copper sulphate. Solutions of 0.1 to 3 per cent. may be employed as stimulant astringents in conjunctivitis, urethritis and vaginitis, but have no particular advantage over silver. Copper sulphate would probably be effective against aphthous stomatitis and other fungous diseases. It has been used internally against chronic diarrhea, 10 mg., $\frac{1}{5}$ gr.

Antiseptic Action and Use in Water Purification.—Copper is markedly germicidal for fungi and algae, and fairly effective against bacteria of the coli group. It may be used to purify water from alloid contamination. The traces of copper remaining in the water are probably harmless. Its use against typhoid contamination seems to be unreliable (Clarke and Gage, 1906). Thomas, 1915, describes its use for the disinfection of swimming pools.

The mechanism of the action of copper on lower plants is discussed by Spiro, 1915.

Copper-alanin.—Shaw-Mackenzie, 1916, claims that this is not-precipitant, and of very low toxicity to higher animals, but that it kills protozoa in dilutions of 1:100,000.

Copper Salts of Amino-acids.—H. C. Huber, 1918, reports that these act locally and systemically almost quantitatively like copper sulphate.

Toxic Actions.—Large doses of soluble copper salts produce mainly gastroenteritis, and characteristic lesions of the spleen, kidneys and other organs. The toxicity is low. The absorption is very limited.

Even on continued use, quantities of the copper sulphate up to 0.5 Gm. per day have been shown to be devoid of bad effects (Du Moulin). It is true that these were not continued indefinitely.

Absorption from Skin.—C. L. Vogt and Burckhardt report that copper oleate is absorbable.

Use of Copper in Foods.—Copper is sometimes used to give a bright green color to preserved vegetables, especially peas and beans. These contain 25 to 120 mg. per kilogram. The copper enters into a very firm compound with the chlorophyll. Older vegetables, which are not so rich in chlorophyll, contain it in much looser combinations with proteins. The chlorophyll compound produces no effects of any kind, even when continued for long periods in quantities corresponding to 12 to 15 mg. Cu per day, the maximum amount which would be taken in food. However, the same quantities, when more loosely combined, produce some digestive and metabolic disturbances. The use of copper with young green vegetables would therefore be harmless; but with older vegetables it could become harmful, and its use should be prohibited (J. H. Long, 1912).

Occurrence of Copper in Tissues.—Copper is not usually present in mammalian tissues; but after its administration, it occurs in the liver mainly as cupric nucleinates, and in the blood and bile. Traces are also retained in the kidneys, spleen and lungs; none in tubercular lymph glands or pus. Colloid copper, injected intravenously, shows a similar distribution (Corper, 1914).

It is found naturally in organic combination in the liver and other organs of cephalopods (octopus), snails and mussels; and as a blue blood pigment, hemocyanin, in mollusks and crustaceans. This is somewhat analogous to hemoglobin and contains about 38 per cent. of Cu in masked form (Henze, 1901). Copper is also a constituent of the feather pigments of certain birds.

Systemic Actions.—Direct contact with copper salts depresses skeletal and cardiac muscle. Intravenous injections therefore lower blood pressure.

The effect of *colloid copper* on tumors was discussed in the general article on "Metals."

Bibliography.—An extensive list is given by Huber, 1918.

PREPARATIONS

* *Cupri Sulphas* (Cupr. Sulph.), U.S.P., B.P.; Copper Sulphate (Cupric Sulphate, Blue Vitriol, Bluestone); $\text{CuSO}_4 + 5\text{H}_2\text{O}$.—Large, deep blue crystals; odorless; metallic taste. Freely sol. in water (1:2.5); slightly sol. in alc. (1:500); freely sol. in glyc. (1:2.8). *Incompatible* with fixed alkalies and carbonates; iodides; tannins; lead salts.

Dose, Emetic, 0.25 Gm., 4 gr., U.S.P.; 0.3 to 0.6 Gm., 5 to 10 gr., B.P.; as Astringent, 0.016 to 0.12 Gm., $\frac{1}{4}$ to 2 gr., B.P., diluted. Maximum dose, 1 Gm., 15 gr.

ZINC

The actions of the soluble zinc salts resemble those of copper, but are milder. Zinc sulphate is employed as emetic, and locally as astringent and antiseptic. Other soluble zinc salts are also used locally. The acetate is milder; the chloride is escharotic. The insoluble zinc oxide and stearate are used externally as protectives, similarly to bismuth. There are no systemic effects under therapeutic conditions.

Zinc Sulphate as Emetic.—This acts like copper, and is generally preferred, being nearly as efficient and less irritating. The short nausea, slight depression and absence of harmful irritation makes it particularly suitable in gastric disturbance from overeating, etc. 1 to 2 Gm., 15 to 30 gr. may be given in a glass of water.

Astringent and Antiseptic Action.—Zinc sulphate or acetate is used in conjunctivitis, particularly that caused by the Morax-Axenfeld bacillus; and in chronic gonorrheal urethritis and other catarrhal conditions. The strength of solution for collyria is 0.1 to 1 per cent.; for urethral injections, 0.5 to 4 per cent. The phenolsulphonate has no advantage.

Zinc Chloride as Escharotic.—This is used as the Liq. Zinci Chlor. on granulations, ulcers, etc.

Zinc Chloride Disinfectant.—This has been extensively exploited and overestimated in proprietary preparations. MacClintic, 1905, finds 1:200 to 1:500 a very poor germicide and feeble antiseptic, though a fair deodorant.

Insoluble Zinc Compounds.—Zinc oxide is mildly antiseptic and astringent. It is extensively used as local sedative application in inflammatory skin diseases and superficial wounds. It may be applied dry or as an ointment, alone or mixed with boric acid, bismuth subnitrate, starch or phenol.

Zinc stearate is perhaps somewhat smoother as a dusting powder, but has no other advantage and the very serious disadvantage that fatal pneumonia results if a considerable quantity of the very light dust is inhaled. Such accidents are not infrequent when infants play with the containers. The latter should be devised so that they cannot spill considerable quantities of the powder (J.A.M.A. 84:750).

Zinc in Food.—Birckner, 1919, found that traces of zinc are common in many foods, including milk (about 4 mg. per quart) and eggs (1 mg. per hen-egg). Zinc is almost invariably present in oysters from the Atlantic ocean. It is probably always associated with copper, but the two metals do not occur in uniform ratio (Hiltner and Wichmann, 1919).

Systemic Action.—The effects of intravenous injection are mainly paralytic. The brain is affected first—*i.e.*, consciousness is lost—but the motor areas are not involved. The blood pressure falls rapidly, but this is mainly due to the cardiac depression. The skeletal muscles are but little affected. Zinc salts are not sufficiently absorbed to produce systemic effects on oral administration. Zinc oxide has been used as a **nervous sedative**, in epilepsy, etc., but is probably useless.

The movements of *excised intestines* are depressed by very dilute solutions; abolished by medium concentrations (Salant and Mitchell, 1916).

Urine.—Rabbits develop glycosuria and generally albuminuria after intravenous injection of zinc malate, also after larger doses hypodermically or by mouth. The quantity of urine is either diminished or unchanged; rarely increased. Rabbits fed on carrots are more resistant (Salant and Wise, 1918).

Industrial Poisoning.—"Brass founders ague" is produced by the inhalation of the finely divided zinc oxide formed in the combustion of the metal—even of pure zinc (Lehmann, 1910). It has not been observed in animals, but only in man. After exposure of several minutes or hours—depending on the susceptibility and ventilation—there is slight irritation of the throat; but the main symptoms occur later, often after the patient has been in the air for some hours. The attack resembles a malarial chill, which may last some hours, with ordinary febrile symptoms—lassitude, headache, nausea, muscle cramps and joint pains, constricting sensation over lungs, etc. The attack ends in perspiration and rapid recovery (W. G. Thompson, 1912; Hayhurst, 1913; Pender, 1914).

The phenomena are presumably analogous to those of the inhalation of zinc stearate. Lehmann attributes the symptoms to the absorption of the remains of the respiratory cells that were destroyed by the zinc. The hypodermic injection of zinc salts also produces fever (Kisokalt, 1912); but so do other irritants.

Repeated exposure to zinc fumes may result in chronic lesions of the respiratory, digestive, excretory and nervous systems (Hayhurst, 1913).

PREPARATIONS—SOLUBLE ZINC SALTS

Zinci Acetas (Zinc. Acet.), U.S.P., B.P.; $\text{Zn}(\text{C}_2\text{H}_3\text{O}_2)_2 + 2\text{H}_2\text{O}$.—Soft, white plates; faintly acetous odor; astringent, metallic taste. Freely sol. in water (1:2.3); sol. in alc. (1:30). *Dose*, 0.125 Gm., 2 gr., U.S.P. 0.06 to 0.12 Gm., 1 to 2 gr., B.P.

Zinc Chlor., U.S.P., B.P.; ZnCl_2 .—White granular powder or porcelain-like masses or in pencils; odorless; highly caustic. Very sol. in water (1:0.25); freely sol. in alc. (1:1.3) or glyc.

* *Liq. Zinc. Chlor.*, U.S.P., B.P.—An acid solution, containing about 50 per cent. of ZnCl_2 .

Zinci Phenolsulphonas (Zinc. Phenolsulph.), (Zinc Sulphocarbonate); $\text{Zn}(\text{C}_6\text{H}_4\text{O}_4\text{S})_2 + 8\text{H}_2\text{O}$.—Colorless, transparent prisms, or tabular crystals or in granular form; odorless; astringent metallic taste. Freely sol. in water (1:1.6) *Dose*, 0.125 Gm., 2 gr. Locally, similar to Zinc. Sulph.

* *Zinci Sulphas* (Zinc. Sulph.), U.S.P., B.P.; Zinc Sulphate (White Vitriol); $\text{ZnSO}_4 + 7\text{H}_2\text{O}$.—Small colorless crystals, odorless, metallic taste. Very sol. in water (1:0.6); practically insol. in alc. *Incompatible* with alkalis, carbonates, sodium borate, tannins, lead salts. *Dose*, 1 Gm., 15 gr., U.S.P. as Emetic, 0.6 to 2 Gm., 10 to 30 gr., B.P., diluted; as Astringent, 0.06 to 0.2 Gm., 1 to 3 gr., B.P. Maximum dose, 2 Gm., 30 gr.

Zinci Valerianas, B.P. (Zinc Valerianate); $\text{Zn}(\text{C}_4\text{H}_9\text{O}_2)_2 + 2\text{H}_2\text{O}$.—White, pearly scales, or white powder; odor of valeric acid; sweetish, astringent, and metallic taste. *Dose*, 0.06 to 0.2 Gm., 1 to 3 gr., B.P.

PREPARATIONS—INSOLUBLE ZINC COMPOUNDS

Zinci Carbonas Præcipitatus (Zinc. Carb. Præc.), U.S.P.; *Zinc. Carb.*, B.P.—Basic Zinc Carbonate is a compound of somewhat variable chemical composition, corresponding to not less than 68 per cent. of ZnO , U.S.P. Impalpable white powder without odor or taste. Insol. in water or in alc.

* *Zinci Oxidum* (Zinc. Oxide), U.S.P., B.P.; ZnO .—Very fine amorphous, white or yellowish-white powder, without odor or taste. Practically insol. in water or alc. *Incompatible* with acids. *Dose*, 0.2 to 0.6 Gm., 3 to 10 gr., B.P.

* *Unguentum Zinci Oxidum* (Ung. Zinc. Ox.), U.S.P. (Zinc Ointment).—20 per cent., in paraffin and white petrolatum.

Ung. Zinc., B.P.—15 per cent. of ZnO in Benz. Lard.

Lassar's Paste, white is used in eczema, contains Zinc. Ox. 1 part, Starch, 1 part, Petrolat., 2 parts.

Zinci Stearas (Zinc. Stear.), U.S.P.; *Zinci Oleostearas* (Zinc. Oleost.), B.P.—A zinc soap. White amorphous, insoluble powder.

Ung. Zinc. Oleat., B.P.—A zinc soap, incorporated with white soft petrolatum.

CADMIUM

This resembles zinc closely.

The chloride is a powerful emetic (15 to 25 mg. per cat). It produces nephritis. Hypodermic injections are followed by local necrosis. Intravenously, it kills by arrest of respiration. Small doses diminish the appetite and growth of rats. The action does not appear to be cumulative (Alsberg and Schwartz).

NICKEL AND COBALT

These metals are only absorbed when given in strongest solutions. The local action is that of metals in general, with nothing particularly characteristic. Nickel salts have been used as emetics, but are not to be recommended. Nickel cooking vessels give up a harmless trace of the metal to the food (Dziedzowski and Schumoff-Sieber, 1906 and 1908; Lehmann, 1909).

Nickel-platers are subject to eczema (see J.A.M.A. 73:782, 1919).

When injected intravenously or hypodermically, these metals affect the central nervous system directly, in addition to the usual metal action on capillaries, heart, and kidneys. There are tremors, chorea, and convulsions, followed by paresis. In frogs the medulla is stimulated before the spinal cord (A. Stuart, 1884). Some habituation occurs.

The urine is increased, and always contains sugar, often proteins. Cobalt salts act as antidotes to HCN poisoning, through the formation of cobalt-cyanides. To be effective they must be introduced subcutaneously in doses which are not devoid of danger. They are therefore not to be used in man.

With *excised intestine*, dilute solutions of nickel salts produce primary depression, which may be followed by stimulation. Higher concentrations abolish the movements. Nickel is much less toxic than zinc (Salant and Mitchell, 1916).

Nickel Carbonyl.—This gas— $\text{Ni}(\text{CO})_4$ —is formed by passing CO over finely divided nickel, as in the Mond process of obtaining pure nickel. It decomposes at 150°C . into CO and metallic nickel. The toxic effects are probably due to the deposition of the metal in the respiratory tract, for the carbonyl is not absorbed as such. The phenomena following its inhalation are very serious. There is transient malaise, with quick recovery in fresh air; but after twelve to thirty-six hours the patient becomes dyspneic, cyanotic, febrile, and delirious, with a blood-stained cough. Death occurs in four to eleven days, with hemorrhages (due to fatty degeneration of the vessel walls) in the lungs and brain, and pulmonary edema (Mond, Langer and Quincke, 1890; Armit, 1907, 1908).

MERCURY

Mercury, particularly in the mercuric salts, has a strongly toxic action on all protoplasm. Mercurial compounds are therefore active germicides; but their usefulness is limited by precipitation, irritation and general toxic effects. The local actions depend on the mercury ions, and are wanting in organic compounds which hold the mercury in molecular form. Intravenous injection of the mercury-fluorescein dyes mercurochrome etc.) produces colloidal "reactions." Even the water-insoluble mercury compounds are generally fairly rapidly converted into soluble compounds and are so absorbed, distributed through all the tissues, and excreted by all channels, but mainly by the urine and feces. Traces remain in the body for many months. Acute poisoning presents chiefly the phenomena of local corrosion. The characteristic features of systemic poisoning are stomatitis, dysentery, and nephritis. In chronic poisoning, nervous symptoms and cachexia appear. Calomel is relatively insoluble and mild, so that it may be employed as a cathartic and diuretic. Novasurol, a molecular mercury compound, is a very powerful diuretic for the elimination of effusions.

The most important therapeutic use of mercury is for the treatment of syphilis. It was one of the earliest and is still one of the most effective agents for this purpose.

Ionization, Protein Precipitation and Local Actions of Mercury Compounds.—The local effects of the mercury compounds depend chiefly on the concentration of mercuric ions in their solution, and on their precipitant effects on proteins. The latter is not a simple function of the ionization, for the protein precipitates redissolve in an excess of protein, and in

a variety of other substances, such as the halide salts of alkalies, especially the iodides, in alkalies, amides etc. When these are present in or added to the mercuric salts, the precipitation of proteins is minimized or prevented. Solutions that ionize weakly also fail to precipitate proteins, presumably because they always leave a sufficient excess of protein to prevent precipitation.

Absence of protein precipitation is important because it diminishes local irritation, because it favors the penetration of the mercury, and because it guards against the adsorption of mercury ions by the precipitates. In the presence of proteins, and in complex culture fluids, the antiseptic action of such non-precipitant compounds may therefore appear equal or greater than that of more highly ionized but more precipitant compounds. Yeast cultures in simple sugar solution are not exposed to this complication, and therefore reflect more directly the mercury ionization (J. Peterson, 1926).

To summarize, the local *irritant actions* depend on the protein precipitation, and this increases with mercuric ionization and decreases with the presence of solvent substances. The *antiseptic activity*, in the presence of proteins, increases with the mercuric ions and with the presence of solvent substances, two antagonistic factors which tend to balance each other. *Systemic toxicity* also depends mainly on mercuric ionization, but is modified by the rapidity of absorption and excretion; and in the case of colloid compounds, by the occurrence of colloidal shock reactions. Tsung-ming Tu found that systemic toxicity is highest with inorganic mercuric salts, then come the organic compounds; inorganic mercurous salts being the weakest.

Classification of Mercury Compounds.—The following list shows the place of the more important mercury compounds. The classification is similar to that of F. Mueller, Schoeller and Schraut, 1911, but it also takes into account the antiseptic action on yeast cultures, as determined by Peterson. This is a convenient index of ionization, the restraining effect for equivalent mercury content being expressed in terms of HgCl_2 as unity, for instance, "yeast-restraint 0.1" signifies that the anti-yeast activity is $\frac{1}{10}$ that of mercuric chloride, after making allowance for the difference in mercury content. The individual compounds are arranged according to this coefficient, in descending order. Those in square brackets were not investigated by Peterson, so that their position is only estimated.

Class I. Simple Highly Ionizable Inorganic Mercuric Salts.—Yeast restraint 1.7 to 1.0; precipitate proteins but redissolve in excess; greatest local irritation; rust metals; readily precipitated by H_2S = Mercuric chloride (HgCl_2).

Class II. Moderately Ionizable Mercuric Compounds.—Yeast restraint, 0.6 to 0.35; protein precipitation, slight or absent; irritation relatively slight; rusting of metals slight; precipitated by H_2S = Potassium-mercuric iodide (K_2HgI_4); mercuric succinimide; sublimine (mercuric sulphate-ethylenediamine); metaphen (aceto-oxymercuro-nitroresol), requires alkali for solution; [Mercurophen (sodium oxymercuro-nitrophenolate), Schamberg, et al., 1917, 1919].

Class III. Poorly Ionizable Mercuric Compounds.—Yeast restraint, 0.06 to 0.01; protein precipitation absent; irritation very slight; rusting of metals absent; H_2S precipitates slowly or imperfectly with the lower members = [Novasurol (sodium mercuri-chlorophenyl oxyacetate-diethyl)-

barbituric acid)]; mercuric oxycyanide ($\text{Hg}(\text{CN})_2\text{HgO}$); mercuric cyanide ($\text{Hg}(\text{CN})_2$); mercuric benzoate; mercuric salicylate (low yeast restraint because of slight solubility; dissolves on adding alkali); meroxyl (sodium hydroxymercuri-benzophenone sulphonate); mercurosol (sodium hydroxymercuri-salicyl oxyacetate); afridol (practically no yeast restraint).

Class IV. *Mercuric Fluoresceins*.—As class III, but with fluoresceins which play a considerable part in the antiseptic and colloidal shock reactions, for which they are principally used = Flumerin (sodium hydroxymercuri-fluorescein); mercurochrome (dibromo-flumerin).

Class V. *Insoluble Mercurials*.—These become active only by their conversion into soluble mercuric compounds = Mercury iodides and oxides, ammoniated mercury, calomel and metallic mercury.

LOCAL ACTIONS AND USES OF MERCURIALS

The application of soluble mercury compounds produces antiseptic and germicidal, stimulant, irritant and escharotic effects. As has been explained, these differ in degree rather than in kind for the various compounds, but the differences are sufficient to assign them to distinctive therapeutic fields, so that it appears advisable to discuss the compounds separately.

CLASS I: MERCURIC CHLORIDE

Antiseptic Action.—In the absence of proteins and other incompatible substances, mercuric chloride and mercuric bromide are the most powerful mercurial antiseptics. Even in ordinary cultures the growth of many micro-organisms is inhibited by 1:300,000; non-spore forming bacteria are killed by 1:20,000, and anthrax bacilli by 1:1000. Tubercle bacilli are rather resistant. Robt. Koch showed that non-ionized mercuric chloride (*i.e.*, in oil) is ineffective.

The practical usefulness of mercuric chloride is limited by the poor penetration, by the interference of organic matter, and by the local and systemic toxicity. It may be used outside of the body, on the hands etc., in the concentration of 1:1,000. It produces rapid corrosion of metallic instruments, and more gradual deterioration of rubber. On mucous membranes and wounds, the concentration should not exceed 1:20,000 to 1:2,000; and these should be used with caution. Irrigation of large serous or mucous surfaces may result in serious poisoning. Dilutions of 1:20,000 to 1:5,000 are used as conjunctival antiseptic, but are very irritating. A 1 per cent. alcoholic solution is used on corneal ulcers. To hasten the solution, to prevent precipitation in the water and to lessen the irritation it is customary to add some sodium or ammonium chloride, as is done in the commercial bichloride tablets. These form double salts which are less dissociated and therefore somewhat less active (Sabbatani, 1906). Hydrochloric, tartaric and citric acids have similar effects.

Local Irritation of Mucous Membranes.—This is especially important in acute mercury poisoning. The coagulation of the protoplasm gives an ashy color and cooked appearance to the mucous membranes that come in contact with the mercuric chloride. The tissues underneath are inflamed. Prolonged contact leads to necrosis and corrosion. *Intramuscular injections* cause severe pain and sometimes local necrosis.

Mercuric Chloride on the Skin.—Concentrations of 1 to 5 per cent. produce irritation, vesication and corrosion; sensitive skins may be inflamed by the more dilute solutions, as used in operations. The absorption

from the intact skin may be sufficient to produce systemic poisoning. Solutions of 1:1,000 to 1:200 are used in the skin diseases (pityriasis, sycosis) for antiseptics and to produce exfoliation of the epidermis.

CLASS II: MODERATELY IONIZABLE MERCURIC COMPOUNDS

Potassium Mercuric Iodide.—Mercuric iodide is insoluble in water, but dissolves in the presence of potassium iodide in the molecular ratio of 1 HgI₂:2 KI, forming a complex salt, K₂HgI₄. A slight excess of KI is required for permanent solutions. This is assured by using equal weights of HgI₂ and of KI (or NaI); or by 3 grams of KI (or NaI) for each gram of mercuric chloride. The antiseptic activity may be somewhat higher or lower than that of mercuric chloride, according to conditions; but in general it does not differ widely in either direction. The local irritation is much less, so that it may be injected intramuscularly, but not without pain. The systemic toxicity is the same, on the basis of mercury content.

Potassium mercuric iodide is used as a germicide in the same concentrations as mercuric chloride. With short contact, one per cent. solutions may be used (Macfarlan, 1924).

CLASS III: POORLY IONIZABLE MERCURY COMPOUNDS

Mercuric Oxycyanide, Cyanide and Benzoate.—These produce very little irritation, and have been used as antiseptics on sensitive mucous membranes, such as the conjunctiva and urethra, as 1:4,000 to 1:1,000 solutions.

Meroxyl.—This was recommended especially by H. Young et al., 1923, as a local antiseptic for wet dressings and irrigation of wounds (0.1 per cent.) and for gonorrhea, cystitis and abscesses (0.5 per cent.).

CLASS IV: MERCURIC FLUORESCENS

Mercurochrome.—This penetrates tissues readily, as may be recognized by the red stain. It causes but little irritation, so that the 1 per cent. solution is easily tolerated by the bladder, renal pelvis and urethra; 2.5 per cent. in the anterior urethra causes only temporary burning. Its antiseptic activity is high, rapid, and not easily hindered by impurities; 1:1,000 in urine kills coli and staph. aureus in one minute (Young et al., 1919). It is, however, incompatible with acids, local anesthetics and most alkaloids. The usual concentrations for mucous membranes or tissues are 1 to 2.5 per cent. solution or 5 per cent. ointment; 2.5 per cent. solution is used in the treatment of ophthalmia neonatorum. The stains of the skin may be removed by sodium hypochlorite solution, or by 2 per cent. permanganate, followed by 2 per cent. oxalic acid.

Intravenous Injection of Mercurochrome.—This has been employed by H. Young et al., to combat septicemias and localized infections, particularly by the colon group of bacteria. The results are difficult to judge, and the dosage used (5 mg. per Kg. as 1 per cent. filtered solution in distilled water) is not without danger. Rabbits die within 24 minutes after 10 mg. per Kg; and 5 mg. produce severe renal damage. Dogs are more resistant, and so evidently are men, but the margin of safety cannot be wide. The therapeutic results are probably due to the colloidal shock-reaction; for the substances leave the blood stream rapidly, to be excreted mainly by the bile; and neither the blood, nor the bile, nor the kneejoint fluid, are even bacteriostatic (Hench, Snell, Greene et al., 1924).

CLASS V: INSOLUBLE MERCURIALS

These produce very little irritation, but considerable antiseptic action on the surface of tissues; since their slow solution and oxidation in the presence of protein furnishes a continuous supply of mercuric ions (Schamberg and Kolmar, 1914).

Mercurials and Iodide on Eye.—The insoluble mercury compounds should not be applied to the eye when the patient is using iodides; the very irritant mercuric iodide is formed on the conjunctiva and causes severe injury. Iodine compounds that do not ionize readily (iodtropin) naturally produce but little reaction (Grumme-Fohrde, 1914). Bromides behave like iodides, but chlorides are harmless (Schloms, 1913).

Yellow Mercuric Oxide.—This is used as an antiseptic and stimulant, especially on the eye, usually as $\frac{1}{10}$ to 1 per cent. ointment. The concentration of the U.S.P. ointment has been changed to 1 per cent.

Ammoniated Mercury.—This is the complex "white precipitate" obtained by precipitating mercuric chloride with ammonia. It is used as a relatively non-irritant antiseptic and stimulant in eczema and other dermatites and parasitic skin diseases, especially pediculosis, as 2 to 10 per cent. ointment.

Calomel.—This is used as dusting powder or ointment for sluggish ulcers, ulceration of the cornea, vesicular conjunctivites, etc. It is non-irritant and may be applied in any concentration. A 33 per cent. ointment is employed in venereal prophylaxis.

Mercurial Ointment.—The Mild Mercurial Ointment, which contains 30 per cent. of finely divided metallic mercury, is used for the destruction of lice. It may produce some local irritation. The *stronger mercurial ointment* (50 per cent.) is used in syphilis.

ABSORPTION AND FATE OF MERCURY

Mercury compounds and metallic mercury are absorbed readily from all surfaces, even from the intact skin. All of these channels are used therapeutically. After their absorption, the mercury disappears rapidly from the blood; being taken up partly by leucocytes, and deposited in various organs, especially the kidney and liver. Here the mercury appears to be fairly firmly bound, forming "depots" from which traces of the metal may be mobilized for six months or longer after discontinuing the administration.

The excretion occurs mainly by the urine and feces (Wellander, 1886). The excretion begins in a few hours, and after a single dose lasts for perhaps eight days; after long-continued administration the excretion persists intermittently for many months.

The excretion will be discussed further under the antisiphilitic use.

Form of Absorption.—The compounds undergo complex changes in the course of their absorption. *Metallic mercury* is readily oxidized, and then behaves as the other forms.

Mercuric salts form soluble organic compounds with the proteins, NaCl, and alkalies. (Voit, 1857).

Distribution in the Body.—The proportion of mercury is greatest in the kidneys; then in descending order, come the liver, spleen, bile, intestinal wall (Ullmann, 1892; Abelin, 1912). Tuwtsungming, 1919, confirmed this distribution. He also found some in the heart, and a little in the brain. The concentration in the brain was greatest with mercuric salts, even though death occurred much more rapidly than with mercurous salts.

Mercury has been reported in the cerebrospinal fluid (Conti and Zuicola, 1906); but Lasarew, 1911, found it absent in mercurial treatment and poisoning. If mercurial

vapor has been inhaled, the metal may be found in the lungs. The deposition in the liver is said to be lessened by potassium iodide (Blumenthal and Oppenheim, 1911).

It is sometimes found in the placenta and in the embryo, but probably only after very large doses, which may injure the vessels. It is claimed, however, that congenital syphilis may be treated by mercurial inunction of the mother (Jung, 1914).

The distribution of mercury in *acute poisoning* is discussed by Kahn, Andrews and Anderson, 1915.

In a case of death occurring 8 days after taking a large quantity of mercuric chloride, Rosenbloom found the largest amounts in the liver (40 mg.); blood (52 mg.); and muscles (26 mg.). The kidneys contained only 6 mg.

The distribution of aromatic mercury compounds is described by Blumenthal and Oppenheim, 1914.

Metallic Mercury Globules in Tissues.—These have been reported in necrotic bone, and in the tissue of an aortic aneurism, presumably after inunction treatment (Kolmer and Mastin, 1918).

MERCURIAL POISONING

Varieties of Mercury Poisoning.—These may be classed under three forms:

(a) *Acute*, occurring generally from the abuse of mercuric chloride, chiefly with local phenomena.

(b) *Subacute*, especially in the therapeutic use of excessive doses.

(c) *Chronic*.—This may also occur medicinally, but is seen especially in industrial poisoning (workers in mercury, manufacturers of thermometers, mirrors, electric lamp bulbs, felt hats, etc.). A large proportion of those exposed to mercury are affected, because the adherence of the metal to the skin, and the inhalation of its vapor, makes protection difficult.

Phenomena of Acute Poisoning with Mercuric Salts.—The immediate effects are due to coagulation, irritation and superficial corrosion, to which mucous membranes are highly susceptible. There is an astringent metallic taste, salivation; burning, swelling and ashy discoloration of the mouth and pharynx; thirst; abdominal distress and pain, at first epigastric, then diffused; vomiting with white or often bloody mucous shreds; sometimes edema of the glottis.

The primary symptoms generally yield to local treatment, including abstinence of food for thirty-six hours; and the patient may be quite comfortable. Signs of mercurial stomatitis usually develop in twenty-four hours, but are not especially severe.

Somewhat later, after absorption, the large intestines and kidneys are chiefly involved. Within two or three days, the urine shows protein and casts, and becomes scanty. Anuria may be complete, with death within a week, without uremic convulsions. If the nephritis is not extreme, a membranous colitis develops, with dysentery and tenesmus, ulcerations and hemorrhages and hepatic degenerations. These phenomena may only appear, and prove fatal, several weeks after taking the poison (Lambert and Patterson, 1915).

The circulation is affected only in the severest cases, with a fall of blood pressure, probably mainly cardiac (v. Mering, 1880), perhaps with some vasomotor involvement. The poisoning then ends with feeble pulse, insensibility of the skin, coma and collapse.

The *course* is therefore variable; death may occur in a few hours, but is generally postponed for several days.

In case of *recovery*, the phenomena of subacute poisoning set in: nephritis, stomatitis and colitis, as described.

If the poison has been taken otherwise than by mouth, the symptoms, except the local ones, are strictly similar.

Postmortem Changes.—The mucous membranes are of an ashy color, congested and corroded. The kidneys show acute nephritis, often with calcification of the epithelium; The lesions in the color are indistinguishable from those of dysentery: coagulation necrosis with hemorrhages and black ulcerations. In experimental poisoning, degenerative changes are found in the kidneys, much less in the liver (Morel, Mouriguand and Policard, 1912).

The viscosity of the blood (not of the serum) is doubled in mercurial, lead, and phosphorous poisoning (Farmachidis, 1912). A neutrophile *hypo-leucocytosis* is a constant phenomenon (Donzello, 1915).

Toxic Doses.—These may be stated as follows:

Mercuric chloride for children 0.18 to 0.6 Gm.; for adults 0.8 Gm. Recovery, however, has occurred, under treatment, after 2.5 Gm. Opium is said to lessen the toxicity.

Mercuric cyanide, which produces the same phenomena, has caused severe poisoning with 0.12 Gm. and death with 0.6 to 1.2 Gm. A case is described by Gettler, 1916.

Calomel.—Even large doses ordinarily produce only diarrhea; exceptionally, more severe and even fatal effects are recorded; for children with 0.4 Gm., for adults with 2 to 3 Gm.

Metallic mercury, which was formerly given in ileus in doses of 100 to 500 Gm., usually passes off by the feces with very little effect; sometimes there is diarrhea and stomatitis; and exceptionally, severe and even fatal poisoning; "and then, a ride in the hearse" ("et postea vectio in curru"), was Archibald Pitcairn's dry comment on the use of mercury in ileus "ad uncias aliquot, vel etiam libras" (Elementae Medicinae, 1740).

Relative Toxicity of Different Compounds.—This is under dispute. It is generally believed that the toxicity is proportional to the ionization, and therefore greatest with the chloride, succinimide, etc. The aromatic compounds are much less toxic (Abelin, 1912). With mercurial dyes, the toxicity, and the efficiency against spirillosis, are not proportional to the mercury content or dissociation (Klages and Schreiber, 1914).

Schamberg, Kolmer and Raiziss, 1915, state that the toxicity for hypodermic and intravenous injection depends practically on the mercury content; and is essentially alike for inorganic and the different types of organic compounds. They explain this by the ease with which ionized mercury is liberated from these compounds.

Treatment of Acute Mercuric Poisoning.—This is fairly successful when started whilst the mercury salt is in the stomach. After the poison has been absorbed, it is not affected by antidotes; and the treatment becomes essentially palliative, and not very successful.

Three raw eggs in a quart of milk are among the best antidotes, if the patient is seen early. They act as precipitants and demulcents (Barlow and Sollmann, 1926).

A hypophosphite-peroxide mixture is almost equally convenient and perhaps more effective.

Fantus, 1916, recommends sodium hypophosphite, 1 Gm.; water, 10 c.c. and hydrogen peroxide, 5 c.c., per 0.1 Gm., of mercuric chloride. This should be followed by lavage with the diluted reagent.

Various other antidotes, precipitants and reducing agents, have been proposed; often with the claim that they would render the mercury harmless even after its absorption. This claim is certainly incorrect, and it is not clear that they have any advantage over albumen. They will be discussed below.

Encouraging clinical results have been reported for the intravenous injection of sodium thiosulphate (see index); but the clinical course of mercury poisoning cannot well be predicted, and under experimentally controlled conditions, the results have been disappointing (Haskell, Henderson and Hamilton, 1925).

Phosphite and Hypophosphite Reagents. Sodium phosphite reduces mercuric chloride to calomel. Its use with sodium bicarbonate as an antidote was proposed by Linhart, 1913, 1917; although it is better known as "Carter's antidote," a mixture of sodium phosphite and sodium acetate. Fantus, 1917, proposed a similar hypophosphite-peroxide mixture (see above).

The phosphite mixtures are quite successful if given within 5 minutes after the poison (Fantus and Hyatt, 1917). They are useless after it has been absorbed; this even if the antidote is injected into the blood (Sansum, 1918).

Sulphides.—Sabbatani, 1907, investigated the antidotal value of hydrogen sulphide. Wilms, 1915 to 1917, makes the very improbable claim that calcium sulphide is effective even when started 12 to 20 hours after the poisoning. He uses it by mouth (0.15 to 0.3 Gm. every hour) and intravenously (in quantity equal to that of the mercury) as a freshly made, boiled and filtered, 0.2 per cent. solution. This contains $\text{Ca}(\text{SH})_2$ and is supposed to form mercuric sulphide.

The advisability of the intravenous treatment is doubtful. Haskell and Courtney, 1917, found the benefits no greater than with simple saline.

Iodide and Quinine.—Hall, 1914, proposed potassium iodide and quinine (a reversal of Meyer's reagent). This might have some effect in the stomach, but naturally not in the blood or tissues (Barbour, 1915).

Charcoal.—Ferreira and MacBride, 1914, advocated animal charcoal, a tablespoon every 2 hours, together with lavage, etc.

The local antidotes must be followed by an emetic or repeated gastric and colon lavage to remove the unabsorbed or re-excreted mercury; and by alkali administration, milk diet, and hot packs, to protect the kidneys.

Lavage.—Lieb and Goodwin, 1915, emphasize repeated gastric lavage to remove mercury excreted into the stomach. Lambert and Patterson, 1915, combine this with continuous rectal irrigation. The success is only limited if the poison has already been absorbed (Sansum, 1918).

Saline Infusions, Alkalies, etc.—Sansum, 1918, determined the minimal fatal dose of mercuric chloride by intravenous injection for dogs as uniformly 4 mg. per kg. This was not modified by the infusion of plain saline, or by sugar solutions, alkalies, Fischer's solution, etc. *i.e.*, these were all unsuccessful against acute poisoning. This does not exclude the possibility of diminishing the nephritic changes of subacute poisoning, which may explain the results claimed for these treatments. However, their benefit is not firmly established; especially since they are generally combined with other measures.

Venesection and Transfusion.—Burmeister, 1917, claims that these diminish the renal changes.

Alkalies.—The use of these is justified by the observations of MacNider that they protect the kidneys against metallic poisons. However, their success is probably quite limited.

D. J. Lewis and Rivers, 1916, aim to increase the elimination by frequent gastric lavage, colon irrigations and hot packs. They also give sodium bicarbonate and glucose by mouth and vein, to combat acidosis and guard against nephritis. W. B. Weiss, 1917, 1918, also advocates alkalies, on Fischer's theory of nephritis. After the local antidotes, he administers sodium bicarbonate freely, so as to keep the urine alkaline to methyl red. Schisler, 1917, claims good results from MgO , 2 to 4 Gm., every 3 hours.

Subacute Poisoning.—This (as seen in sequence to acute poisoning or in the ordinary medicinal use, and which is also produced by the inhalation of concentrated mercurial vapors) presents especially the phenomena of nephritis, stomatitis and colitis; more rarely skin eruptions. The stomach and small intestines usually escape.

Stomatitis.—This is important as the earliest symptom of excessive therapeutic use or of chronic poisoning. It occurs about as readily when the mercury is administered otherwise than by mouth. It begins with fetor, then metallic taste, soreness of the gums and some salivation (ptyalism). This is as far as the therapeutic use should go. If it is pushed further, the teeth loosen, the edges of the gums blacken, and they, and later the tongue, become swollen and ulcerated. The irritation and infection cause very severe salivation and progressive exhaustion, and sometimes fatal ulcerative stomatitis. With a more chronic course of severe poisoning there may be loss of the teeth and necrosis of the jaw.

The susceptibility to stomatitis varies greatly and is markedly influenced by the hygienic condition of the mouth and teeth, as well as by the dosage of mercury.

Treatment of Stomatitis.—The stomatitis is most effectively prevented and treated by hygiene and care of the teeth. The mouth should be in the best possible condition before mercury is started. Hydrogen peroxide or potassium chlorate (a tablespoonful of the saturated solution to a glass of water) should be used as a mouth wash several times a day. The use of tobacco is said to be injurious.

Cause of the Stomatitis and Colitis.—These are generally attributed to irritation during the excretion of the metal. Almkvist, 1906 and 1916, however, points out that they have no relation to the excretion but depend upon the presence of hydrogen sulphide and the precipitation of mercuric sulphide which can be shown chemically in the capillary endothelium of these situations. Similar deposits and irritation can be produced experimentally elsewhere by exposure to hydrogen sulphide. He therefore explains the process as due to bacterial action causing injury and desquamation of the epithelium, and the production and absorption of H_2S , which precipitates the mercury in the capillaries from where it is deposited in the endothelium. Here it acts as an irritant and disturbs the function and nutrition of the vessels, leading to necrosis. The explanation is somewhat hypothetical.

Bismuth also gives similar precipitates but they are less toxic. Lead and copper are not so easily precipitated.

Mechanism of Salivation.—This is not definitely known. It is inhibited by atropine. It could be explained by reflex irritation from the gingivitis, or by direct irritation. Giani, 1913, reported degenerative histologic changes in the parotid glands.

Mercurial Nephritis.—Some degree of albuminuria is common even in the ordinary therapeutic use of mercurials. It is attributed to the excretion of the mercury. After severe intoxication it may last for years.

The *acute nephritis* is primarily tubular. When severe, it may be accompanied by hemorrhagic glomerular nephritis. The lumen of the tubules, and sometimes the epithelium, may contain crystals of calcium carbonate (Saikowsky, 1866), the origin of which is not explained. These may occur as early as 48 hours after the administration (Schamberg et al., 1915).

In the *milder or more gradual cases*, the nephritis is mainly interstitial; although the glomeruli, and with large doses the epithelium may be involved. Later the kidney becomes cirrhotic.

The anatomical and chemical changes in acute clinical mercury nephritis are further described by W. R. Campbell, 1917; those in the subacute form by Foster, 1915.

Functional Changes in Experimental Mercury Nephritis.—The acute form generally shows polyuria (Schlayer and Hedinger, 1907) and often renal glycosuria (Franck, 1913). The blood of rabbits is hydremic (Blix, 1916).

MacNider, 1918, found in subacute poisoning, accompanied by partial or complete suppression of urine, a diminished phenolsulphonephthalein output, retention of urea, and rapid reduction of reserve alkali.

These changes may not have time to develop in animals that die very acutely. Otherwise, the degree of *acidosis* is parallel to the morphologic changes (MacNider, 1917).

Hepatic Degeneration.—MacNider, 1919, found that dogs poisoned by mercuric chloride, 15 mg. per Kg., by mouth, react with severe gastro-enteritis, but usually recover. The liver of these animals shows degenerative changes, beginning with deposition of fat in the cells around the central veins, then cloudy swelling and necrosis, the process extending toward the periphery. The intensity is parallel to the nephritis, rather than to the gastroenteritis.

Metabolism.—The effects are imperfectly known but appear to resemble those of arsenic, lead and phosphorus. Small doses, therapeutically and in animals, often cause considerable *increase of weight* (fat). The *red corpuscles* are also increased (Schlesinger, 1884). In chronic cachexia they are diminished. In acute poisoning there is often *glycosuria* and disappearance of glycogen. On the other hand, mercury is sometimes beneficial in *diabetes*, presumably of syphilitic origin.

Chronic Mercury Poisoning.—If this takes a slow course, there are, in addition to the subacute symptoms, nervous and nutritional phenomena. The most common are tremor; erethismus (psychic irritability and restlessness), and other psychoses; cachexia with anemia, malnutrition and muscular atrophy; bone changes (decalcification) and more rarely neurites or pareses.

Treatment of Chronic Poisoning.—Prophylaxis is of the first importance; it is doubtful whether treatment materially influences the course after the appearance of symptoms. Potassium iodide and hot baths are generally tried, with the intention of hastening elimination.

Mercury Vapor Poisoning.—Metallic mercury vaporizes at ordinary temperature, and more rapidly if heated. It is very doubtful whether these vapors can be absorbed directly, but they are condensed or adsorbed on exposed surfaces, and therefore on the respiratory mucous membranes and in the mouth, whence the mercury may be swallowed, or oxidized in situ to absorbable compounds. These give rise to focal irritation, for instance in the lungs (Ricke and Hesse, 1914), and to the systemic effects. The more concentrated vapors may result in subacute mercurial poisoning. The more dilute vapors, as encountered in mercury mines, etc., gradually develop the phenomena of chronic poisoning, tremors, stomatitis, some digestive derangements; these are observed after 2 or 3 months or later, in men exposed for 3 to 5 hours per day to concentrations of 0.02 mg. of mercury per cubic foot of air; the daily absorption being estimated as 0.8 to 1.3 mg. (Turner, 1924). These dilute mercury vapors may be fatal to small animals, but not usually to man.

CALOMEL AS CATHARTIC AND INTESTINAL ANTISEPTIC

Mercury compounds produce intestinal irritation and therefore catharsis; but with the more soluble salts these effects are generally too violent. Calomel, the mercurous or "mild" chloride, dissolves so slowly and to so limited a degree that the irritation is mild, largely independent of the dose, and restricted mainly to the duodenum. Calomel is practically insoluble in water, and almost insoluble in the stomach and large intestine (Nemser, 1906), but in the small intestines it tends to be decomposed by the alkaline reaction of the pancreatic juice, bile and intestinal juice into mercury and mercuric oxide, and the latter dissolves slowly in the presence of proteins (T. W. Schaefer, 1910). This dissolved mercuric salt irritates the intestines to increased peristalsis, and diminishes the absorption of fluid (Fleckseider, 1912). Radiologic examinations show that generally both small and large intestines are stimulated (Meyer, Betz and Gebhardt, 1912); but if the conditions are not favorable for solution, or with small doses, the small quantity of dissolved mercury may have been absorbed before the colon is reached, and the duodenal contents may be propelled into the colon without evacuation. Ordinarily, calomel produces dark-green semisolid stools in 10 to 12 hours. The irritation is generally so mild that calomel may be used even in enteritis; but some patients appear to be hypersusceptible, and respond with marked griping and tenesmus. These also result from excessive doses. The catharsis is checked by opium or atropine. It is not influenced by the presence or absence of bile (Valeri, 1909).

The green color of the stools is due mainly to bile, possibly somewhat darkened by mercurous sulphide. Numerous investigations with biliary

fistulas have shown that calomel does not increase the flow of bile (Okada, 1915); but the antiseptic action of the dissolved mercury, and the rapid propulsion of the intestinal contents, prevent the ordinary destruction of the bile pigments. This may also be demonstrated in vitro (references, v. Oettingen and Sollmann, 1926). The antiseptic action in the intestines is also reflected by decrease of the urinary indoxyl. Larger doses of calomel may favor bacterial growth by diminishing intestinal resistance.

Dosage.—This is relatively unimportant, because any excess is generally expelled before it is dissolved. It is customary to give either a single dose of 0.125 to 0.5 Gm. (2 to 7 gr.); or fractional doses of 15 mg. ($\frac{1}{4}$ gr.) every hour until 0.15 Gm. ($\frac{1}{2}$ gr.) have been taken. The divided doses insure better solution, because they are spread over a large surface, and because there is more opportunity for the coincidence of calomel and alkalinity. Formerly much larger doses were used but they are superfluous; and while usually harmless, they may become dangerous should conditions become exceptionally favorable to absorption.

Calomel is not suited for long-continued use on account of its systemic actions. These may also be produced by large single doses, if they are not expelled in the usual time. It is therefore advisable to follow the calomel in six hours by a saline; or it may be mixed with Resin of Podophyllum (5 mg.; $\frac{1}{32}$ gr.).

Calomel should not be perscribed with iodides, alkalies or organic substances.

Interaction of Calomel and Salt.—Mialhe attributed the solution of calomel to interaction with sodium chloride, forming mercury and mercuric chloride, and complex double salts. Similar reactions were claimed by Joly to occur with hydrochloric and citric acids, alkalies, carbonates and sugar. These reactions do occur in pure solutions, especially at high temperatures and with concentrated solutions; and to some extent even under conditions resembling those of the body. The amount dissolved would be very small (at most 1 to 4 mg. per 0.5 Gm. of Calomel). However, mercuric chloride could not exist as such in the alkaline intestine, and the chloride can therefore not be made responsible for the solution of calomel (as was suggested, *f.i.*, by Carracido, 1906).

Iodides, bromides, sulfocyanides, thiosulphates, etc., dissolve larger quantities of calomel.

MERCURIAL DIURESIS

The administration of suitable doses of mercury compounds sometimes produces very marked diuresis, especially in the presence of edemas. Calomel has been used for this purpose, but the variable absorption makes it unreliable. It has been practically displaced in this use by novasurol, a soluble complex mercury-phenyl salt with barbital, which can be injected intravenously and intramuscularly, and which acts very promptly. It is most effective in cardiac edemas, in which it may succeed completely when digitalis and the caffeine group have failed. The urine flow may amount to 7 or 8 liters per day. The diuresis may also be successful in nephritis and in hepatic edema, especially if combined with restriction of water and salt income; but in these it is not always effective, and may sometimes increase the renal irritation. Its employment is still regarded as somewhat hazardous, and is therefore generally reserved until other methods have failed.

The mechanism of the mercurial diuresis is not yet established. The most plausible theory is that of alteration in the colloid-water affinity, although this is not based on direct evidence. It is evidently not due to changes of the blood pressure, nor to increased water absorption; the

latter would not explain the draining of the edemas. Renal irritation also does not appear a satisfactory explanation, although it has not been definitely excluded. In normal individuals, novasurol may increase the excretion of sodium and chloride even when it does not produce diuresis.

Dosage of Novasurol.—This is administered by vein or intramuscularly, as 10 per cent. solution, from 0.75 to 1 or 2 c.c., beginning with the smaller dose, with intervals of 3 to 7 days, according to the effect. The intramuscular injections generally cause only slight and transient discomfort and at most temporary induration.

Diuretic Dosage of Calomel—0.2 Gm. was administered 4 or 5 times a day, until slight stomatitis appeared; the bowels being meanwhile regulated with opiate.

Historical.—The diuretic effect of calomel in cardiac dropsy is said to have been well known to the physicians in the latter half of the eighteenth century. It was used, *f.i.*, by Alex. Munro. However, it fell into neglect, and was practically rediscovered by Jendrassik in 1886-1891. His results were very similar to those that are now generally accepted. Novasurol was originally introduced by Zieler, 1917, as an antisyphilitic. Its diuretic effect was described by Saxl and Heilig, 1920. References to the literature are given by Rowntree, Keith and Barrier, 1925.

Mechanism of Mercurial Diuresis.—The older data may be found in the papers of Fleckseder, 1912. The latter showed that all mercury compounds, by all methods of administration, produce a diuretic effect in rabbits. He believes that mercury lessens absorption of food-water from the small intestines; the water would therefore reach the large intestines in excessive quantity; and when absorbed from this place would act as a diuretic. The explanation is not altogether satisfactory; *f.z.*, it does not explain the absorption of exudates. The diuretic action of mercuric chloride has been studied in rabbits by Ferron, 1912.

Hydremia in Calomel Diuresis.—Fleckseder found the blood of rabbits hydremic. This would speak against the diuresis being of renal origin. However, the result was probably accidental, for all other workers have found the blood, in man or mammals, either unaffected or rather concentrated by the diarrhea. The lymph-flow is not increased (Yanagawa, 1916; Loria, 1912).

Influence of Other Drugs.—The diuresis is suppressed by atropine; this would favor Fleckseder's explanation; but opium which also lessens peristalsis increased the diuresis. Schargorodsky, 1911, found it suppressed by ether or morphine. Excessive doses of mercury also produce anuria.

The constituents of the urine after calomel were studied by E. Frey, 1906.

Water-affinity.—Mollitor and Pick, 1922, reported that mercurials increased the water imbibition of winter-frogs. The significance of the observation is difficult to interpret.

Mercurial Diuretic in Nephritis.—The theoretical objections to the use of so powerful a renal irritant are mercury in nephritis, were early emphasized, especially by Cohn, 1887, and supported by some clinical observations. It was claimed that there is a very marked tendency to mercurial symptoms, and that the nephritis is often made worse. The greater number of observers, however, hold the opposite view, *viz.*, that calomel does not render the nephritis worse, whether it has a diuretic action or not. This is defended by Jendrassik, and by Heuck, 1889. Schild, 1892, reported three cases, in which he claims that a diuretic effect was obtained, together with a lessened per cent. of albumin; the daily output of protein being unchanged.

Briefly, it seems certain that the doses of calomel which are advocated have never produced albuminuria in normal individuals, but the question of their effect on an existing nephritis is not sufficiently investigated to admit of a decisive answer. Great conservatism in its employment is therefore indicated.

MERCURY IN SYPHILIS

The antisyphilitic effect of mercury was discovered about 1500, very soon after the discovery of the disease; according to Rhaenodaeus, it was first used by one Jacobus Carpenis, "whose use was so successful that he presently became rich thereby." Originally, the administration was pushed energetically until profuse salivation occurred, so that the improve-

ment must have been prompt and striking. However, the treatment was stopped as soon as the secondary lesions were healed, since the latent course of the tertiary syphilis was not understood. By the time that this was realized, the therapy had been made less energetic to avoid the risks of severe stomatitis. Between the inadequate dosage and deficient persistence of treatment, the results were often imperfect. This was difficult to recognize by the course of the symptoms alone, so that little progress was made until the recognition of the spirochetes and the Wassermann reaction furnished more definite criteria, and the transfer of the disease to animals furnished experimental controls. These have shown that it is not safe to trust to mercury alone; that the combined use of mercury and arsphenamine lead to permanent arrest and clinical cure of the disease; but that, even with the aid of the arsphenamine, the administration of mercury must be more energetic and more persistent than was commonly realized. The mechanism of the mercury action, as that of all anti-protozoal agents, is not definitely established; but there is no conclusive evidence against the natural assumption that the mercury is directly toxic to the spirochetes.

Spirochete Cultures are killed by dilute solutions of mercuric chloride (1:100,000). Continuous cultivation produces some tolerance, ("fastness"), but this is lost in a few generations of the culture, and is therefore practically unimportant (Akatsu and Noguchi, 1917).

Importance of Early Treatment.—It was formerly taught that mercury should be postponed until the onset of the secondary symptoms, so as not to interfere with the clinical diagnosis. This consideration became superfluous with the introduction of the laboratory methods. It is now recognized that the chances of complete success are the greater, the earlier the treatment. This should be started as soon as the diagnosis is made. If the administration is delayed, or if it is not sufficiently energetic and relapses occur, treatment becomes much more difficult and requires larger doses. This may be because the parasites gradually become surrounded by fibrous tissue that is difficultly accessible to the circulation and to drugs.

Abortive Treatment.—If treatment can be started within 4 or at most 8 hours after exposure, the site of suspected infection should be disinfected and dressed with an ointment containing 33 per cent. of calomel or 0.3 per cent. of sublimate ("Neisser-Siebert Ointment"). This should be followed by systemic treatment. (See also under Organic Silver Preparations.)

Mercury should not be used locally, after 12 hours have elapsed, until a diagnosis has been made, for it makes it more difficult to find the spirochetes.

Principles of Anti-syphilitic Therapy.—When the protozoa have established themselves in the body, and have had time to penetrate and to lodge in the tissues, chemotherapy may still promptly suppress all symptoms, by destroying the main mass of the parasites in the blood stream; but those which are in secluded capillaries, and in some of the tissues that are not easily reached, escape and eventually multiply and spread and reinfect the patient. Those that reach the circulation may again be destroyed by chemotherapy, but again leave some protected individuals. This is at least a plausible explanation of the fact that

single or occasional doses are effective temporarily, but rarely result in permanent cure. In treating syphilis, therefore, it is necessary to continue the drugs so as to kill the protozoa as soon as they leave their protected location, and in this manner to prevent their dissemination. Eventually this tends to check and suspend multiplication in the foci themselves. As further medication, at that time, would do little good, the "course" of medication may be suspended, and a "rest-period" introduced allowing the tissue-cells to recuperate from the injuries that they have suffered from the drug and permitting the excretion of any accumulated excess. When the drug concentration has fallen below a certain level, the remaining parasites would again proliferate; but before this proceeds to a serious degree another course of treatment is started. The courses are continued, with appropriate rests, until the incarcerated and weakened parasites succumb to the immunity reactions of the tissues. This is the type of intermittent or "course" treatment that is generally followed for chronic protozoan infections. It was originally introduced by Fournier, on the assumption that the syphilitic "virus" acquired immunity to the continued administration of mercury, and reestablished its susceptibility by temporary rest; according to the above working theory, the immunity and susceptibility would simply be one of location. An important advantage of the intermittent method is that higher concentrations of mercury may be employed temporarily than could be safely maintained continuously.

In the intermittent method, the mercury is given to slight pyalism, in courses of five to six weeks' duration, with intermissions of one to six months, for at least one and a half years; or longer if the disease is not eradicated (see under Arsphenamine).

Whatever method is used, it should be aimed to introduce the maximum of mercury that the patient can tolerate; something like 2 Gm. of Hg during the first year, and 1 Gm. in the two succeeding years. The relative failure of the older methods may be attributed to insufficient dosage.

If sclerotic syphilitic lesions have set in, mercury is of little use. The chemotherapy of mercury is discussed, with a bibliography, by Schamberg et al., 1917.

Depot, Stored and Active Mercury; Excretion Index.—With most methods of administration, the absorption of mercury is rather slow and incomplete, so that there are usually "*depots*" of unabsorbed mercury from which absorption takes place for some time after the administration is stopped; *i.e.* in the hair follicles with inunction; in the muscle tissue with intramuscular injection; and on the intestinal surface with oral administration. The mercury action therefore continues to some extent, which varies with the method, during the apparent rest periods. With intramuscular injections, however, the depots gradually become encapsulated in fibrous tissues, and absorption ceases.

A considerable, and generally the major part of the absorbed mercury is not excreted at once, and must therefore be stored, probably as complex protein compounds, mainly in the liver. This *stored mercury* is presumably without action on the parasite. Gradually, however, as the storage cells break down, the mercury becomes liberated and is partly excreted by the bile, and partly re-enters the circulation, as is shown by the continued excretion in the urine. This liberation, however, occurs so slowly that it could not contribute materially to the therapeutic effects.

The therapeutic effects are presumably due to the mercury that is in soluble form in the circulation and in the tissues, and that has not yet been immobilized. The concentration of this *active mercury* is presumably in equilibrium in the tissues, blood, urinary excretion and excreta; so that the rate of excretion of mercury furnishes a fair index of the effective concentration of mercury. The excretion rate of mercury is therefore found to vary with the quantity of mercury that is being absorbed, and not with the quantity of stored and accumulated mercury (Cole et al., 1926).

Choice of Methods of Administration.—This may be guided by practical considerations, convenience, local irritation, feasibility of supervision, etc., as well as by the efficiency of the mercury. The latter, as has been pointed out, depends largely on the concentration of active mercury that may be attained and maintained; and this in turn depends on securing adequate, continuous, controllable absorption, with avoidance of excessive local damage, of sudden and especially of unpredictable and therefore dangerous exacerbations of absorption, and of unnecessary accumulation of inactive "stored" mercury.

Criteria of Efficiency.—This may be judged by the clinical improvement, by the disappearance of the spirochetes from the lesions; by the Wassermann reaction; and less directly but perhaps more accurately by the rate of excretion. The absorption of intramuscular injections may be followed by radiography (Cole, Littman and Sollmann, 1920). The occurrence of stomatitis proves that considerable absorption has taken place; but it is greatly influenced by the local conditions of the mouth, and is therefore subject to wide individual variations.

Mercury Excretion after Therapeutic Administration.—The accurate determination of small quantities of mercury in the excreta requires considerable time and care, so that reliable data are scanty (Cole et al., 1926; Lomholt, 1920; Buergi, 1906; Buchtala, 1913). The data will be discussed under the individual methods. Effective therapy apparently corresponds to the daily excretion of 0.5 to 2.5 mg. of mercury. The share of the urine and feces show marked variations which require further study.

Potassium iodide, diuretics and sweating were said to hasten excretion; but there is little evidence for this. Buchtala found that the iodide rather delayed the urinary elimination of mercury.

Minor Channels of Excretion.—Variable traces are generally found in the bile, sweat (Tachau, 1911; Lambert and Paterson, 1915), gastric (Lieb and Goodwin, 1915) and intestinal juice and saliva (literature in Almquist, 1912).

Excretion of Metals in Cow's Milk.—Lead is excreted into the milk, but not mercury, antimony or zinc (Koldewijn, 1910).

Details of Methods of Administration.—The following paragraphs aim to give the principal facts that may aid in the choice and application of the various methods and preparations.

Oral Administration.—This has the advantage of convenience to the patient, and effective quantities of mercury are absorbed from the ordinary therapeutic dosage, without difficulty. The urinary excretion of mercury during continuous administration of the mercurous iodide, 0.06 Gm. per day, remained steadily at 3 mg.; with 0.08 Gm. at 4 mg. The latter was also the urinary excretion for 0.6 Gm. of calomel (Buergi, 1906). The gastro-intestinal irritation is a serious disadvantage which restricts the oral administration mainly to the less soluble preparations; but it is

not quite absent from these and they have the further disadvantage of variable absorption, according to the solution and catharsis. The most serious disadvantage of the oral method is, however, that the patient is under less perfect control. It has therefore been largely abandoned except for new-born infants. To these mercury with chalk may be given in doses of 0.015 to 0.03 Gm. three times per day.

For adults, the oral method was used continuously: Beginning with a small dose, this is increased daily by about 10 per cent., to tenderness of the gums. The dose is then reduced to one-third or one-half and continued at this point till the end of the treatment. The usual preparations are, in order of preference:

Hydrargyri Iodidum Flavum ("Proto-iodide") ..	0.01 to 0.05	Gm. ($\frac{1}{16}$ to 1 gr.).
Hydrargyrum cum Creta.....	0.05 to 0.2	Gm. (1 to 3 gr.).
Hydrargyri Chloridum Corrosivum.....	0.005 to 0.015	Gm. ($\frac{1}{12}$ to $\frac{1}{4}$ gr.).

(These doses three times daily.)

The mercuric chloride should be prescribed in solution, with an excess of potassium iodide, and administered in milk, to prevent local corrosion.

Rectal Administration.—Suppositories containing emulsified mercury have been suggested as a convenient method; but the absorption appears insignificant; the daily urinary excretion after 10 days of administration was only 0.03 mg. *i.e.*, $\frac{1}{100}$ that excreted with inunctions, (Cole et al., 1926).

Inunction.—This is performed by rubbing about 2 Gm. of Ung. Hydrargyri fortius (*i.e.*, 50 per cent.) into the skin, until it is entirely absorbed, *i.e.*, for about half an hour. The skin may then be sponged with benzene, to remove the tell-tale excess. The "rubs" are usually repeated every night on a different skin-area, so as to increase the absorbing surface, and also to prevent excessive local irritation; making the tour of the body in six nights. The seventh night a hot bath is substituted, and so on. The course lasts for four to six weeks. Salivation usually starts after 10 to 20 rubs.

The absorption of the mercury occurs mainly from the hair follicles, into which it is forced by the rubbing, and where it is gradually converted into soluble compounds. The epidermis does not participate in the absorption (Zwick, 1925; I. Neumann, 1871; Fuerbringer, 1880). In case of volatile preparations, such as metallic mercury, some absorption may also occur through inhalation (Wile and Elliott, 1917; Schamberger et al., 1918); but this is of very minor importance.

The total excretion of mercury varies considerably in different individuals, presumably due to differences in the structure of the skin. It increases materially with the continuance of the treatment, since each rubbing forces more mercury into the follicles, and so gives a larger surface for solution and absorption. In four patients studied by Cole et al., 1926, the total daily excretion at the end of the first week ranged from 0.2 to 0.8 mg., median 0.45; at the end of the fourth week it was about 4 times as high, *i.e.*, 0.5 to 3.5 mg., median 1.65 mg. The excretion remains high for nearly a week after discontinuing the inunctions, since absorption from the skin continues; it then declines gradually. In brief, the active mercury concentration rises more slowly than with the intramuscular injection of soluble mercury salts, but by the end of the course it is almost twice as high.

Inunction is therefore a very effective method of administering mercury, with a minimum of undesirable local effects. On the other hand, it is time-consuming, dirty and disagreeable, difficult to keep secret, and the

dosage is uncertain. The benzol-washing (Cole et al., 1924) has largely removed the esthetic objections.

The absorption is probably influenced by the ointment base, because this would influence the facility of rubbing the mercury into the follicles; the details cannot be predicted, and have not been investigated. The U.S.P. uses oleate of mercury, *i.e.*, a mercury soap, to facilitate the emulsification of mercury; the use of rancid fat also forms mercury soaps, and these may further increase on keeping. Menschel, 1923, believes that they are more easily absorbed than metallic mercury. Further evidence is needed.

The rapidity of absorption could, of course, be greatly increased by inuncting larger areas of the skin, from the start. Formerly, two ounces of mercurial ointment were rubbed in at each sitting, daily or on alternate days. One to three of these inunctions generally sufficed to produce extensive salivation (Geoffroy, *Tractatus de Materia Medica*, Paris, 1741).

Calomel Inunctions.—These are absorbed much less efficiently than metallic mercury. Cole and Littman, 1919, found no salivation even after 40 rubs; nor was there any improvement in the secondary syphilides.

Inhalations, fumigations and plasters are obsolete methods.

Inhalation of Mercury or Calomel Vapor.—This has been abandoned, mainly because of the uncertain dosage. It also produces marked pulmonary hyperemia (Ricker and Hesse, 1914).

Mercury vapor is not absorbed as such. When it is inhaled, it condenses in the mouth and on the respiratory mucous membrane and undergoes slow oxidation and combination. The compounds are then absorbed. In other words, mercury inhalation amounts practically to the administration of gray powder, except that the dosage is much less definite, and there is a possibility of focal injury to the lungs (Cole and Sollmann).

Intramuscular Injections.—These are made deep into the gluteal or lumbar muscles; injection into the subcutaneous tissue may result in sloughing. Intramuscular injections are therapeutically effective and have the advantage principally that they keep the patient under more effective observation. They avoid direct gastro-intestinal irritation, but the stomatitis, colitis and nephritis which are produced by the absorbed mercury would be the same as with other methods. On the other hand, intramuscular injections of all mercurials cause considerable pain, which lasts some hours with the soluble preparations, and for some days with the insoluble. Of the latter, calomel is the most, "gray oil" the least painful. The immediate pain may be lessened by injecting 1 c.c. of 2 per cent. procaine from the same syringe; the later pain, by adding 1 per cent. of phenol and 5 per cent. of camphor to the oily injection. The muscle fibers at the site of injection are more or less destroyed (Robertson, 1913), but this is not practically important. The most important disadvantage is the variable and incomplete absorption. The absorption depends not only on the direct solubility of the preparation, but mainly on its conversion into more soluble compounds, which varies with conditions. The slow absorption of the insoluble preparations is utilized with the idea of establishing depots so that weekly injections would furnish a continuous supply of mercury. However, if the absorption is not promptly completed, the remaining mercury becomes encapsulated with inflammatory and fibrous tissue, which slows absorption to an incalculable degree. Roentgenographs (Cole, Littman and Sollmann, 1920) show that mercury salicylate is generally absorbed within a week and calomel in two weeks; while the greater part of metallic mercury suspension ("gray oil") remains unabsorbed after 4 weeks. The mercury that remains unabsorbed at the time of the next injection is a source of danger; for if conditions should become more favorable for absorption, the multiplication of depots may give rise to serious cumulative poisoning.

Absorption from Intramuscular Injections.—The mercury, in whatever form it is introduced, acts on the proteins to form albuminates of mercury. These are strongly chemotactic, and attract leucocytes. Some of these are killed, but others take up the mercury, especially in their nuclei, and distribute it through the body; its final fate being the same, as with other methods of administration (Conti and Zuicola, 1906; Lombardo, 1912). The quantitative excretion, however, is very capricious. Wallfisch, 1912, finds that the solubility of the preparations is of subordinate importance; but that all inorganic salts are absorbed and excreted much less readily than the organic salts.

Schamberg et al., 1915, found in animal experiments that after intramuscular injections of insoluble preparations, calomel and gray oil, 50 per cent. of the mercury was unabsorbed after 6 or 7 weeks. However, their conclusions could not be transferred to the clinic, since the doses would have corresponded to about 10 gm. in man.

Quantity of Mercury Introduced by the Different Preparations.—This may be seen from the following table (adapted from Neisser, 1911):

	Per cent. used	Per cent. of Hg.	Usual single dose, c.c.	Hg. content (mg.)	Number injections in six-week course	Grams Hg. in six-week course
Oxybenzoate.....	I	44	I	4.35	42	0.19
Cyanide.....	I	79	I	7.9	42	0.33
Sublimate.....	I	74	I	7.4	42	0.31
Salicylate.....	10	59	I	59.0	11	0.65
Calomel.....	10	85	I	85.0	11	0.94
Asurol.....	5	40	2	40.0	15	0.61
Ol. Cinereum.....	40	40	$\frac{1}{4}$	140.0	10	1.40

The preparations used for intramuscular injections fall into two classes; according to whether they are absorbed rapidly or slowly. These have distinctive uses.

The Easily Absorbable Injections.—These include all the soluble salts; and the salicylate, which is insoluble in water but is dissolved by sodium chloride or carbonate.

The soluble preparations act more promptly, the dosage is under better control, and there is less probability of cumulative action. The effects are correspondingly less persistent, and the injections must be repeated at more frequent intervals—every day to every third day.

The average daily dosage is about 1 c.c. of 1 per cent. (= 0.01 Gm., $\frac{1}{6}$ gr.), in courses of five to six weeks' duration. The treatment may be intensified by beginning with 2 c.c., increasing slowly to 3 or 4 c.c. (0.03 to 0.04 Gm.), or until mild ptyalism occurs, when the dosage is reduced so as to keep the patient just short of salivation.

The local irritation is proportional to the precipitant action on protein, and to the ion-concentration. *Mercuric chloride* is so irritant that its use as such is not advised. *Mercuric iodide* ("biniodide") dissolved with an equal quantity of sodium iodide, is much less destructive, and is often used. The bromide may be similarly employed. The *succinimide* is also similar. The *cyanide*, *oxycyanide* and *mercurosal* are less irritant.

The excretion of this type has been studied by Cole et al., 1926, on mercuric bromide, which is strictly analogous to the biniodide. With daily injections of 10 mg., corresponding to about 5.5 mg. of Hg, for 3 to 4 weeks, the excretion rate averaged about 1 mg. both at the end of 5 and 20 injections. In other words, mercury accumulated in the body at

the rate of 4.5 mg. per day. This must have been stored as "inactive" mercury, since it does not increase the excretion rate.

Mercury Salicylate.—This is nearly insoluble in water, but dissolves in the presence of salts. It is used as a 10 per cent. suspension in oil, 1 c.c. being injected once a week, with relatively little irritation. The excretion is highest on the following day (8 mg.), then drops rapidly, to 0.5 mg. at the end of the week (Lomholt, 1920; Buchtala, 1913). The treatment is therefore intermittent rather than continuous.

Lanolin emulsion is a better medium than simple oil for the suspension of mercuric salicylate (Nitardy, 1919). The following yields a useful

Permanent and Anesthetic Ten Per Cent. Mercuric Salicylate Suspension

	GM. OR C.C.
Anhydrous lanolin.....	40
Distilled water.....	10
Sweet almond oil.....	150
Calomel or mercuric salicylate.....	29
Phenol or creosote.....	20
Camphor.....	40

Mercury Benzoate.—This is but slightly soluble in pure water, but is rendered more soluble by the addition of sodium chloride or benzoate, and is injected in these solutions. Its excretion is fairly continuous, declining from 7 to 3 mg. in a week (Lomholt, 1920), so that it acts rather like the insoluble preparations. Perhaps it is precipitated at the site of injection.

The Insoluble Injections.—These are used with the purpose of establishing "depots" from which the mercury may be gradually absorbed, so that injections need only be made at intervals of 5 to 7 days, in courses of about 15 injections. The dangers of these mercury accumulations has been discussed.

Calomel.—This is injected as a 10 per cent. suspension in oil, $\frac{1}{2}$ c.c. each week to 1 c.c. twice weekly. This introduces a rather large quantity of mercury, and is therefore somewhat dangerous; it is also very painful. The absorption is slow, and the excretion, with 50 mg. per week, increases slowly, from 0.5 mg. the first week to 3 mg. by the fourth week (Lomholt and Christianson).

Oleum Cinereum (gray oil), a 40 per cent. suspension of metallic mercury in oil. This is the most slowly absorbed of the mercurials. The injections ($\frac{1}{4}$ c.c.) are therefore spaced a week apart, and after five injections an intermission of five or six weeks is made to discount capricious absorption; five further weekly injections are then given. (Semiweekly injections of $\frac{1}{2}$ c.c. may be substituted for the weekly injections.) The excretion indicates that the absorption is very variable (Lomholt, 1920). This is reflected by the occurrence of fatal poisoning. It is advised that this method be abandoned.

Intravenous Injections.—These were introduced (by Bacelli, 1892) to secure the maximal concentration of mercury in the blood, and to avoid the local actions of the mercurials. However, they irritate the veins at the site of the injection and tend to produce fibrosis which precludes the use of the vein for further injections, a rather serious matter for syphilitic patients. They also present some danger of embolism and colloidoclastic shock, at least in inexperienced hands. The temporary high concentration in the blood has no direct bearing on the spirochetes in the tissues. The mercury rapidly leaves the blood; but a large part is rapidly excreted (often half, within 24 hours; Buchtala, 1913). The remainder presumably passes promptly into the inactive storage forms, which to judge by their slow excretion are probably not readily re-converted into active forms. The active mercury must therefore be secured from the continuous supply, and this is better assured by the older methods of administration.

Mercuric chloride, iodide or cyanide are used in 1 per cent. solution, 1 to 3 c.c. daily or every second day, injected into a superficial arm vein, with glass syringe and platinum-

iridium needle (Crume, 1908). Similar injections have been tried in puerperal infections, and other septicemias, influenza etc. (Barsony, 1909; Ferrarini, 1918; Perez, 1918). Vecki, 1918, endorses this use, but reports severe poisoning, exceptionally from 3 mg.

The less-ionizable organic preparations, mercurosal, flumerin etc. are perhaps somewhat less objectionable, but probably no more efficient. It is not inconceivable that depots of absorbable mercury might be established by the intravenous injection of colloidal preparations, analogous to the arsphenamines. This, indeed, may be done with colloidal suspensions of metallic mercury. These are effective therapeutically; but the uncontrollability of the depots and of the absorption from these makes them dangerous (Cole et al., 1924).

Spinal Injections of Mercurialized Serum.—This was introduced by Byrnes, 1914, and is endorsed by Ireland and Wilson, 1915, against cerebro-spinal syphilis, as being about equally successful and safe as the Swift-Ellis serum. It has the advantage that the serum may be kept on hand. It is prepared by adding 1 c.c. of 0.13 per cent. mercuric chloride to 12 c.c. of normal human or horse serum, heating to 56°C. for one-half hour. This gives a clear solution. This dose (double would be safe) is injected by gravity, at body temperature, after withdrawing cerebro-spinal fluid till its pressure is 30 mm. E. L. Hunt, 1916, also reports encouraging results. Hall, Culbertson and Slaght, 1916, describe the reactions following the intraspinal injection. They are usually not serious.

Swift, 1916, however, believes that repeated injection of mercurialized horse serum renders the membranes hypersensitive, and tends to produce chronic meningitis.

Pittenger, 1917, finds that mercuric chloride when dissolved in serum produces the same systemic effects as when dissolved in water, and is equally toxic, by any channel; but that it causes practically no local irritation.

Contraindications to Mercury.—Caution should be exercised with weak or anemic individuals, with albuminuria, during digestive derangements, and with diseases of the mouth or teeth. Pregnancy is not considered a contraindication. It is safer to begin treatment with small doses, since some patients are hypersusceptible.

Vegetable Antisyphilitics.—The prejudice against mercury has led to the introduction of a number of vegetable "alteratives"—Echinacea, Phytolacca, Iris, Sarsaparilla, etc., but their uselessness is attested even by modern eclectics (Hilton, 1909).

MERCURY IN TUBERCULOSIS

This was advised by B. L. Wright, but Hartz, 1910, found the ultimate results detrimental and never beneficial.

PREPARATIONS—METALLIC MERCURY

Hydrargyrum (Hydrarg.), U.S.P., B.P.; **Mercury** (Quicksilver); Hg.—A fluid, silver-white heavy metal. It is used only in finely divided form, as in the following preparations:

***Hydrargyrum cum Creta** (Hydrarg. c. Cret.), U.S.P., B.P.; Mercury with Chalk (Gray Powder).—Contains 38 per cent. of Hg., U.S.P.; 33 per cent., B.P., with honey and chalk. A light gray, rather damp, sweetish powder. Used especially to secure the constitutional effect of mercury in infantile syphilis. *Dose*, 0.25 Gm., 4 gr., U.S.P., equivalent to about 0.1 Gm. of metallic mercury; 0.06 to 0.3 Gm., 1 to 5 gr., B.P.; dispensed in powders.

Emp. Hydrarg., B.P.—33 per cent. of Hg. in lead plaster base. Used against glandular enlargements, etc.

Lin Hydrarg., B.P.—50 per cent. of Ung. Hydrarg., with ammonia, in Camphor Liniment.

Massa Hydrargyri (Mass. Hydrarg.), U.S.P., *Pil. Hydrarg.*, B.P. (Blue Mass, Blue Pill).—33 per cent. of Hg. *Dose*, 0.3 Gm., 5 gr., U.S.P.; 0.25 to 0.5 Gm., 4 to 8 gr., B.P. Used similarly to Calomel.

***Unguentum Hydrargyri Fortius** (Ung. Hydrarg. Fort.), U.S.P. Stronger Mercurial Ointment.—50 per cent. of mercury, emulsified by 2 per cent. of mercury oleate, in prepared suet and benzoinated lard. Used for inunction.

***Ung. Hydrarg. Mite**, U.S.P. **Ung. Hydrarg. B.P.** (Blue Ointment).—Contains 30 per cent. mercury. Used in the United States mainly against cutaneous parasites; in Europe also for inunction.

Ung. Hydrarg. Co., B.P. (Scott's Dressing).—12 per cent. of Hg and of Camphor. Used in synovitis, etc.

PREPARATIONS—INSOLUBLE MERCUROS COMPOUNDS

* *Hydrargyri Chloridum Mite* (Hydrarg. Chlor. Mit.), U.S.P.; *Hydrargyri Subchloridum* (Hydrarg. Subchlor.), B.P.; Mild Mercurous Chloride (Calomel, Protochloride of Mercury); HgCl .—Fine white powder, odorless and tasteless. Practically insol. in water or alc. *Incompatible* with alkalis; oxidizing acids; iodides and bromides; and with a mixture of sodium bicarbonate and antipyrine (J.A.M.A., 56:287, 1911). *Dose*, laxative, 0.15 Gm., 2½ gr., U.S.P.; 0.03 to 0.3 Gm., ½ to 5 gr. B.P.; as powder or tablets. Maximum dose, 0.6 Gm., 10 gr.

Pil. Hydrarg. Subchlor. Co., B.P. (Plummer's Pill).—22 per cent. of Hydrarg. Subchlor.; 22 per cent. of Antim. Sulphur; 43 per cent. of Guaiac Res. *Dose*, 0.25 to 0.5 Gm., 4 to 8 gr., B.P.

Ung. Hydrarg. Subchlor., B.P. (Calomel Ointment).—20 per cent., in Benz. Lard.
* *Hydrargyri Iodidum Flavum* (Hydrarg. Iod. Flav.), U.S.P.; Yellow Mercurous Iodide (Mercurous Iodide; Protoiodide of Mercury); HgI .—Bright, yellow amorphous powder, without odor or taste; almost insol. in water, wholly insol. in alc. On exposure to light, it darkens by decomposition into mercuric iodide and metallic mercury. *Incompatible* with oxidizing agents, alkalis and carbonates, chloride, bromides and iodides. *Dose*, 10 mg., ¼ gr., U.S.P.; maximum dose, 0.05 Gm., 1 gr. "*Green Iodide*" is an analogous salt prepared by a different method. It is said to be less potent.

Lotio Hydrargyri Nigra (Lot. Hydrarg. Nigr.), B.P.; Black Mercurial Lotion (Black Wash).—A suspension of mercurous oxide, obtained by mixing 0.685 Gm. of Calomel with 95 c.c. of Lime-water and 5 c.c. of Glycerin. Used on venereal sores and foul ulcers.

PREPARATIONS—INSOLUBLE MERCURIC COMPOUNDS

Hydrargyrum Ammoniatum (Hydrarg. Ammon.), U.S.P., B.P.; Ammoniated Mercury (White Precipitate); NH_2HgCl .—White, amorphous, insoluble powder, obtained by precipitating HgCl_2 with ammonia. Represents about 80 per cent. Hg. Irritating and not used internally. Employed externally against eczema and parasitic skin diseases, especially pediculi, as dusting powder, but chiefly as:

* *Ung. Hydrarg. Ammon.*, U.S.P., 10 per cent. in woolfat, white petrolatum and liquid petrolatum.

Ung. Hydrarg. Ammon., B.P.—5 per cent. in Benz. Lard.

Hydrargyri Oxidum Flavum (Hydrarg. Oxid. Flav.), U.S.P., B.P.; Yellow Mercuric Oxide; HgO .—Light orange-yellow amorphous powder, turning darker on exposure to light. Odorless; somewhat metallic taste. Nearly insol. in water or alc. *Incompatible* with acids. Maximum dose, 0.03 Gm., ½ gr. Applied chiefly as:

* *Ung. Hydrarg. Oxid. Flav.*; U.S.P., 1 per cent.; B.P., 2 per cent.—It is used in ophthalmology against inflammations of the lids and conjunctiva, being diluted with petrolatum so as to contain ¼ to 2 per cent. of the oxide. "Pagenstecher's Ointment" contains 4 per cent.

Lotio Hydrargyri Flava (Lot. Hydrarg. Flav.), B.P.; Yellow Mercurial Lotion (Yellow Wash).—A suspension of mercuric oxide, obtained by mixing 0.46 HgCl_2 with 100 lime-water. Used as application to venereal sores.

Hydrargyri Oxidum Rubrum (Hydrarg. Oxid. Rubr.), B.P.; Red Mercuric Oxide (Red Precipitate), HgO .—Orange-red crystalline scales or powder. Because of its gritty character it can not be used on the eye, but its Ointment is employed in skin diseases, etc.

Ung. Hydrarg. Oxid. Rubr., B.P.—10 per cent.

Oleatum Hydrargyri (Oleat. Hydrarg.), U.S.P.—Made by dissolving 25 per cent. of yellow mercuric oxide in oleic acid.

Hydrarg. Oleat., B.P.—20 per cent. of Mercuric Oxide in Oleic Acid.

Ung. Hydrarg. Oleat., B.P.—25 per cent. of the Oleat.

* *Hydrargyri Salicylas* (Hydrarg. Salicyl.), U.S.P.—A compound of mercury and salicylic acid containing about 57 per cent. Hg. White, slightly yellowish or slightly pinkish powder; odorless and tasteless. Nearly insol. in water or alc.; sol. in alkalis, forming a double salt. *Incompatible* with alkalis. *Dose*, intramuscular, 0.06 Gm., 1 gr., as 10 per cent. suspension in oil twice a week U.S.P.

PREPARATIONS—SOLUBLE MERCURIC SALTS

Hydrargyri Benzoas, N.N.R.—Slightly soluble in water. Used as urethral injection 1:2,000 to 1:1,000, against gonorrhea; and hypodermically, 0.02 to 0.03 Gm. in 40 c.c. of normal saline.

* *Hydrargyri Chloridum Corrosivum* (Hydrarg. Chlor. Corr.) U.S.P.; *Hydrargyri Perchloridum* (Hydrarg. Perchlor.), B.P.; Corrosive Mercuric Chloride (Corrosive Sublimate; Bichloride or Perchloride of Mercury); HgCl_2 .—Heavy, colorless crystals or white powder of acrid metallic taste. Slowly sol. in water (1:13.5), freely sol. in alc. (1:3.8), sol. in glyc. (1:12) or eth. (1:22). Its solubility is increased by ammonium or sodium chloride and tartaric or citric acid ("Sal Alembroth" = 2 parts HgCl_2 , 1 part NaCl). *Incompatible* with alkalis and carbonates; iodides; many alkaloids and other organic compounds and reducing agents. *Dose*, 4 mg., $\frac{1}{15}$ gr., U.S.P.; 2 to 4 mg., $\frac{1}{32}$ to $\frac{1}{16}$ gr., B.P. Maximum dose, 30 mg., $\frac{1}{2}$ gr.

Liq. Hydrarg. Perchlor., B.P.—0.1 per cent. *Dose*, 2 to 4 c.c., $\frac{1}{2}$ to 1 drachm, B.P.
 * *Toxibelle Hydrargyri Chloridi Corrosivi* (Toxibell. Hydrarg. Chlor. Corr.) U.S.P.; Poison Tablets of Corrosive Mercuric Chloride (Corrosive Sublimate Tablets; Bichloride Tablets).—In order to guard against accidents, the U.S.P. directs these tablets to be of an angular, not disk shape, each having the word "*Poison*" and the skull and cross bones design distinctly stamped upon it. Each tablet contains not less than 0.45 Gm. nor more than 0.55 Gm. of HgCl_2 , and about 0.5 Gm. of NaCl, and is to be colored blue, preferably with sodium indigotindisulphonate. Poison Tablets of Corrosive Mercuric Chloride should be dispensed in securely stoppered glass containers on the exterior of which is placed a red label bearing the word "*Poison*" and a statement of the amount of corrosive chloride in each tablet. A tablet to a pint of water makes an approximately 1:1,000 solution.

Hydrarg. Cyan., N.N.R.; $\text{Hg}(\text{CN})_2$.—Sol. in water (1:12.8) or alc. (1:15). Used like Hydrarg. Chlor. Corr. Maximum dose, 20 mg., $\frac{1}{3}$ gr.

Hydrarg. Oxycyan., N.N.R.; $\text{Hg}(\text{CN})_2\text{HgO}$.—Sol. in water (1:17). Used like Hydrarg. Chlor. Corr.; explosive.

(The preparation first used as "oxycyanide" was a mixture of one part of the true oxycyanide with two parts of mercuric cyanide.)

* *Hydrargyri Iodidum Rubrum* (Hydrarg. Iod. Rubr.), U.S.P., B.P.; Red Mercuric Iodide (Biniodide); HgI_2 .—Scarlet red powder, odorless and tasteless. Nearly insol. in water, slightly sol. in alc. (1:115); rendered sol. in water by the presence of four-fifths its weight of KI or NaI. *Incompatible* with alkalis and carbonates and alkaloids. *Dose*, 4 mg., $\frac{1}{15}$ gr., U.S.P.; 2 to 4 mg., $\frac{1}{32}$ to $\frac{1}{16}$ gr., B.P. Maximum dose, 20 mg., $\frac{1}{3}$ gr.

Ung. Hydrarg. Iod. Rubr., B.P.—4 per cent.

Potassium Mercuric Iodide, N.N.R.; K_2HgI_4 .—This is usually made as extemporaneous solution, by dissolving HgI_2 or HgCl_2 in excess of KI (1:4). For intramuscular injection, the corresponding sodium salt is preferred ($\text{HgI}_2 = 1$; NaI = 3; Water = 100).

(*Liq. Arsen. et Hydrarg. Iod.*—See Index.)

Liq. Hydrarg. Nih. Acid., B.P.

Ung. Hydrarg. Nit., B.P. (Citrine Ointment).—7 per cent. of Mercury, dissolved in Nitric Acid, and diluted with Lard (and olive oil, B.P.). Used as antiseptic, irritant and caustic.

Ung. Hydrarg. Nit. Dil., B.P.—20 per cent. of the Ointment.

Hydrargyri Succinimidum (Hydrarg. Succinim.), N.N.R.—Sol. in water (1:75); slightly sol. in alc. (1:300). *Dose*, 10 to 15 mg., $\frac{1}{6}$ to $\frac{1}{4}$ gr.; Intramuscular, 0.5 to 1 c.c. of 2.5 per cent., daily. Relatively non-irritant.

* *Mercurochrome* (220-Soluble).—The disodium salt of 2:7 dibromo-4 hydroxy-mercuri-fluorescein, containing 23 to 24 per cent. of mercury. Iridescent green scales or granules, permanent in the air, freely soluble in water, soluble in alcohol, insoluble in chloroform or ether. The aqueous solution is of a deep cherry-red color, and is stable. *Incompatible* with acids and with most alkaloids and local anesthetics. Locally, as 1 to 5 per cent. solution. Intravenously, 5 mg. per Kg. as 1 per cent. solution. Caution!

* *Novasurol*.—The double salt of sodium mercuri-chlorophenyl oxyacetate with barbital; contains 34 per cent. of mercury. White crystalline powder, odorless, soluble in water, with slightly alkaline reaction. *Dose*, as diuretic or antispylilitic, 0.75 to 2 c.c. of 10 per cent. solution, intramuscularly or intravenously, once or twice a week.

LEAD

The lead salts precipitate proteins and therefore act as local astringents. Their acute toxicity is low, as they are absorbed rather slowly; but they

tend to produce cumulative effects. Chronic lead poisoning is a quite common disease with characteristic symptoms: The "lead line" at the margin of the gums; marasmus and anemia; paroxysmal colic and arthralgias; "drop-wrist" and other peripheral motor paralyses; central motor stimulations (tremors and convulsions); psychic changes (encephalopathia), etc. The mechanisms and relations of these effects are not definitely known. On withdrawal from the lead, these phenomena generally recede more or less completely; but the patient may remain in bad health and over-susceptible to lead, for some time. Prophylaxis against lead poisoning is more important than treatment.

Fuller discussion of lead poisoning and bibliographies may be found in books of Aub et al., 1926; T. Oliver, 1914; Brouardel, 1914; Legge and Goadby, 1912; and in the article of Shie, 1921.

Astringent Actions.—Lead acetate and subacetate ("lead water") produce more astringent and less irritant effects than other soluble metallic salts. They are effective in diarrhea and catarrhal inflammations; but they are so liable to produce chronic poisoning that they should never be used internally nor on open surfaces; and even on the skin their use should not be long continued. "Lead and opium wash" is used in superficial contusions. Saturated alcoholic solution of lead acetate is employed in Rhus ("Ivy") poisoning. Emplastrum Plumbi—"Diachylon plaster"—acts as a mild irritant.

ABSORPTION FATE AND EXCRETION

These are so important for the systemic effect of lead that they may be considered first.

Absorption.—Lead and all its compounds (with the possible exception of the silicate) are absorbable from all mucous membranes and exposed tissues. Absorption from the intact skin has not been definitely proven, but could probably occur to a limited extent through the cutaneous glands and hair follicles. The digestive and respiratory tracts are the principal avenues of entrance; their relative importance is difficult to judge, since inhaled lead fumes or dust or paint-spray are largely swallowed. There is no doubt, however, that abundant absorption occurs directly from the nasopharynx and from the respiratory tract (Aub et al.). Lead on the hands generally reaches the mouth with food, etc., and is therefore absorbed from the digestive tract.

The lead must be in solution before it is absorbed; but even the most "insoluble" lead salts and metallic lead if finely divided are somewhat soluble in the digestive juices and tissues; whilst the "soluble" salts are to a considerable extent precipitated. Consequently, only a limited amount of lead can be absorbed in a given time; and a quantity of lead that is harmless as a single dose, may be toxic when divided into smaller doses and thus spread over some days. Brouardel states that he has prescribed 0.2 Gm. of lead acetate at one dose, without plumbism; but that this would doubtless have occurred if 0.01 Gm. per day had been given for 20 days. All but a small fraction of the single dose would be eliminated unabsorbed by the feces.

Solubility of Lead Compounds in the Digestive Tract and Tissues.—This is independent of their solubility in water. In the stomach, lead carbonate and even lead sulphate are dissolved fairly readily, being largely converted into chloride, by the aid of gastric juice. The solubility corresponds to

that in HCl of corresponding strength. Peptone (0.2 to 1 per cent.) facilitates the solution of lead salts; bile does not. Alkalies including milk diminish the solution (Carlson and Woelfel, 1913). Alkalies of the concentration of the pancreatic and intestinal juices convert lead sulphate into carbonate and lead carbonate into a mixture of neutral and basic carbonate (Auerbach and Pick, 1913). In the large intestine a part of the unabsorbed lead is converted into sulphide, as indicated by the black color of the stools; but this is prevented or diminished, or the sulphide may be redissolved, if an acid reaction prevails. Lead is also rendered soluble on the bronchial mucosa, presumably as protein combinations. The sulphide was supposed to be inabsorbable, but Woelfel and Carlson, 1914 showed that it is absorbed sufficiently, even from ores, to be dangerous. Lead silicate appears to be unabsorbable (Shie, 1921).

Absorbability of Different Lead Compounds.—This is determined by their relative solubility in the digestive canal. The sulphate is therefore less toxic than the carbonate; but both produce poisoning in adequate doses; for instance 0.1 Gm. per Kg. per day (Carlson and Woelfel, 1913). The toxicity of various lead pigments is reviewed by A. Hamilton, 1912.

Absorption from Respiratory Tract.—Lead may enter the respiratory passages as dust, for instance in white-lead works; as spray, in painting; and as fumes from heated lead. Lead volatilizes below its ebullition temperature; for instance at 750°F. (Shie, 1921). The fumes are converted into oxides (Teleky).

The greater part of inhaled lead is caught in the nasopharynx and swallowed. In an experiment with respiration of lead dust, for instance, 70 per cent. were swallowed and only 12 per cent. reached the lungs (Lehman and Saito). Carlson and Woelfel, 1913, also conclude that the absorption of lead dust is by swallowing rather than by the lungs. Lead poisoning often develops more rapidly with inhalation than with other methods, partly because inhaled lead is likely to be more finely divided (Teleky). However, it has been shown by ligation experiments that lead compounds are readily absorbed directly from the lungs (Tanquerel des Planches, 1839; Minot, 1924) and from the nasopharynx (Blumgart, 1923).

Absorption from Conjunctiva.—Poisoning has been produced by the long continued use of a lead eye-wash.

Absorption from Skin.—The application of lead-washes or ointments to the skin may lead to poisoning; but the positive results may be referred to transfer of the lead to the mouth, or to injuries of the skin, so that absorption from the intact skin has not been established. The coloring of hair by lead indicates, however, that this may penetrate at least into these structures, and therefore presumably also into the epidermis; and metallic lead and finely powdered compounds could presumably be rubbed into the hair follicles and then be dissolved and absorbed analogous to mercury and calomel inunctions; but the amount of this absorption appears to be negligible.

Canuet and Drouet found that dogs or rabbits may be poisoned by baths of lead acetate; but Potain showed that poisoning does not occur if the animals are prevented from licking the skin (Brouardel).

Beresina and Engling, 1887, found blood-changes in guinea pigs after 2 days of inunction with 10 per cent. lead carbonate ointment. The changes were greater when a lanolin base was used, than with petrolatum base.

Lewin, 1883, reported poisoning from the skin after long continued scrubbing with a hard-brush. This, however, amounts to absorption from partly denuded skin.

Absorption from Denuded Skin.—This is universally admitted. It may be an occasional source of poisoning in workers, whose skin is often thinned, macerated or chapped.

Absorption from Hypodermic Injections of Lead Carbonate.—Straub and Erlenmeyer, 1913, utilized this for the production of experimental plumbism. In cats, the lead was absorbed from the hypodermic deposits at the rate of 0.1 to 1 mg. per Kg. per day.

Absorption from Bullets, etc.—This will be discussed under the sources of lead poisoning.

Excretion.—This occurs mainly by the feces and urine. The fecal lead is partly unabsorbed, partly excreted by the bile and probably by all parts of the gastro-intestinal tract. Insignificant traces of lead may also occur in milk (Baum and Selig, 1895), saliva (Pouchet, 1880), sputum

(Meillere, 1903), and sweat (after pilocarpine, Spillmann). The excretion by the skin is negligible. The application of sulphur and sulphides to the skin of lead-workers often gives a black color, which indicates exposure to lead, but this is due to adherent nonabsorbed lead, and not to excreted lead (Miura). The lead also passes into the fetal circulation (Annino, 1893) and this may be a factor in the frequent abortions.

Quantitative Excretion by the Feces and Urine.—The feces generally excrete the larger share, but the proportion varies considerably. During the ingestion of lead, a large part of the fecal lead may be unabsorbed lead sulphide. After the patient has been withdrawn from exposure for some time, the ratio becomes more nearly equal. In seventeen such patients, recovering from chronic plumbism, Aub et al. found the daily excretion by urine to range from 0 to 0.32 mg., median 0.1 mg.; by feces, 0 to 0.68 mg., median 0.3 mg. The ratio of urine: feces ranged from 1:0.4 to 4.8, median 2.5. Older statements are rather qualitative, because of inadequate quantitative methods.

Causes Determining the Channel of Excretion.—It is probable that renal excretion depends directly on the proportion of lead that is circulating at the time in true solution in the blood (modified perhaps by the permeability of the kidney); and that the bile reflects the mobilization of lead that has been stored in the liver. This is greater if the lead has been absorbed from the digestive tract (Harnack, 1897) than for the respiratory tract (or for subcutaneous injections). However, the significance of the fecal lead is obscured by the excretion from the intestinal epithelium, whose origin is presumably the same as the urinary lead.

Excretion by Urine.—It would be expected that lead would always be found in the urines of chronic plumbism; but this is not the case, perhaps because the excretion is subject to periodic changes. Some investigators succeeded only occasionally in finding lead in the urine. Others consider it an important aid to diagnosis (Oliver, 1914). L. D. Harris, 1918, found it present in about half the painters that showed clinical signs of plumbism, and in a $\frac{1}{2}$ of those that did not show any clinical symptoms. It appears therefore, that the presence of lead in the urine is an important factor in the diagnosis, but that it is not decisive. It may be present without other signs of lead injury; or it may be absent even when the injury has been severe.

Time of Excretion in Urine.—After 0.02 Gm. of lead, taken by mouth, Riva, 1913, found demonstrable quantities of lead in the urine only after three or four days. The excretion continued for a considerable time after the administration had ceased.

Compounds Excreted.—Unabsorbed lead occurs in the feces largely as sulphide; but absorbed lead is said to be excreted entirely as organic compounds (Erlenmeyer, 1913). The subject requires further investigation.

Conditions that Influence the Excretion of Lead.—Aub et al. showed on animals and men that the excretion of lead is modified by the agents that modify the excretion of calcium, and in the same direction. This may be attributed to the fact that the lead is stored mainly in bones, along with calcium phosphate, and very probably in a similar form, and that the deposition and mobilization of the two elements is therefore also similar.

In plumbism patients who had been withdrawn from lead for some time, and whose total daily excretion averaged 0.1 to 0.5 mg., this was increased $2\frac{1}{2}$ to 3 times by the administration of acid producing drugs (mineral acids or ammonium chloride), and to about the same degree by sodium bicarbonate. Potassium iodide also nearly doubled the excretion. The effect of magnesium sulphate was doubtful. No effect was produced by neutral ammonium phosphate, by lactic acid, by sodium citrate, or by potassium chloride.

The mobilization by acidosis may be referred to the solvent action on bone. The sodium bicarbonate action is not understood; it can not be referred to increased alkalinity, since it is not produced by sodium citrate. The iodide action is also obscure. The increased excretion through iodide has been noted by previous workers, although others had failed to confirm it, chiefly because they confined themselves to the urine, while the increase is mainly in the feces. The effect is quite definite, the iodide causing the reappearance of lead in excreta from which it had been absent. It is also claimed that the mobilization of lead by iodides has caused the outbreak of acute lead symptoms.

The following doses were used to produce the above effects: Ammonium chloride, 1 Gm. in a glass of water, 10 to 12 times per day; dilute phosphoric acid (10 per cent.) 20 c.c. in a glass of sweetened water every hour, about 10 times daily; sodium bicarbonate, 20 to 40 grams per day; potassium iodide, 0.5 to 2.5 Gm. per day; magnesium sulphate, 30 Gm. per day.

Retention.—The excretion of lead, after chronic poisoning, is slow and intermittent, traces appearing periodically in the urine and feces, sometimes for months or even years after the absorption has been stopped. Traces are therefore retained in the tissues, during this time, in insoluble form, which may be mobilized by various conditions.

Distribution of the Retained Lead.—The greater part of the retained lead (from 39 to 100 per cent.) is deposited in the bones and teeth; next comes the liver which accounts for 0 to 28 per cent. of the lead; then the kidney (0 to 14 per cent.). Only small quantities are therefore contained in the other parts. These figures are from experimental animals (Aub), but the concentrations in human cases indicate that the phenomena are strictly analogous. The concentrations in the more important organs of lead poisoning, under a variety of conditions, ranged as follows, mg. per 100 Gm. of moist tissue:

	CATS*	HUMAN
Teeth		5-20
Skeleton	4.4-84	2.2-15 (total, 200-800 mg.)
Liver	1.1-7.2	0.1-5
Kidneys	0.5-9.7	0.1-1
Central nervous system	0-3.2	0-0.36
Muscle	0.1-0.5	0
Blood		trace to 0.27

* Total retention, 25 mg. of lead.

"Normal Lead."—Small amounts of lead are often present in normal individuals, not as a necessary element, but because exposure to lead is very common. The difference from that found in lead poisoning is merely quantitative.

Influence of Conditions on Distribution.—The proportion of lead in the liver is distinctly greater if the lead has been absorbed from the digestive tract, than when it was administered by trachea or subcutaneously: doubtless because in the former case, the absorbed lead reaches the liver in more concentrated solution through the portal vein. If the administration of lead by the digestive tract is stopped for several months the proportion of liver lead to total lead declines to a low figure. On the other hand, the proportion of lead in the skeleton varies inversely as that in the liver, and rises in time to 97-100 per cent. of the total. The bones therefore retain the lead most tenaciously, but it may apparently be mobilized from them by agencies that cause the absorption of their calcareous tissue. The lead is confined to the solid portion of the bone, and is presumably laid

down as the insoluble tri-lead phosphate (Minot), along with the calcium phosphate; analogous to the deposition of strontium, etc.

Form of Lead in Blood.—Practically four-fifth of the lead in the blood is in the plasma. The quantity of lead found in lead poisoning, at most 0.3 mg. per 100 c.c. of blood, is too small to identify its combinations with certainty. It was generally assumed to exist as albuminate, but according to electrometric measurements and other considerations, it exists most probably as tri-lead phosphate, $\text{Pb}_3(\text{PO}_4)_2$, which is formed when any lead-salt meets with sodium phosphate. This is soluble in water only to the extent of 0.13 mg. per liter, *i.e.*, $\frac{1}{20}$ th of the quantity that may exist clinically in blood; indeed, serum *in vitro* may dissolve 12.5 to 33 mg. of lead carbonate per liter. It is therefore evident that the tri-lead phosphate must exist in the blood in colloidal and not in true solution.

In acid reaction, the tri-lead phosphate is changed into bi-lead phosphate, PbHPO_4 . This is nearly a hundred times more soluble in water than is the tri-lead phosphate, and therefore exists presumably in true solution and ionized. It could not exist at the pH of the blood; but Aub believes that it could be formed locally, by local acidosis, and that this transformation is connected with the lead-actions, as well as with the mobilization of lead from the bones; the latter along with the similar mobilization of the calcium salts.

PHENOMENA OF LEAD POISONING

These present a number of interesting and disputable problems. Ordinarily the symptoms occur only when the exposure has lasted some time; sometimes for only a few days, generally for several weeks, months or years. The phenomena of the prompt and delayed, of acute and chronic lead poisoning, pass into each other without sharp demarcation; the time of onset and the severity of the immediate symptoms are largely matters of dosage or of mobilization; but long persistence of the plumbism is likely to lead to become complicated by secondary disturbances. The lead actions may be conceived as a product of the concentration of active lead and the duration of the action. The cumulative character of lead poisoning is probably due to the summation of successive lead injuries, and not to the accumulation of lead; for the latter is deposited in inactive form in the bones, and therefore probably does not increase the concentration in the active tissues, except during periods of mobilization. The lead effects are presumably due mainly to the dissolved lead, which is reflected by the concentration of the lead compounds of the blood—the colloidal tri-lead phosphate; and possibly the formation of soluble, acid and ionized bi-lead phosphate on cell surfaces. Such solutions are in unstable chemical and colloidal equilibrium and are apt to “flocculate;” and many of the most characteristic phenomena of lead poisoning are analogous to the “flocculation-phenomena” of anaphylactoid reactions: The blood changes, colic, arthralgia and gout, and nephritis. The paralysis and encephelopathias are not so directly related, but might be secondary consequences. This agreement of phenomena is suggestive of a common mechanism, but does not establish it.

Experimental Plumbism.—This may be produced in mammals by various methods, depending upon the object: By *feeding* with lead compounds, especially the carbonate, either rapidly (Carlson and Woelfel, 1913), or slowly (rats, Weller, 1915; Sollmann, 1921); by scattering the carbonate on the sawdust of the cage (Wassermann, cats, 1916); in birds, by shot placed in the crop (Wetmore, 1918; Hanzlik, 1921); *Hypodermically*.

with lead carbonate (cats and guinea pigs, Straub, 1911 and 1914; Erlenmeyer, 1913). These methods require some weeks for the development of the typical symptoms.

Somewhat similar symptoms may be produced acutely by the cautious intravenous injection of lead salts (Hirschfelder), but it is probable that the resemblance is merely superficial, and that these acute effects probably have a quite different mechanism from the phenomena of chronic plumbism.

The differentiation of lead poisoning into acute, subacute and chronic is still useful from the clinical standpoint.

ACUTE LEAD POISONING

Occurrence.—This is a rather rare intoxication, generally produced by the acetate of subacetate, sometimes by the carbonate (white lead). The phenomena are at first local and not immediately dangerous, but they are often followed by chronic poisoning. Application to the skin (lead wash, Diachylon plaster) has rarely if ever caused acute poisoning (Paessler, 1804). Diachylon pills (as abortifacient) have proven toxic (A. Hall and Ransom, 1906; W. F. Warner, 1907).

Acute Symptoms.—These start with the taste, which for the soluble salts is at first sweet, then disagreeably metallic and astringent, with dry throat. This is followed in 15 or 30 minutes (rarely after several hours) by thirst; burning abdominal pain (not to be confused with "lead colic") and vomiting, which often appears milky from lead chloride; this is followed by diarrhea, more rarely by constipation. The stools are black from lead sulphide. The urine is often scanty, with albumen and casts.

Severe colic may occur in 2 or 3 days, especially if the administration is continued. It is generally accompanied by constipation; rarely by diarrhea. The patients are debilitated. There may also be muscle cramps.

Severe cases of acute lead poisoning develop collapse with slow pulse and finally coma, which is probably uremic. Convulsions may or may not appear. Death occurs usually within 36 hours.

Recovery.—Most patients recover in two or three days from the acute effects, but the convalescence is very slow; and after a few weeks they show the phenomena of chronic poisoning (also animals, Dauwe, 1907).

Pathology of Acute Lead Poisoning.—The local effects are quite superficial. The gastric mucosa is somewhat blanched (astringent action); sometimes with ecchymoses or slight erosions. These changes may extend into the intestines; but the lower intestines are tinted black by the lead sulphide.

Intravenous injections of soluble lead salts produces enteritis (paralysis of capillaries). This does not involve the stomach (Orfila). If death is delayed, nephritis develops. Thouvenet also described liver changes (Brouardel).

Toxic Dose.—Of *soluble lead salts*, 10 Gms. are said to have produced death; and 30 Gms. may be survived (Kunkel). 50 Gms. of lead acetate are probably always fatal. Formerly, lead acetate was used therapeutically in doses of 1 to 4 Gms.; but 2 to 3 Gms. have produced toxic effects. Of *lead carbonate*, 40 to 50 Gms. are said to have caused death (Brouardel). Of *lead chromate* a few centigrams are fatal, but this is attributed to the chromic acid (Brouardel). The toxicity of various lead pigments is reviewed by A. Hamilton, 1913.

Treatment of Acute Poisoning by Soluble Lead Salts.—The stomach must be emptied, preferably with lavage. This may be preceded by the administration of a soluble sulphate (sodium or magnesium). Animals are thus saved from several times the fatal dose (Dauwe, 1907); 1 per cent. sodium sulphate may be used in the lavage. Milk, eggs or tannin are useful. A cathartic should be given after the stomach has been emptied.

Subacute colic is treated as in chronic plumbism. Iodide is commonly given in the after-treatment.

SUBACUTE LEAD POISONING

Occurrence.—This is produced by repeated administration of acutely toxic or slightly subtoxic doses, with criminal interest, or in food contaminations, or therapeutically or experimentally.

Phenomena.—With large doses, each administration is followed by the gastrointestinal symptoms of acute poisoning; dyspepsia and anorexia in the intervals. With subtoxic doses, the gastrointestinal symptoms develop more slowly. Typical phenomena of chronic poisoning may start in a few days, with the lead-line, headache, cramps, paralysis, especially of the upper extremities, nephritis and uremic coma and convulsions, ending in death (Brouardel).

CHRONIC LEAD POISONING (PLUMBISM; SATURNISM)

The daily absorption of small quantities of lead occurs commonly in the numerous industries that employ lead or its compounds, and sometimes also from contaminated water or food. Chronic lead poisoning (plumbism, saturnism) is therefore quite common. It is especially dangerous because it develops insidiously, and is often not recognized until it is far advanced.

The symptoms involve the nutrition, the blood, and nervous and muscular structures, apparently independently. Eventually there may be degeneration of the kidneys and of other organs. The effects are arrested if the patient is withdrawn from exposure to lead; usually with fairly prompt and apparently complete recovery, aside from anatomic lesions.

Animals are also subject to chronic lead poisoning, and show practically the same symptoms. Some of the phenomena may be produced acutely by the injection of organic lead compounds; but it is questionable whether these are really identical with those of chronic poisoning.

Sources of Chronic Lead Poisoning.—These are found in many industries, especially through the use of paint; also in food or drink contaminated by lead-containing vessels or pipes and other accidental sources; by cosmetics and sometimes medicines; by leaden bullets; etc. Artisans working with paints are the most common victims. The manufacture of storage batteries is also an important source of poisoning. However, the metal is so widely distributed that every one is to some extent exposed.

Industrial Lead Poisoning.—Layet (Brouardel, 1904) gives data on 111 trades that employ lead. Shie, 1921, stated that it is used in about 200 American industries, with the number constantly increasing. The more important trades are:

Production.—Roasters of lead ore; manufacture of lead pigments and paints (white and red lead; lead chromate).

Pigments.—Painters, enamelers; varnishers; automobile work; glazers; dyers, paper; silk; artificial flowers; rubber goods; potters; children gnawing paint.

Amongst *painters*, about 40 per cent. show active symptoms. Less than half of those who have passed the age of 40 years are free from plumbism. The heaviest incidence is among those who have been painters for 10 years or longer (Harris, 1918). The spraying method of painting presents special dangers (Hamilton).

Metal.—Plumbers; printers (handling type); file-cutters; glass and gem cutters; storage batteries.

Comprehensive reviews of industrial lead poisoning are given by A. Hamilton (potteries, 1912; painters' trades, 1913; lead smelting, 1914, general review, 1924).

Water-pipes.—These were formerly prolific sources of danger. They are especially treacherous because the solubility of lead varies greatly with circumstances. If perfectly pure water is allowed to flow through bright and clean lead pipes, poisoning results invariably. In this case the surface of the lead is changed into a hydrate (Clowes, 1902), and this is sufficiently soluble to cause the intoxication. The danger is much less with old lead pipes; these become lined with a layer of lead oxide, $PbO + Pb$. This is quite insoluble, and does not readily form a hydrate. The solubility is increased by oxygen and salts, especially by nitrates (Fortner, 1905), but even by sulphates; it is diminished by carbonic acid and carbonates (Paul, etc., 1906). Hard water is therefore much less dangerous than soft water. (Details and older literature in Wolffhügel, 1887.)

Old lead pipes with hard water therefore present relatively but little danger; but should the water stand in the pipes for a time some solution will occur. The use of lead pipes should therefore be avoided.

The actual lead content of water delivered from lead pipes has been found as 0.5 to 12 mg. of Pb per liter (Kunkel). In two lead-epidemics it was 14 mg. per liter (Brouardel). Angus Smith considered 0.35 mg. per liter as dangerous. From data to be quoted later, there is reason to believe that even 0.05 mg. is not indifferent.

Lead, Tin and Pewter Vessels.—The employment of leaden cooking utensils and containers for food or drink is highly dangerous, and should be entirely discarded. Tin plate (cans), solder, pewter and tin foil, however, usually also contain some lead. If the percentage does not exceed a certain limit (1 per cent. for tin-plate; 10 per cent. for solder) the lead is held so firmly in the alloy that it is not dissolved even by moderately acid fluids, such as vinegar. These are deemed harmless. Higher proportions give up their lead and are dangerous. Some enamel-ware also contains soluble lead; but this is now believed to be exceptionable. Earthenware and porcelain are glazed with lead silicate, and this is contained in varieties of glass; but if the lead is present only as silicate, it is harmless.

The safety of vessels and containers may easily be tested by boiling them with vinegar or dilute acetic acid for half an hour, or letting them stand with the vinegar for 24 hours; and then passing a current of hydrogen sulphide through the liquid. If no black precipitate forms there is no danger.

Other Sources of Food Contamination.—Only a few of the more important need be mentioned:

Flour and bread, from millstones repaired with lead (Brouardel).

Wine, clarified by lead acetate. The cleaning of dirty bottles by leaden shot is dangerous.

Fruits from orchards sprayed with lead arsenate contains traces of lead (Sonntag, 1915). Ordinarily this is not sufficient to be harmful, but death has been reported (Hayhurst, 1920).

The smoke and fumes of lead smelters may contain considerable lead which is harmful, not only by direct inhalation, but also by being deposited on vegetables cultivated in the vicinity. Animals grazing in such localities are often affected.

Children may be severely poisoned by gnawing the lead paint of their toys or beds (Blackfan, 1917).

Cosmetics.—Lead carbonate, used as face powder or pomade, has caused plumbism. Lead and sulphur hair-dyes present at least a theoretical danger; although serious poisoning by them must be uncommon.

Medicines.—The internal use of lead is not advisable, although it may be harmless, if it is very temporary. Similarly with lead washes, brief use is safe, but prolonged application, especially to the denuded skin, is dangerous. This probably applies also to lead plaster. The plaster is said to have been taken as abortifacient, with toxic results (Pope, Brit. Jour. July, 1893).

Swallowing of Leaden Bullets and Shot.—This usually produces plumbism; depending however on the time of sojourn in the digestive tract. Brouardel states that shot was formerly administered in volvulus, but that this was strongly condemned by Van Helmont and other masters of that period. He also describes some modern cases, in man, cows, dogs, etc.

Birds are especially subject to this form of plumbism, as the shot is picked up with food, and remains indefinitely in the gizzard or crop, where it is slowly ground and macerated. Six No. 6 shots are fatal to a duck (Wetmore, 1919). Hanzlik, 1921, found that ducks and pigeons die in 2 to 3 weeks, when 0.16 to 0.6 Gm. of lead per Kg. of bird have been absorbed. Other birds are similarly susceptible. When the total absorption averaged 0.01 Gm. per Kg. per day, the survival averaged 83 days; when the absorption averaged 0.02 Gm., the survival averaged 20 days. The immediate cause of death was inanition, due to anorexia; and this in turn largely to disturbed peristalsis.

The symptoms consist in progressive anorexia and emaciation, starting in a few days, and proceeding to a loss of 40 per cent. of the body weight at the time of death. The birds show visible crop-peristalsis with regurgitation of fluid; diarrhea; paresis of extremities, with a "drop-wing" simulating the "drop-wrist" in man. The animals also develop dyspnea.

Metallic lead is more toxic than its compounds when fed to birds (Hanzlik and Presho, 1923); doubtless because its softness permits it to be ground to a more colloidal powder, which can be more rapidly dissolved. It is questionable whether the solution occurs in the gizzard, since its secretion is generally alkaline or at most very faintly acid (Collip, 1922).

The toxicity of the lead is somewhat diminished by the administration of sodium iodide, magnesium sulphate or calcium sulphide. These all retard the solubility of metallic lead in 0.2 per cent. hydrochloric acid (Hanzlik and Presho, 1923).

Toxicity of Other Metals to Pigeons.—These are much less toxic and do not produce the characteristic phenomena of the lead poisoning (Hanzlik and Presho, 1923).

Lead-poisoning from Imbedded Bullets.—Projectiles that are left in the tissues do not readily give up their lead to the circulation, so that they may be harmless. Not infrequently however, they produce severe and sometimes fatal plumbism, sometimes after a latent period of months or even years (Lewin, 1892; Curschmann, 1920, bibliography). The chances of intoxication are greater when the lead offers a large surface, as with small shot (Curtillet and Lombard, 1912). In the delayed cases, it is usually impossible to say why the solubility should have been suddenly increased. The possibility of eventual plumbism renders the removal of bullets advisable, even when they are not causing mechanical injury. However, in Curschmann's case an encephalitis saturnalis was precipitated by the manipulation of the scattered lead in the wound during the operative removal.

Susceptibility.—This varies greatly, in the first place according to the precautions against exposure; but even when these are apparently the same, with men working side by side, some may be attacked in a few weeks, others may continue to work for 40 years without notable symptoms (Shie). These differences depend partly on absorption and excretion, partly on the acid balance: the character of the food, digestive disturbances, starvation, anemia, infections, alcoholism and nephritis, etc., may therefore be important factors. Patients who have had an attack appear to be more susceptible to subsequent exposures; but this may only mean that the attack has revealed the susceptibility. Negroes are said to be more susceptible to encephalopathia.

Quantity of Lead Required to Produce Poisoning.—Epidemics of severe lead poisoning have been produced by water containing lead in quantities corresponding to the ingestion of 10 to 20 mg. per man, per day. This would be a maximal figure and very much smaller quantities are probably harmful. Brouardel believes that poisoning may result from 1 mg. per day; others place it much higher. Gaertner claims that symptoms occur in man only after several months with a daily ingestion of 4 to 7 mg.; in three to four weeks, if the daily dose is 60 mg. (Fluegge and Heffner 1912). In cats, 0.1 mg. per Kg. (corresponding to 6 mg. for man) may be absorbed daily for weeks without lead symptoms. Fatal lead poisoning requires the daily absorption of 1 mg. per Kg. or the daily ingestion of 12 to 30 mg. per Kg. However, interference with appetite and growth may occur in rats with much smaller doses (Sollmann, 1921).

Time of Exposure.—The time required for the onset of noticeable symptoms varies greatly; in animals, from a day to several months; in man, from a few weeks to many years. The delay was formerly attributed to the gradual accumulation of effective concentrations of lead in the body; but as has been explained, the retained lead is practically entirely in inactive form in the bones. Straub, 1913, and Erlenmeyer, 1913, suggested that the cumulative action is due to the progressive accumulation of injuries, produced by the "stream" of circulating "active" lead, in course of absorption and excretion. The "stream" measured by the rate of absorption, required to produce fatal encephalitis of cats, amounted to about 1 mg. per Kg. per day, for about 60 days.

Characteristic Symptoms of Chronic Lead Poisoning.—These have a slow and vague beginning and run an irregular and intermittent course, with paroxysmal symptoms and recurrences. They may develop only some months after stopping work with lead. They are quite independent of the channel of introduction.

They begin generally with rather indefinite manifestations of *ill health*; digestive disturbances, especially anorexia and constipation; gingivitis and "lead-line;" anemia, stippling of the corpuscles, disproportionate pallor; progressive loss of weight and of strength; rheumatic pains. Neph-

ritis, gout, hypertension and arteriosclerosis, sterility, tuberculosis, and other chronic diseases are frequently associated with long continued exposure to lead, probably mainly as secondary consequences.

A second group of phenomena occur as acute paroxysmal attacks of colic or sometimes arthralgias. A third group consists of motor paralyses, especially the "drop-wrist." A fourth group are cerebral and bulbar phenomena, caused probably by hemorrhagic encephalitis, which are fortunately rare and confined to the most severe poisoning.

Frequency of Individual Symptoms.—Harris, 1918, found the named symptoms to occur in the following percentage of active cases among painters:

Digestive disturbances generally are frequent.

Loss of weight and of muscular strength are common complaints.

Constipation, 72 per cent.

Backache (generally lumbar) 56 per cent.

Arthralgias, 56 per cent.

Anemia, 53 per cent.

Colic, 51 per cent.

Headache, severe frontal, 46 per cent.

Lead in urine, 46 per cent.

Hypertension (above 140 mm.), 39 per cent.

Pain in chest, 35 per cent.

Metallic taste, 18 per cent. (This has no connection with the lead-line.)

Lead-line, 14 per cent.

Stippling, 12 per cent.

Wassermann test; negative, except in luetics.

Digestive Disturbances.—These are among the earliest and most common phenomena. They begin with mild stomatitis, foul breath, sweet, metallic taste, anorexia and nausea. Diarrhea is frequent in the early stages; later there is usually very obstinate constipation, or the two may alternate. The abdomen may be tender. These effects are based partly on mild inflammation of the whole alimentary tract, which later on is complicated by the colics. The anorexia is mainly responsible for the emaciation (sunken cheeks) and partly for the anemia, pallor, malaise, headache, insomnia, lethargy, weakness and tremors. Chronic parotitis sometimes occurs, perhaps as a part of the stomatitis.

The Lead-line.—This consists in a slate-colored margin of the gums where they meet the teeth. It is one of the earliest and most constant signs, and occurs also in animals. It is due to the precipitation of lead sulphide in the vascular sub-epithelial connective tissue. This is formed when the lead in the circulation comes in contact with hydrogen sulphide formed by putrefaction around unclean and carious teeth. The lead-line therefore depends on the condition of the mouth, and may be prevented by oral hygiene. Its presence shows that the patient has absorbed notable quantities of lead, but it need have no relation to the lead symptoms. The buccal mucosa opposite carious teeth may also be blackened, (Oliver's sign). A similar black line is given by bismuth, silver, mercury, iron, and perhaps other metals. It may also be simulated by charcoal tooth-powders.

Nutrition and Growth.—All investigators have pointed out that malnutrition, i.e., loss of weight, or checking of growth, is the earliest and most constant objective sign and almost quantitative index of lead poisoning. In experimental animals, it starts within a few days, if ordinary amounts of lead are administered; with rats the growth may sometimes be checked by feeding 0.001 mg. of lead carbonate per Kg. per day, corre-

sponding to $\frac{1}{1,000}$ grain for a man. The loss of weight is parallel to the diminished appetite, and may occur without other symptoms (Sollmann, 1921; references).

Blood Changes.—The hemoglobin and red corpuscles are diminished in about half the patients. The corpuscles contain basophilic granules, staining with methylene blue. This "stippling" is an important early diagnostic sign (van Emden and Kleerekoper, 1904); although the basophilic granules may occur in other anemias, and are sometimes absent in lead-poisoning. Many of the corpuscles are destroyed, producing icterus and widely distributed "hemosiderin," and the appearance of hematoporphyrin in the urine. The latter is also an important diagnostic test for lead poisoning (Curschmann). The large mononuclear cells of the blood are very often increased; the polymorpho-nuclear may be decreased (Shie).

In clinical cases the anemia is usually moderate, the count rarely falling below four millions. The color index is rather variable. In animals, the erythrocytes often drop rapidly, from the first or second day, to about $\frac{2}{3}$ of the normal, and remain at this level till death. In case the lead is removed, the count also rises rapidly. This severe anemia is probably due in part to inanition.

The lead anemia is apparently caused by increased destruction of the corpuscles. At the same time the resistance of the corpuscles to laking is increased; and this is sometimes used as a diagnostic test of lead poisoning. This is also seen when corpuscles are exposed to very dilute lead solutions in vitro; it has been suggested that the lead hardens the surface, and so renders the cells less elastic and therefore more vulnerable to mechanical injury, and at the same time more resistant to chemicals (Aub).

The significance of the basophilic granulations is in dispute. Their occurrence varies in individuals and especially in species. They appear in some animals, and not in others which are equally anemic, (Aub).

Bone-marrow Changes.—These correspond to those produced by mercury, iron, phosphorus; and many infective and wasting diseases. They are perhaps secondary to anemia. At first there is marked increase of leucoblastic cells with disappearance of fat, and sometimes with moderate hyperemia; then, gelatinous degeneration and atrophy of the whole marrow tissue (R. Stockman and Charteris, 1903).

Lead Pallor.—The color of the skin and mucous membranes is conspicuously pale and often slightly icteric in nearly but not quite all victims of lead poisoning who have been exposed at least eight weeks. This lead-complexion ("Blei-kolorit") is of great diagnostic value; it is too subjective to be decisive, but it should lead to the search for other signs. The pallor is greater than would correspond to the blood-count, and the combs of roosters grow cold and shrink. It is usually attributed to vascular spasm, but this is improbable, since it does not vary periodically, as do the other lead spasms. It might be due to diminished blood volume, a suggestion that has not been tested.

Menstrual Disturbances.—Dysmenorrhea, menorrhagia and amenorrhea are rather common.

Pregnancy.—Lead always exerts an unfavorable influence upon pregnancy. The number of miscarriages in women affected by lead poisoning is very large; and of the children born, by far the largest proportion die during the first year of life (Legge, 1901).

Plumbism of Father on Offspring.—The clinical evidence is quite slender. Sterility, still birth and early death of the children are common clinical occurrence. If the

children survive, they are particularly liable to various nervous effections (Adami). Experimental feeding of lead acetate to male rabbits and fowl also result in smaller offspring of low vitality (Cole and Bachhuber, 1914). Weller, 1914-1916, confirmed this on male guinea pigs fed on lead carbonate; finding sterility or reduction of birth-rate, early death of the fetus, and especially retarded development (underweight), which persists through life.

In most of the lead-fed guinea pigs, there are no demonstrable histological changes in the testes; a few, however, show complete aspermatogenesis, with atrophy and vacuolar degeneration of the germinal epithelium.

Gradual recovery occurs if the administration of the lead is stopped, indicating that the deleterious action is confined to the maturing cells.

The literature of the effects of lead on reproduction is reviewed by Weller, 1915.

Later Visceral Lesions.—Chronic degenerative renal, arterial, hepatic, pulmonary and other visceral diseases occur probably more commonly in lead victims than in normal individuals. It is doubtful in how far they are due to direct injury by the lead, or to low resistance.

The long-continued administration of sublethal doses of lead carbonate to guinea pigs produced severe degenerative and necrotic change in the renal and hepatic epithelium, hemorrhagic edemas, and chronic pleurisy (Ophuls, 1915).

Hepatic Cirrhosis.—This is produced in animals by lethal or slightly sublethal doses of lead (McJunkin, 1915).

Nephritis is common in acute, and especially in chronic clinical lead poisoning. It is primarily vascular, followed by epithelial degeneration, deposition of calcium phosphate, and finally cirrhosis (Bright, 1827). The uric acid and non-protein nitrogen of the blood are increased (Folin and Denis, 1913).

The urine flow and chlorides are diminished during the colic, increased after the attack (Nistico, 1913); the urinary nitrogen increases during the acute attacks; the uric acid is said to be diminished during attacks (Goetze, 1893).

Gout.—This is of fairly frequent occurrence in lead workers. The urate topi are said to be rich in lead.

Arterial Hypertension.—It is doubtful whether this is more common in lead workers than in others. It does not occur in rabbits with long continued lead administration (Dominguez). Adler, 1914, failed to produce arteriosclerosis in dogs. During the colic attacks, the blood pressure rises (Riegel and Frank, 1874) through the compression of the intestinal vessels (Welch and Mall) and by the pain-reflex. Excised arteries and perfused organs are also constricted by lead (Siccardi, 1913), but this is not parallel to the condition of lead in vivo. In poisoning by organic lead compounds, Harnack found no rise or other direct change in the circulation, except with fatal doses. These paralyzed the heart and respiratory muscles in common with the skeletal muscles.

Tuberculosis.—The high incidence in printers is said to vary with the protection against lead (Hamilton).

Colic.—This is preceded by continued minor digestive disturbances; pressure sensation in the epigastrium; anorexia; obstipation; and some abdominal tenderness. The acute attacks consist of paroxysms of intense pain, radiating from the umbilicus, and relieved by pressure. The patient therefore instinctively retracts the abdomen so that this often appears boat-shaped (scaphoid); and he may lie on the face with the fists pressed against the painful region. The skin is very pale and dry; the temperature low; the blood pressure high; the pulse hard, wiry and slowed, often to 40 or 50. The colic is sometimes accompanied by dyspnea (spasm of the bronchial muscles); and sudden severe muscular pains, especially in the flexors of the legs.

After some hours the pain disappears completely; but the constipation lasts some days. Nausea and vomiting are frequent. Relapses are the rule. The colic is very painful and wholly incapacitates the patient, but it is not dangerous. Entirely analogous effects may be produced in animals; except that with these diarrhea may be more common than obstipation. Radiography shows either increased peristalsis (producing

diarrhea) or extreme tonic spasm (obstipation), so that the intestines appear like a cord (Herz; Wassermann, 1916). These effects are not prevented by section of the vagi (Harnack); so that they must be peripheral. They may sometimes be arrested by atropine, but this may fail clinically, and also in animals (Hanzlik). The action appears analogous to barium and allergic stimulation, *i.e.*, it is probably independent of the innervation.

Intestinal spasm may also be produced acutely by the intravenous injection of lead acetate (Hirschfelder, 1915) and in excised intestines (Siccardi, 1915), but it is questionable whether these are analogous effects.

Nervous Phenomena.—These include a variety of manifestations, some quite distinct, others more or less confused. The greater part may be reproduced in animals. They generally develop rather late, and are difficult to localize sharply, because they tend to spread. They involve probably direct peripheral actions on the sensory and motor elements; neurites; and meningites.

Arthralgia.—This occurs in about half the patients. After some preceding muscular weakness there are sudden paroxysmal attacks, generally at night, of violent remitting pains and disturbed functions of joints and groups of muscles, especially those of the shoulder and the flexors. Pressure gives some relief. The attacks last generally from five to eight days and often recur. They bear a resemblance to attacks of gout, and it is possible that they are due to a similar cause, perhaps precipitation of lead phosphate about the joints. Or they may be neuralgic, neuritic or central.

Other occasional sensory nervous phenomena are: Neuralgia, anesthetics and hyperesthesias occurring in attacks of eight to eleven days' duration; amaurosis, amblyopia, deafness.

Drop-wrist and Other Muscular Paralyses.—Special groups of muscles, most commonly the extensors of the forearm (distribution of musculospiral below supinator longus), or others most exposed to fatigue (Mellon 1913) become gradually paralyzed. The condition generally begins with weakness, tremors and disturbed sensation and passes through progressive paralysis, with the "reaction of degeneration" (muscles responding to galvanic and not to faradic stimulation, Eulenberg; Erb). Finally there is muscular atrophy and contracture. The contracture begins usually at the metacarpo-carpal articulation of the two middle fingers, then the two outer fingers and the thumb, and then the wrist. The onset is sometimes sudden. There is no pain. Restoration may occur even from advanced stages.

The mechanism of the paralysis is in dispute: Harnack showed on frogs that organic lead compounds have a late effect on muscle, so that it is very rapidly fatigued. This occurs on direct stimulation, so that the contractile substance itself appears depressed. On the other hand, the nerve trunks in clinical poisoning show interstitial neuritis; and in Erlenmeyer's cats, the main lesion was degeneration of the bulbar nuclei. The latter, however, probably belong to the rapid encephalic type. The clinical paralyses are generally peripheral, and the neuritis is probably the primary feature (S. Moritz). The paralysis sometimes involves the recurrent laryngeal nerve (change of voice); and rarely the phrenic, with fatal termination.

General asthenia, lassitude and neurasthenia are very common. They may be early manifestations of the paralysis; or they may be merely the

consequences of anemia and malnutrition. *Tremors* of the fingers, tongue, lips and eyelids are nearly always present. They may be due to weakness, or to neuritis, or early manifestations of encephalitis.

Encephalopathia Saturnalis.—Cerebral symptoms are relatively rare. They occur especially in the rapid, severe cases; particularly with the easily absorbable tri- and tetra-ethyl lead; but also experimentally with hypodermic injections of lead carbonate in cats and clinically with oral administration. Negroes are said to be especially susceptible. The phenomena are the same in man and in animals (Harnack, 1878; Erlenmeyer, 1913). They set in rather suddenly after a latent period of variable duration, usually some weeks, with restlessness, hallucinations, delirium, melancholia, pseudoparalyses, coma and epileptiform convulsions. The prognosis is grave. The symptoms have an anatomic basis in meningitis with hemorrhagic edema and degeneration of the bulbar cells.

Diagnosis of Plumbism.—The chief points may be recapitulated as: The history of exposure; lead line; ammonium sulphide reaction on the skin; black stools; especially the chemical demonstration of lead in the stools or urine; pallor, anemia, stippling, pinched features, asthenia, rheumatic pains, digestive symptoms, colic, obstipation, drop-wrist, recovery when removed from exposure to lead. The concurrence of most of these signs is highly characteristic; but none of them is absolutely constant, and most may be simulated individually by other conditions (Linenthal, 1914).

Prophylaxis.—The public and especially the artisans, should be thoroughly educated to the insidious dangers of lead, and the chances of poisoning carefully guarded against.

The sources of danger—lead pipes, etc.—should be eliminated. Tin cans, foil, etc., should be frequently examined by authorized persons. Proper precautions are required in lead factories and in exposed trades. Lead-laden dust is especially dangerous. Since the main channel of poisoning is by the mouth, extreme cleanliness should be encouraged and made possible by liberal facilities for washing. Sulphates are useless (see absorption). Food should not be permitted on the premises, and the clothing should be changed before leaving the works. More stringent laws are greatly needed.

The Treatment.—This consists in resting the patient in hygienic surroundings until the lead has been eliminated and the general health fairly restored. Milk diet and perhaps additional alkali are valuable to hasten the deposition of lead in inactive form in the bones.

Symptomatic measures may be used: Against the colic, magnesium sulphate should first be tried, but morphine is most effective. To this may be added atropine or scopolamine, and hot applications or baths. Amyl nitrite (Riegel, 1878) gives slight and only temporary relief.

Constipation is treated with magnesium sulphate, or olive oil enemas; or 200 to 500 c.c. of oil by mouth. These are better than castor oil or calomel, which increase the pain if they do not relieve the constipation.

The palsies may be treated with massage and electricity.

Mobilization of the lead should be avoided during the acute attacks. When the symptoms have subsided, it might conceivably be desirable to hasten the excretion of lead by administration of acids, ammonium chloride, sodium bicarbonate, or potassium iodide. The advisability of this mobilization is doubtful, it is probably better generally to let the excretion take its natural course.

Lead Injections in Cancer.—W. Blair Bell, 1922, claimed that the intravenous injection of colloidal lead is beneficial in cancer, both directly and by increasing the efficiency of X-ray treatment. It seems advisable to await critical confirmation, especially since the treatment may cause serious plumbism.

TETRA-ETHYL LEAD

The addition of this compound, $\text{Pb}(\text{C}_2\text{H}_5)_4$, increases the efficiency of gasoline in motors, by preventing premature explosion (Midgeley and Boyd, 1922). It is highly toxic, being readily absorbed by the lungs and skin, and producing the phenomena of acute or subacute lead poisoning. Its combustion with gasoline results in lead chloride, bromide and sulphate, in the form of fine dust, which would therefore also be highly toxic (A. Hamilton et al., 1925). Acute fatalities occurred in the manufacture and blending, until proper precautions were taken. The danger to the public appears to be slight, although decisive data are still scanty. The official U.S.P.H.S. committee reports that drivers of cars showed no lead effects after two years; employes of garages and service stations showed some absorption, but slight in comparison in typical lead industries (J.A.M.A., 1926, 86: 370).

Properties.—Tetra-ethyl-lead is a clear, heavy oily liquid of peculiar odor, somewhat volatile at ordinary temperature. It is practically insoluble in water, soluble in alcohol and lipid solvents. It may be absorbed from the lungs and skin, as well as from the digestive tract, and it somewhat irritates the skin. Its immediate distribution in the tissues presumably differs from the water-soluble compounds. The excretion occurs as inorganic compounds and may reach 8.4 mg. of lead in the daily urine (Kehoe).

Phenomena of Tetra-ethyl-lead Poisoning.—These are quite similar to other lead poisoning (Kehoe, 1925). They occur usually by a combination of skin-absorption and inhalation of vapor over considerable periods, but may set in after a few days if high concentrations of the vapor are inhaled, or large skin surfaces have been covered. Nervous symptoms tend to predominate. Insomnia and mental irritability and instability are among the earliest and most constant features. Other subjective symptoms are nausea, anorexia and vomiting; vertigo and headache; asthenia and itching of the skin. The most constant objective phenomena are pallor, due to subnormal blood pressure, with subnormal temperature; loss of weight; and tremor. Relatively infrequent and unimportant are colic, lead line, and stippling. The hemoglobin is usually normal. In severe acute cases the nervous irritability culminates in maniacal delirium; death occurring from exhaustion.

Experimental Poisoning by Organic Lead Compounds; Relation to Chronic Lead Poisoning.—Harnack, in 1878, aimed to hasten the actions of lead by introducing it as a soluble and non precipitant organic compound, with the expectation that this would penetrate as such into the cells, and be there decomposed, with the liberation of lead in active form. He experimented with triethyl-lead acetate, $(\text{C}_2\text{H}_5)_3\text{Pb}.\text{C}_2\text{H}_3\text{O}_2$. If this is injected intravenously or hypodermically, the effects develop in three stages:

1. The immediate phenomena, quite different from those of plumbism, and due doubtless to the compound as a whole.
2. Rapid recovery, with absence of symptoms.
3. After one to several hours, gradual development of phenomena identical with the neuro-muscular symptoms of clinical or experimental chronic lead poisoning, and with those produced slowly by the same compound when administered in small doses on long periods.

These actions are attributed to the liberation of lead ions from the compound. This is based partly on the complete decomposition of the compound in the body; partly on the latent period; and partly on the close resemblance of the symptoms to those of chronic lead poisoning. This suggests strongly that the effects are the same as in chronic plumbism, and it is therefore worth while to discuss them more fully. However, it is well to remember that resemblance of symptoms is not incontrovertible proof of identity of action. For instance, the cardiac symptoms of acute and chronic nicotine poisoning are similar, but the "tobacco heart" is probably not due to the direct nicotine action that occurs in acute poisoning.

Immediate Effects of Intravenous Injection of Lead Triethyl.—As has been stated, these are due to the organic molecule, and not to the lead as such. Harnack observed signs of agony; salivation and vomiting; psychic disturbances; distress and arrest of respiration. The course is rapid, so that the animal may be dead or completely recovered in a few minutes.

E. C. Mason, 1921, made a more detailed study of the immediate effects on anesthetized dogs; giving $\frac{1}{4}$ to $\frac{1}{2}$ mg. of $(C_2H_5)_3PbCl$ per Kg., by vein. He attributed the phenomena to very active stimulation of the central nervous system, especially the medullary and higher centers. The main symptoms are convulsions of the medullary (cyanide) type.

The blood-pressure reacted in a peculiar manner; the first injection producing a very marked fall, whereas all subsequent injections resulted in marked and prolonged rise. Mason attributed the fall to stimulation of the cardio-inhibitory vagus center; to sudden dilation of the vessels of some of the viscera, including the kidneys and spleen, probably through stimulation of vasodilator centers; and to direct depression of the heart. The rise he referred to extension of the stimulation to other medullary centers, i.e., the vasoconstrictor center for the same organs; and to the cardio-accelerating center. The convulsions exaggerate the rise.

The respiration showed a similar sequence, being stopped by the first, and greatly increased by subsequent injections. Mason assumed stimulation, first of inhibitory, then of augmentory centers. The bronchi are not constricted.

Intestinal movements were increased, which he also attributed to stimulation of the vagus center.

These effects are not produced by similar doses of trimethyl lead, nor of triethyl antimony, so that a peculiar relation of ethyl and lead is indispensable.

Delayed Effects of Lead Triethyl, Stimulating Phenomena of Plumbism.—Harnack observed that these develop several hours after recovery from the acute effects. They take three directions: (1) direct depression of striped muscle; (2) peripheral stimulation of intestine; (3) central motor stimulation. These differ relatively in different animals. Frogs and rabbits show mainly the muscular paralysis, whereas dogs die from the central effects before the muscles become paralyzed. Cats are intermediate. The intestinal phenomena occur with all the mammals.

PREPARATIONS—SOLUBLE LEAD COMPOUNDS

Plumbi Acetas (Plumb. Acet.), U.S.P., B.P.; Lead Acetate (Sugar of Lead); $Pb(C_2H_3O_2)_2 + 3H_2O$.—Colorless or white granular crystals or masses, of faintly acetous odor and sweetish astringent, afterward metallic taste, efflorescent. Freely sol. in water (1:1.4), sol. in alc. (1:38). Incompatible with alkalis and carbonates; iodides, chlorides and sulphates. Dose, 0.06 Gm., 1 gr., U.S.P.; 0.06 to 0.3 Gm., 1 to 5 gr., B.P. Maximum dose, 0.3 Gm., 5 gr.

Pil. Plumb. c. Opio, B.P.—12 per cent. of Opium; 80 per cent. of Plumb. Acet. Dose, 0.12 to 0.25 Gm., 2 to 4 gr., B.P.

Supp. Plumb. Co., B.P.—0.2 Gm., 3 gr., of Plumb. Acet.; 0.067 Gm., 1 gr. of Opium.

Glycer. Plumb. Subacet., B.P.—About 20 per cent. of Subacetate.

Liquor Plumbi Subacetatis (Liq. Plumb. Subacet.), U.S.P.; Solution of Lead Subacetate (Goulard's Extract; Bleiessig).—An aqueous, clear colorless, alkaline solution; containing lead subacetate corresponding to not less than 18 per cent. of Pb. Should be diluted 15 to 30 times before application. Used as astringent and antipruritic in inflammatory conditions of the skin, and in sprains and bruises. It should not be applied to denuded surfaces, and should be used with caution on the face.

Liq. Plumb. Subacet. Fort., B.P.—About 35 per cent. of Subacetate.

Liq. Plumb. Subacet. Dil., B.P. (Goulard's Lotion; Leadwater).—Prepared by diluting the stronger solution, in the ratio of 1:80. May be applied directly.

Ung. Plumb. Subacet., B.P.—12.5 per cent. of the Strong Solution.

PREPARATIONS—INSOLUBLE LEAD COMPOUNDS

Plumbi Carbonas (White Lead); $(Pb CO_3)_2Pb (OH)_2$ —Insol. Used as Ointment, 10 per cent., against dermatitis, burns, etc.

Plumbi Iodidum (Plumb. Iod.), B.P., PbI.—An insoluble, bright yellow powder. Used externally as mild counterirritant against glandular swellings, etc., in the form of the Ointment.

Ung. Plumb. Iod., B.P.—10 per cent.

Plumbi Monoxidum (Plumb. Monoxid.), U.S.P., B.P. (Litharge); PbO .—Heavy, yellowish powder, without odor or taste. Almost insol. in water. Used in making the Subacetate.

Emplastrum Plumbi Oleatis, (Emp. Plumb. Oleat.), U.S.P.; *Emp. Plumb.* B.P. (Lead Plaster, Diachylon Plaster).—A lead soap, made by heating lead monoxide with 2 parts of fat (olive oil and lard, U.S.P.; olive oil, B.P.) in the presence of water.

Ung. Plumbi Ol., U.S.P. (Diachylon Ointment, Hebra's Ointment).—50 per cent. of lead oleate plaster, with white petrolatum, flavored with lavender oil.

THALLIUM

The metal is almost as toxic as arsenic. The acetate has been given internally (5 to 10 mg. per day) against the night sweats of phthisis, and both internally and externally as a depilatory. The therapeutic use has repeatedly caused severe poisoning and is scarcely justified. It is not anti-syphilitic (Buschke, 1911).

The toxic phenomena are: stomatitis, diarrhea, dyspnea, pain in the extremities, alopecia (also in animals; Buschke, 1910), depression and other neuroses and neurites, diuresis and persistent albuminuria (Olmer and Tiau, 1909; Swain and Bateman 1910).

APPENDIX A.—CHECK-LIST FOR THE STUDY OF IMPORTANT PREPARATIONS

The student should keep a separate notebook, ruled in columns as illustrated in the schema, into which the names of the drugs and the relevant data are entered as they are studied. The preparation of these tables is probably the most efficient method of learning the subject. The synonyms, origin, miscibility, dose, and remarks will be found in the text. The appearance, odor, and taste should be studied directly from the specimen. It is highly desirable that the physician should be somewhat familiar with the physical characters of the principal drugs, if for no other reason than that it will give him some confidence, save him some embarrassment, and assure the proper dispensing of his prescriptions. This knowledge may be of vital importance for the prompt diagnosis of poisoning.

The specimens should be learned sufficiently, so that the student is able to decide whether or not an unlabelled sample *may* or may not be whatever is suggested. For instance, whether a white powder *may* be arsenic trioxide; whether a colorless fluid may be Tincture of Nux Vomica, etc. The drugs which are bracketed in the list are for inspection only. No data need be entered for them.

The labels should indicate whether the drug may be tasted. Separate gummed slips, distinguished by colors, are handy for this purpose.

Strong Poison! **Do Not
Taste.**

(Red Label)

Poison! **Taste
Cautiously.**

(Blue Label)

Practically Harmless.

(Green Label)

SCHEMA FOR THE TABULATION OF MATERIA MEDICA NOTES

English and Latin name and synonym (1)	Average dose (U.S.P.)		Origin: (2) Part of plant used. Important constituents	Percentage	Physical Characters: Appearance. Odor. Taste	Miscibility or solubility in water	Remarks
	Metric	U.S. system					

Explanatory:

(1) Enter the full Latin name and the abbreviation. Synonyms or English Names need be entered only if they differ markedly from the Latin name.

(2) The origin need be given only for drugs or preparations derived from the organic kingdom.

CHECK LIST OF IMPORTANT PREPARATIONS

"H" means that the drug is harmless.

"C" that it may be tasted cautiously.

"Dnt.": Do Not Taste!

"O": Specimens may be omitted.

The official abbreviations of the U.S.P. are generally used.

APPENDIX B.—TABULATION OF AVERAGE DOSES

The following lists may aid in memorizing and reviewing the subject. They are arranged in the order of ascending doses, generally those of the U.S.P., in Grams.

GROUP I.—HIGHEST IMPORTANCE

Atropin. Sulph.	0.0005
Scopolamin. Hydrobr.	0.0005
Strophanthin.	0.0005
Ars. Triox.	0.002
Strychnine Salts.	0.002
Mercuric Salts.	0.004
Apom. Hydrochl. (Emetic)	0.005
Pilocarpine salts.	0.005
Morphine salts.	0.008
Hydrarg. Chlor. Mit.	0.015
Codeine salts.	0.03
Opium.	0.06
Santonin.	0.06
Sp. Glyceryl. Nitrat.	0.06
Caffeine.	0.15
Liq. Pot. Ars.	0.2
Iodides.	0.3
Methenam.	0.3
Arsphen.	0.4
Barbital.	0.5
Chloral Hydr.	0.5
Neoarsphen.	0.6
Tr. Opii.	0.6
Bismuth Sub-salts.	1
Liq. Pituitar.	1
Tr. Digit.	1
Tr. Opii Camph.	4
Inf. Digit.	6

GROUP II.—IMPORTANT

Physostig. Salicyl.	0.002
Antim.et Pot. Tart. (Expectorant)	0.003
Hydrarg. Salicyl.	0.004
Hydrarg. Iod. Flav.	0.01
Res. Podoph.	0.01
Aloin.	0.015
Ext. Bell.	0.015
Emetin. Hydrochl.	0.02
Phenobarb.	0.03
Ferr. Reduct.	0.06
Ferr. Sulph. Exsicc.	0.06
Phenolphthal.	0.06
Sod. Cacodyl.	0.06
Sod. Nitris.	0.06
Thyroid.	0.06
Digit.	0.1
Novasurol.	0.1
Quinine salts.	0.1

(Antimalarial, 1)

Resorcin.	0.125
Acetan.	0.2
Amyl Nitris.	0.2

Liq. Iod. Co.	0.2

INDEX

NOTE.—The **bold-face** folios refer to preparations

- "A" VITAMINE, 114 to 117
 Abietis, oleum, **191**
 Abortion, 150
 Abrin, 233
 Absinthe, 188, 194, 702
 Absorbents, 137 to **139**
 Absorption conditions influencing, 76 to 78
 Acacia, **135**
 for infusion, 850
 Acaciæ cortex, **177**
 Acapnia, 764
 Acer, 474
 Aceta, 33
 Acetanilide, 605 to **610**
 Acetannal, 176, **177**
 Acetates, 941 to **942**
 Acetic acid, 941 to **942**
 ether, 740
 Acetone, 706
 type of acidosis, 926 to 928
 Acetonitrile test, 895
 Acetozone, 662
 Acetphenetidin, 605 to **610**
 Acetum, **942**
 Acetyi choline, 404
 salicylic acid, 619, **620**
 tannic acid, **177**
 Acetylene, 743
 Acidosis, 920 to 928
 alkalies in, 934 to 936
 Acids. The individual acids may be
 found under their proper names.
 and alkalies, remote effects of, 913 to
 931
 caustic, 170 to **172**
 dilute, mineral, **931**
 organic and their salts, 941 to 945
 Aconite and aconitine, 546 to **552**
 Acrid principles, 209
 Acridine dyes, 651, **652**
 Acridlavine, 651, **652**
 Acroleine, 654
 Acupuncture, 215
 Adalin, 759
 Addictions, 302 to 309
 Addison's disease, 446
 Adeps, **130**
 benzoinatus, **130**
 lanæ and hydrosus, 130, **131**
 Adjuvant, 58
 Administration of drugs, 70 to 76
 Adonis, 500, 529
 Adrenal cortex, 446
 Adrenaline, 425 to **446**
 Adsorbents, 137 to 139
 Adsorption, 785
 Æther, **740**
 aceticus, **740**
 Ætheris nitrosi, spiritus, **499**
 Æthylis, chloridum, 739
 Æthylmorphinæhydrochloridum, **317**
 Afridol, 1026
 Agar, 237, **238**
 Agaricin, **390**
 Age on drug action, 82
 Agmatine, 451
 Agropyron, **136**
 Agurin, 281
 Air, impure, 762
 Ajowan, **68**
 Albamyricetin, 282
 Albumoses, 475 to 477
 Albutannin, 176, **177**
 Alcohol, 683 to **703**
 Alcoholic beverages, peculiarities of, 702,
 703
 Alcohols, higher, 704
 Aldehydes, 654, 754
 Aletris, 474
 Aliphatic hypnotics, **747** to **760**
 Alkali reserve of plasma, 925
 tolerance test, 925
 Alkalies, caustic, dilute, 180, **181**
 mild, remote effects, 913 to **937**
 Alkaline salts, 180
 equivalents, 917
 Alkalinity, actual and potential, 180
 Alkaloids, 19
 Alkalosis, 920, 923, 934
 Allergic hypersusceptibility, 86
 phenomena, 481 to 492
 preparations, 667, 675
 Allocaïne, **343**
 Allspice, **193**
 Allyl alcohol, 706
 Allyl compounds, 199
 Allyl-sulphocarbamide, 199
 Almond oil, artificial, 644
 expressed, 127
 volatile,
 Aloes and aloin, 228, **229**
 Alopecia, 211
 Alpha lobeline, 416
 Alphozone, 662

- Alstonia, 597
 Althæa, 136
 Alum, 1006
 Aluminum compounds, 1005 to 1007
 Aल्पine, 326, 343
 Amanita, 402
 Amber, oil of, 193
 Amblyopias, toxic, 416
 Ambrine, 133
 Amebic dysentery, 567
 Amido-azo-benzene, and amido-azo-toluol, 653
 Amidopyrine, 603 to 605
 Amines, 349
 aromatic, 461
 Ammonia, 179, 860
 Ammoniacum, 197
 Ammonia, spiritus, fetidus, 189
 Ammoniated mercury, 1028 to 1044
 Ammonium. For the ammonium salts, consult the anions.
 bases, quaternary, 405
 carbonate baking powders, 1007
 chloride acidosis, 858
 compounds, 856 to 862
 metabolism in acidity, regulation, 919
 Amygdala amara, 778
 dulcis, 136
 Amygdalæ expressum, oleum, 129
 Amygdalin, 778
 Amyl acetate, 740
 alcohol, 704
 Amyl nitrite, 492 to 499
 Amylamine, 349
 Amylene hydrate, 755
 Amyloform, 657
 Amylum, 137
